The management of cases wherein *both legs* are fractured is very difficult, and in the country, where proper beds and appliances are wanting, it rarely happens but that some considerable deformity of one leg follows: the difficulty of keeping the leg steady in the necessary movements of the body, especially in evacuating the bowels, is hardly surmountable, and occasions the displacement of the bones. Now this is materially obviated when one limb is so effectively supported as it is by the plaster cast, inasmuch that I was particularly struck with the advantage in Orchard's case, and felt assured that it would be particularly useful in fractures of both legs*.

Since the occurrence of the above case I have attended several others, and treated them in the same way with equal success, and an increasing conviction of the value of the plan. I have now a patient under treatment, a man who for three weeks was treated with the common splint and bandage, but as there was no approach to a union of the fractured ends of the bone, I recommended in consultation the employment of the plaster cast, which was no sooner applied, and the limb at rest, than the man expressed himself delighted with the ease he enjoyed, compared with his former state.

Several advantages accrue from the employment of the plaster cast; such as the uniformity of support given to the

* I had some years since a case of a man whose legs were fractured by a cart passing over them, and all my efforts to keep one leg steady were unavailing: the man declared he could not "mind both legs," nor help moving *one* when the bowels were evacuated. I reasoned with him, and said that his restlessness would bring my fair fame into discredit: he replied quaintly "Never mind, sir, I'll tell every body who may ask me, that *you* cured the right, and *I* the left leg." The former turned out well, but the latter was sadly deformed, although the man was enabled to walk nearly as well as before he received the injury.

whole limb, and its permanently fixed state, without the possibility of motion, and at the same time with freedom from painful constraint or the partial pressure of a bandage, however skilfully applied. Patients continually complain of great pain from pressure on the heel on which the limb, when the patient is placed on his back, rests; this is mainly owing to the imperfect manner in which the hollow space between the heel and calf is filled up: pads become hard, and slip, and we are constantly called upon to make some alteration, to the great risk of displacing the fracture, in order to give the patient ease; and we too often find the patient himself, or some vexatious meddler, interfering and disarranging our plans, and doing considerable damage. This cannot occur when the plaster cast is used; for being employed in a semi-fluid state, it takes the exact shape of the limb, filling up every hollow, and presenting a uniform and perfectly smooth surface for it to rest upon.

Whilst the patient is materially benefited by this method, to the surgeon also it is of considerable advantage, for having once carefully reduced the fracture, and put it in a proper position, no further interference is necessary; hence he is saved a vast deal of trouble, which, in hospital and parochial practice, is highly desirable; but, at the same time, great care and circumspection are necessary, for should the fracture be put up in a hurried or heedless manner, irreparable mischief must ensue, as well to the patient as the reputation of the practitioner.

I am in the habit of placing the limb in a kind of trough of the shape represented in the diagram: it is made of

N.B.—These measurements are taken out and out.

deal; the part on which the leg and thigh rest one inch thick; the sides half inch; the pieces which form the sides of the trough also half inch thick; the first board is moveable, to suit persons of different heights; the width seven inches; and height of the sides four.

The bottom of the trough should be a little hollowed, so as to have a better bed for the leg to rest upon; and two pieces of board projecting from the bottom of each side, about four inches long, to prevent the upsetting of the apparatus. Having poured the plaster into the trough so as to cover the bottom, the limb is put into it whilst in a semi-fluid state: the fracture having been properly adjusted, the trough is filled with the plaster, and the limb retained in its proper position by assistants till the plaster is set, there to remain as long as the surgeon is of opinion that the case requires. It is desirable that a groove should be left on the upper surface of the cast, about a quarter of an inch wide, for the purpose of pouring in an evaporating lotion if required. Mr. Bond recommended a mixture of whiting with the plaster of Paris, but from experience, I decidedly prefer the plaster alone: which after using may be broken up, fresh burnt, and powdered, and employed again and again.

It is hardly necessary to observe that it is desirable that a fractured limb should not in the first place be put up in plaster, but rather suffered to remain at rest supported by a pillow and splint lightly braced upon it, until the swelling and inflammation shall have in a good degree subsided.

I will in conclusion only express my hope, that the plan recommended in this paper may be fairly tried, and that the result of the experience of my professional brethren will be from time to time reported.

Bridport, Nov. 24, 1837.

GRANULATING SURFACE

MEASURING SIX HUNDRED SQUARE INCHES.
RECOVERY.

To the Editor of the Medical Gazette.

SIR,

In presenting the following case to the profession, I am desirous of ascertaining from any authentic source whether I am not warranted in believing it to be the largest sphacelated wound of the integuments recorded in the annals of surgery as having been successfully treated. I have not given it publicity with a view to describe any novel mode of treatment, but as an example of the

amazing power of the system in effecting the restoration of lost structures. Owing to the protracted term of the cure, I am not able to state the daily or weekly condition of the patient; neither would this be interesting to the practitioner; my object, therefore, will be to generalize under its different stages.

I remain, sir,
Your obedient servant,
JOHN GRANTHAM.

Crayford, Kent,
Dec. 5, 1837.

Erith, Nov. 5th, 1835. — Edmund Clark, aged 16 years and 9 months, in consequence of the explosion of some fire-works, was burnt to the following extent:—From the upper and fore part of the neck, extending laterally down the left arm to the insertion of the deltoid muscle; occupying both axillæ; passing backwards to within three inches of the spines of the vertebræ; over the chest, body, and genitals, to the verge of the anus; extending along the upper part of the right thigh, and down the left thigh to the knee, destroying the cuticle, rete mucosum, and corium. The whole measured above six hundred superficial inches, or four feet twenty-four inches, and averaging a quarter of an inch in depth. Also the subcutaneous structure was completely lost, so that the arteries and veins were seen as if neatly dissected, lying on the surface of the muscles and fascia. In recording the treatment it will be better to divide the case into six stages, namely, depression, reaction, exfoliation, ulceration, granulation, and cicatrization. During the whole of the treatment I adhered to three principles: first, a nutritive supply of food; secondly, a proper protection of the wound in reference to the regulation of the animal heat; and, thirdly, the external and internal use of antiseptic agents.

The treatment during the stage of depression, which lasted the first forty-eight hours, consisted in bathing the edges of the destroyed parts with spirit. terebinthinæ, covering the whole of the trunk with flour, and enveloping the patient in a blanket, external to which stone bottles, filled with hot water, were placed at the feet and sides of the patient, and replenished every three hours. He took thirty drops of the tincture of opium, in brandy and

water, every six hours. His diet consisted of beef-tea, thickened with arrow-root. While this depression remained, the sensorium was in a comatose state; the pulse fluttering and rapid. The stage of re-action was, at the onset, attended with great irritability of the brain and violent action of the heart; the pulse ranging between 150 and 200. The stomach so irritable as not to retain any liquid until I administered an enema of beef-tea, highly salted, which acted very beneficially in quieting it. I now gave a drachm of the carbonate of soda, with a drachm of the sp. ammon. arom., according as the stomach could bear them, and applied yeast poultices to the wound where exfoliation had commenced. This stage continued four days. The process of exfoliation, which lasted about twenty five days, was accompanied with a typhoid form of fever, and the effluvia from the sphacelus during this time were most offensive. The application of yeast and linseed-meal poultices was continued, with chalk and cinchona to the exfoliated parts; while the diet was altered to port-wine, beef-tea, &c., and oxymuriatic gas was evolved in the room every two or three hours. Injections of beef-tea, mutton broth, thickened with oatmeal, were also administered every six hours. The stages of ulceration, granulation, and cicatrization, may be said to have commenced from the fourth day, and continued to the end of the case. As the typhoid symptoms abated, I ordered a milk diet; to which article I ascribe, in great measure, the circumstance of the system being able to support such an immense quantity of purulent discharge; the patient taking, on an average, six pints of milk in twenty-four hours. And here I must be allowed to remark on the advantage milk has over all other aliments; though, like every other article of food, it requires discrimination in its use. I believe, in ninety-nine cases out of a hundred, whenever there is fever, the stomach will be found to contain an undue quantity of acid, and in such a state milk would be inadmissible, unless an alkali be taken with it. The wound was now dressed with chalk and cinchona, sprinkled or dredged on it, over which a plaster of spermaceti was laid, and this was covered with a thick layer of wadding or carded wool, and calico

rollers applied with graduated pressure, which was increased as the case progressed.

About three months from the time the accident occurred, the patient suffered from a sphacelated wound in the sacrum; and about four months from this time the unfortunate youth became a sufferer, from an attack of bronchitis, attended with expectoration of blood. When this subsided, I entertained sanguine hopes of his ultimate restoration, as he kept improving more or less, till April 1837, when he was sufficiently recovered to walk a short distance. On the 23d of this month, when apparently in health, he was seized with a fit of shivering, succeeded by erysipelatous inflammation, which increased the dimensions of the wound from 45 inches to upwards of 150 inches, and finally settling in the lowest extremity, destroyed the integuments of the upper part and sides of the foot. The poor fellow's death seemed inevitable, and my expectations, from being raised to the highest pinnacle of hope, became completely depressed. But with a steady adherence to the recumbent posture, the use of small doses of opium, nitric acid, &c., he was again, as it were, recalled to life, since which time the healing has gone on with great rapidity. He is now enabled to ride on horseback a distance of fifteen or sixteen miles in the day, and is free from all contraction, excepting a slight one in the left groin. The wound is reduced to less than twelve inches.

CASES OF

PULMONARY AFFECTION:

WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

THE following cases of pulmonary affection I have transmitted to you, thinking they would be found worthy of being placed upon record in your journal. I have ventured to add a few remarks upon them.—I am, sir,

Your obedient servant,

T. LAYCOCK,

House Surgeon, &c. to York
County Hospital.

Nov. 22d, 1837.

CASE I.—Convulsive Cough, having first a quotidian, then a tertian type; Sputa very copious, and of a highly faecal odour—Recovery.

Sarah Battley, aged 20 years, wife of Hospital-serjeant Battley, of the 10th Hussars, was attacked in January 1837, with a pain under the right scapula, extending round the side to the anterior lateral region of the chest; it was aggravated when she coughed or breathed, catching her suddenly. She was relieved by bleeding, and suffered from nothing but a slight cough until April 17th. She was then exposed to cold, and experienced some fatigue and anxiety. The pain now recurred, and extended to beneath the right mamma; she had daily pyrexial paroxysms, commencing about noon, and not terminating in sweat. Her cough also became more severe, the expectoration more profuse; and on the 23d she observed the sputa to have a very disagreeable smell, which gradually became more perceptible, and at last highly offensive. The thirst she had suffered from since the commencement of the attack now became excessive. She was admitted into the hospital April 27th, under the care of Dr. Belcombe. The following was her state:—She suckled her first child for twelve months, and weaned it six weeks ago; milk can be squeezed from the nipples. Complaints of violent cough, attacking her in paroxysms, which continue from fifteen minutes to two hours, causing great pain in her head, and accompanied with a profuse expectoration of a muco-purulent fluid, having a distinctly faecal and highly offensive smell. Her bowels have not been moved for two days; she is pale, and has an anxious expression of countenance. Her friends suppose her to be in a *galloping consumption*. There is bronchophony in each upper and anterior region of the chest, most marked on the right; pulse 80, steady and feeble; tongue clean and moist; appetite impaired, and fastidious; thirst excessive, the patient drinking two or three gallons of fluid every day; temper irritable and desponding.

Apply a blister to the upper part of the right side of the chest. To take a dose of Calomel and Colocynth Extract immediately; and every four hours two table spoonful of the following mixture:—

Infusion of Digitalis, Liquor of Acetate of Ammonia, of each 4 ounces; of Camphor Mixture, 8 ounces.

April 27th, evening.—She is obliged to sit up in bed with her body slightly bent forward. Seeing her in this unusual position, and perceiving a strongly faecal smell, I concluded the purgative was

operating, and walked away. I was much surprised, on returning for the purpose of inspecting the evacuations, to be informed that her bowels had not been opened, and that the stench I perceived was caused by her breath and sputa.

28th, evening. — Cough still severe, dyspnœa great; and if she attempt to lie down, is so much increased as to threaten suffocation.

To take with each dose of the mixture a pill, composed of Extract of Henbane and Conium, of each gr. ii. s.; powdered Ipecacuanha and Squill, of each gr. ss.; also, to have dilute Nitric Acid for common drink to any extent.

29th, morning. — Breath and sputa have still the fecal odour; the latter is of a whitish-grey colour and muco-purulent consistence. Cough relieved; pulse 78, full and steady; tongue clean; thirst excessive, — to allay it she has a gallon pitcher at her bed-side full of water acidulated with nitric acid, of which she constantly drinks; bowels constipated. There is an enlarged and painful gland near the right sterno-clavicular articulation.

To have two or three leeches applied to the inflamed gland. Either continue her remedies, take ℞ij. of the Compound Powder of Senna, and have a solution of Chloride of Lime about her bed to destroy the offensive smell.

Evening. — Bowels have been moved once, the fæces of the usual colour and odour; tongue moist, and moderately clean; appetite improved; thirst diminished; pulse 96, round, incompressible; cough much less frequent; sputa in small quantity, and very slightly offensive.

Let her take a Senna draught.

30th, noon. — Slept last night, but coughed incessantly, in paroxysms like whooping-cough, from six to half-past eight o'clock this morning, during which period she expectorated two pints and a half of a muco-purulent dirty grey fluid, having a peculiarly offensive odour, like that of some kinds of discharges from the bowels. Breath not offensive; other symptoms unchanged.

Evening. — Blister irritable, and ordered to be poulticed. Sputa have the odour of decayed apple, and are in small quantity; no fætor of the breath.

May 1st, evening. — Sputa more fecal, but cough and expectoration less.

2d, morning. — Pain in the right anterior and upper portion of the chest; in the same region, puerile respiration and pectoriloquy. On the opposite side, puerile respiration and bronchophony; *no rattle on either side*; sputa and breath of a more fecal odour; pulse 90, full and

steady; tongue clean; appetite good; has slept tolerably well.

Evening. — Has vomited to-day; complaints of being very weak, and sweats; pulse 104, small and soft; tongue moist, and clean; fæces of the natural odour. Has coughed very much to-day, and the sputa is so offensive as to make the ward smell like a foul privy; her breath has a similar smell when she coughs; the sputa are copious, grey, muco-purulent, and swim on water. Cannot lie supine or on her right side, on account of the pain and incessant coughing the attempt to do so produces: is most easy when sitting upright, or leaning forward a little.

3d, evening. — Has been so much better as to walk in the garden; coughed and expectorated less; sputa not so distinctly fecal; can lie on her left, but not on her right side or back.

4th, evening. — Feels great pain beneath the right mamma and scapula. She says the right side feels weak, as if there were no bones in it. Has coughed incessantly during the day; sputa very copious; tongue clean; appetite moderately good; pulse 90, steady.

5th, evening. — Better in every respect. Pulse 114, and soft; sputa much less offensive, and (as she says) of a sweet taste; breath offensive; pectoriloquy on the right side, bronchophony on the left.

6th, evening. — Has had a very severe fit of coughing to-day, with copious and very offensive expectoration; pulse 108; tongue clean. Left the hospital.

A few weeks after this date, I learnt that she soon and rapidly recovered, and joined her husband at Nottingham in good health and spirits. The tertian type which the disease assumed, (a peculiarity I noticed only while copying the case for the press,) is not less remarkable than the quantity and fætor of the expectorated matter.

CASE II. — *Pneumonia; pultaceous, grey, and excessively fetid expectoration — Death in twenty-eight days — Gangrene (?) of the left Lung.*

John Elder, aged 45 years, was admitted on the 27th September last, under the care of Dr. Belcombe, with symptoms of pneumonia. He had severe pain in the left side of the chest (as I was informed), violent cough, and gelatinous adhesive expectoration. On the 2d of October the expectorated matter suddenly increased in quantity, and became decidedly puriform; on the 5th there were pectoriloquy and a distinct blowing, as of air, into a cavity. The breath and sputa exhaled a highly disagreeable fætor, so that I was nauseated while using the stethoscope; the strength was prostrated, and the patient constantly

demanded nourishing diet, which he loathed when offered him.

On the 16th October all the symptoms, which had gradually increased in severity, became much aggravated; the sputa were very copious, of a yellowish grey colour, and excessively offensive. Amphoric resonance could be heard over the whole chest, but very loudly over the second and third ribs. The moment the stethoscope touched the ear, and before it was adjusted, the sound could be felt. His strength now rapidly failed. On the 22d he laid supine, a grey, pulraceous, and horribly stinking fluid, flowing from his mouth. On the 24th he died.

While cutting through the cartilages and intercostal muscles of the ribs mentioned, eighteen or nineteen hours after death, the knife slipped into the cavity in the left lung, and let out a quantity of abominably stinking gas. Raising the sternum, this cavity was found to occupy nearly the whole of the lung. Anteriorly it was bounded by the ribs and softened intercostal muscles; a portion of the third rib near its cartilage was denuded of periosteum. The cavity was half filled by a grey, pulpy, stinking fluid, resembling that expectorated; the lung was of a similar colour, was for the most part softened to the consistence of pap, and when sliced where most solid, the cut surface appeared grey, glairy, and homogeneous. The right lung was dotted with black spots, but in other respects, excepting a few small tubercles, was healthy.

Laennec and Andral give seven cases of gangrene of the lung: in five the left lung was affected, as it was in this case.

REMARKS.—Remarkable factor of the sputa is not a common sign in pulmonary affections. About 1200 in and out-patients of this hospital have come under my notice during the last 20 months; and I have noticed it in none other than the two cases just described. Turning my attention to books, I was surprised to find so little mention made of this symptom. Hippocrates, Arctæus, and the Greek and Latin authors included in *Medica Artis Principes* of Hen. Stephani, A.D. 1567, simply mention it as a bad symptom sometimes observed in phthisis. Galen (*De Febr. Lib. I. cap. 3.*) says, "it is dangerous to be with those affected with *tubæ*, who breathe forth such a putrid stink as to make the room smell strongly." Benedictus (*Tabid. Theat.*), Talpins, and Van Swieten, follow Galen, and considered the disease contagious, in proportion as the breath and sputa were

stinking. Sauvages has a species named *Dyrodia pulmonica*, but merely states that it is observed in some cases of phthisis. Dr. Good, in the first edition of the "Study of Medicine," published in 1822, follows the preceding; nor can I find so much as mention made of gangrene of the lungs. Laennec is the first author I have met with, who refers specially to factor of the sputa. Treating of chronic mucous catarrh, he states the expectoration becomes sometimes more or less fetid, and assumes the smell as well as the other physical qualities of the different kinds of pus, occasionally approaching the gangrenous factor; this may disappear and return in the course of a year*. Van Swieten observed some such cases when he declares, in opposition to the opinions of various illustrious and ancient authors, that he has seen persons who expectorated the most fetid sputa, and yet lived long, and were able to transact their ordinary business. He mentions the case of a youth, as particularly astonishing, who had been ill for some time, when he began to expectorate, early in the morning, sputa so stinking "ut ferre vix potuerim, licet me non adeo delicatam credam, ut a similibus facile afficiat." This expectoration continued for two years without injuring the general health, when it became suddenly increased, the patient emaciated, and death quickly ensued. Andral has given cases in his *Clinique Médicale* resembling this; and Dr. Elliotson, in his excellent and practical lectures†, very clearly draws a distinction between such and gangrene of the lungs. It cannot be doubted that similar cases have been observed in all ages; and included, together with bronchitis, and gangrene, vomica, and tubercular disease of the lungs, under the general term *phthisis*, or *tubæ*. Modern research has taught us to distinguish some of these from each other, but not all, and, when complicated with fetid sputa, they are still confounded.

When fetid sputa are observed in *chronic mucous catarrh*, there is not necessarily any derangement of the general health. Dr. Elliotson has seen persons going about without any par-

* On Diseases of the Chest, &c. by Forbes, 3d edit. p. 75.

† Commentarii apud H. Boerhaave, 2d edit. Leid. tom. iv. p. 72.

‡ MEDICAL GAZETTE, vol. xii. p. 92.

ticular ailment, except that they had a copious expectoration, exceedingly fetid*. Andral mentions a case in which a similar expectoration continued many years†; this patient died of œdema in the lungs; the bronchi were filled with a fluid like that expectorated, and the mucous membranes of the smaller tubes were of a deep red colour. In this case, the expectoration was as copious as if it came from a large excavation; this circumstance is more remarkable in those in which dilated bronchi followed chronic bronchitis or chronic mucous catarrh. Laennec remarks when the dilatation is very extensive the expectoration is sometimes so copious as to simulate the rupture of a vomica‡. This occurred in Case I. related by him. A child, aged three years and a half, brought up by mouthfuls a copious yellow very fetid puriform fluid. After death, bronchi of the left lung were found dilated, and containing a fluid like that expectorated§. Andral gives a case|| in which there was fetid expectoration for four months. Nine or ten weeks before the patient died it was a greyish liquid, which followed in a continued stream, very fetid and in great quantity. There were pectoriloquy, diarrhœa, and other symptoms, from which Lermnier considered the patient laboured under the pulmonary phthisis. After death, a cavity was found in the left lung, formed by a dilated bronchitis, containing a fluid like that expectorated, as also did other dilated bronchi¶. One of the cases given by the same author as gangrene of the lung**, and two by Laennec, as in cases of partial gangrene and of gangrenous eschar††, differ in no essential particular from this, and were really cases of dilated bronchi, with fetid secretion. Indeed, Andral himself seems to have doubt of the correctness of his diagnosis, for, after remarking upon the case, and stating that the grey and fetid sputa are as certainly diagnostic of gangrene, as the red, transparent, and viscid sputa, are of pneumonia, he acknowledges that these very characters induced him to

give an erroneous opinion in a case of fetid tubercular phthisis*. The same remarks are applicable to cases of reported cure of gangrene of the lungs, and this opinion I give the more confidently as it coincides with the sentiments of Laennec himself. He says, "From the result of several cases of recovery, I am tempted to believe that the fœtor and aspect of the expectoration above described, do not necessarily indicate the existence of a gangrenous eschar in the lungs.†" Dr. Elliotson makes a similar remark‡. Confirmatory of this is the opinion of so able and experienced a writer as Forbes, who says, "Gangrene of the lungs is an extremely rare disease. I do not think that I ever met with a case in practice—I do not know where to refer to any case recorded in our medical literature, the nature of which was unequivocal§."

A case of recovery from gangrene of the lungs is related by Dr. Crane, in a recent volume of this journal|. The fetid sputa continued for three months; the general symptoms differed very little from those observed by Andral in the case of chronic bronchitis before quoted. An analogous case is copied into the Medico-Chirurgical Review¶ from the Revue Médicale, in which the diagnosis is derived from the fœtor of the sputa, which continued a long time. For the reasons already given, a diagnosis so made is very likely to be fallacious.

The anatomical characters of this disease differ little from those of chronic bronchitis. Andral and Laennec give six cases. In all, the bronchi contained a fetid fluid, and the bronchial mucous membrane was of a deep red, or a livid colour, and thickened: the bronchi were dilated in five; those of the left lung only in three; and both in two. It seems to be essentially chronic; is characterized by violent cough and profuse expectoration of a fluid of a yellow, green, grey, or other similar colour, and having an abominable stench. The digestive functions and arterial system little disturbed.

The case of Battley seems to be a well-marked instance of the affection

existing without any important complication.

Laennec, Andral, and Elliotson, mention five cases of true uncircumscribed gangrene of the lung. In these, the affection was characterized by great disturbance of the arterial system and digestive organs, great prostration, cadaveric paleness of the countenance, emaciation, and death, before or about the thirtieth day. The anatomical characters may be thus stated:—The pulmonary and costal pleuræ of the side affected have contracted strong adhesions; the lung affected is hollowed into a cavity containing a very fetid and pulpy or pap-like matter. The surrounding parts are hepatized at some distance from the cavity; are of a grey, chocolate, or dark green colour, and terminating in a soft, greenish, or grey *pourriture*, which forms the parietes of the cavern.

This description so closely resembles that of the form of phagedæna termed *hospital pulpy*, and *contagious gangrene*, *malignant* or *sloughing sore*, and *gangrenous phagedæna*, that one might be inclined to suspect there was some analogy between the two diseases.

When I commenced my letter, I proposed entering upon an inquiry into the nature and causes of the fætor of the sputa in certain cases of chronic mucous catarrh, but I fear I have already trespassed too much on your pages. I may be permitted to add, however, that this disease, curable in itself, may present all the *physical* signs of tubercular phthisis, and of vomica and gangrene of the lungs; and, in the latter stages, most of the *rational* signs of those diseases. Accurate and practised observers have experienced this difficulty in diagnosis, and it is not improbable that many of the cases reported as cures of tubercular phthisis, have been aggravated forms of chronic mucous catarrh.

REMARKS

ON

A NOTE IN DR. ELLIOTSON'S
PHYSIOLOGY, PART II.

To the Editor of the Medical Gazette.

SIR,

SOME of your readers probably will recollect that soon after the publication

of Professor Elliotson's *Physiology*, Part I., I took the liberty of animadverting, in two letters, to be found in the *MEDICAL GAZETTE* for November 1835, on the views of that gentleman concerning life and mind. My purpose was, in a candid spirit, to refute certain notions, generally current by the name of *materialism*, which he thought it right, in very plain terms, to make public: and this I undertook not *uninvited*, for in his Preface he had solicited of his readers, as a valuable favour, the correction, either "publicly or privately," of any errors they might discover in the work. The points which I took upon me to examine are chiefly contained in such assertions as these:—"The brain thinks, feels, and wills, and has this power, medullary matter though it be, as obviously as that the liver secretes bile; brutes are as really endowed with mind as man; every child is conscious that it thinks with its head; the qualities of mind are corporeal conditions; when the body dies the mind ceases." There were several other points, as also much inaccurate reasoning concerning life and the qualities of matter, but the above particulars were the most important. It was my object to prove, and I trust I perfectly succeeded in proving, that the mind, which by the help of the senses examines, perceives, and reasons, concerning external objects, is, *in its nature*, different from all objects it thus examines, perceives, and reasons about; that, indeed, no rational being *is able* to believe that a thing (suppose the brain within his own skull) which he can think about as an object of sense, is identical with his thinking mind; and, consequently, that if the brain be really the thinking principle, we not only *can never know* the fact, but, by a necessity of nature, are compelled to believe the contrary.

A few months subsequently, I republished my letters somewhat amplified, with the addition of one or two chapters and a few notes, in the form of a small volume, which I entitled "Critical Remarks on certain recently published Opinions concerning Life and Mind." Not having the honour of a personal acquaintance with Dr. Elliotson, I hesitated to send to him a copy of the work as from the author. I, therefore, adopted a different course; as it turned out, an unfortunate one, for I requested a mutual friend to send a copy, and I was sorry to find that it was immediately

returned by Dr. Elliotson, accompanied (if I do not mistake, and I believe I am correct) with an angry letter.

Here the affair rested. A few days ago Part II. of Dr. Elliotson's *Physiology*, "On the Animal Functions," recently published, came into my hands. In glancing over the pages, I discovered that a considerable space, as might be expected, is devoted to a display of phrenology; and somewhat, perhaps, out of place, two lengthy notes to his favourite topic—materialism.

In these notes I find such profound and important announcements as the following:—

"I consider that a soul stands upon the same foundation as a Centaur or a Briarius." "Our own minds, and those of all other animals, are known to us only as powers generated merely by matter." "The brain, matter though it be, is seen, in positive fact, to have these [mental] capacities and endowments." "The properties of simple life, such as vegetables have in common with us, have neither dimensions, nor weight, nor colour, nor form, &c. They, I suppose, are not now ascribed to a soul, though they once were, and ought to be still, by such believers in souls." "The vital properties of a cabbage, I presume, are allowed to result from a well mixed combination of elements; and if such a combination produce such a result, other combinations *may* and *do* produce results still higher." "What property of dimension, weight, &c. is that possessed by mercury, iron, and so many other elements, of variously affecting living natures both corporeally and mentally?" "The vital and mental phenomena are unexampled in the inanimate world, result from no combination nor organization there, *simply because no such combination and organization occur in the inanimate world.*" "No mind exists in nature but as a property or power of matter. We never see mind." "We internally feel our personality in that part of space where our head is." "We possess no such thing as an immaterial soul." "If an animal can live when divided into two or more, its mind can do the same; so that a *planaria's* consciousness may be made into two or ten if we please; each new animal made from sections having its sense of personality, and, therefore, its pretension to an immaterial principle as much as the original, and as much as

the philosopher." "Cases occur in which a man has the consciousness of two persons*."

These passages (there are many others not less curious) which although separated from their context have each an independent meaning, will enable the reader to form a tolerably correct estimate of their author's uncommon profundity, and of his fitness for maintaining and propagating his *new* doctrine, so elevating and *flattering* to human nature. Part II. is throughout a singular and amusing production, covertly intended by its author, perhaps, to exhibit an illustration of his hypothesis, that it is *the brain that thinks*: and to prove how well an author can write who has discovered that he is destitute of a soul.

It is time I should inform the reader what it is that induces me at this time to notice, however cursorily, Dr. Elliotson's opinions. In the pages which have furnished me with the foregoing passages, I find one passage to which I take the liberty of requesting particular attention. "The doctrine of the existence of mind independently of matter [a notion, by the by, never maintained by those thoroughly conversant with the question] indicates a want of modern knowledge, and involves us in endless absurdity. *Its studied display usually proceeds, in our profession, from rank hypocrisy and malice, as though a materialist may not be a devout Christian; and these Pharisees say aloud, 'I thank thee, Lord, I am not as other men are, even as this materialist.'*"

As one of "the profession," also one who, in opposition to Dr. Elliotson, has made a "studied display" in favour, not of "the existence of mind independently of matter," but of the mind's being in its nature distinct from matter, it would be affectation in me to doubt, and in Dr. Elliotson to deny, that there is allusion to myself in the foregoing sentences. I say I cannot but conclude, coupling these with the private transaction before referred to, that such is the case; and this, I may say, is the opinion of more than myself. Lest, however, I should be assuming for myself too much importance—an error I am solicitous to avoid—I will suppose that I am alluded to only in common

* Human Physiology, by Dr. Elliotson, 5th edition, Part II. pages 360—365.

with that part of the profession who are guilty (apparently a most provoking offence) of disclaiming the learned Professor's materialism.

The allusion is of so offensive a nature that it is perplexing to know how it should be dealt with. Against the heavy charges it contains I will, if not for myself alone, as one of the implicated, offer a very brief defence. Having a slight taste for speculative inquiries, I wrote a criticism on Dr. Elliotson's views, partly as a mental exercise, but chiefly to maintain what I regarded as important truth. Dr. Elliotson had publicly challenged the judgment of his readers, and in offering mine I meant no offence. By the charge of "rank hypocrisy" may be understood an *affected* concern for religion. If this be the meaning, I think a reply unnecessary; or, it may mean that the opposition to Dr. Elliotson's sentiments was insincere; flowing not from a regard to the interests of truth, but from sinister and discreditable motives. My answer to this would be, that I now am, and have long been, sincerely persuaded, that materialism is both *illogical* as an hypothesis, and extremely pernicious in its moral tendency. As to the charge of malice, having no personal knowledge of this eminent physician, it is not easy to fancy a ground for such a feeling on my part. The learned professor knows human nature too well to be ignorant that often, when an author is the most loudly complaining of the stings of envy and malice, his sufferings are quite of another kind; that they are inflicted by the darts of contempt.

To say nothing of the bad taste in parodying a portion of Scripture, who has said that a materialist may not be a "devout Christian?" I have not. If a materialist professes to be *devout* it is only reasonable he should be believed. In asserting, on a former occasion, that Dr. Elliotson's views lead by no circuitous route to Spinozism, I was careful to add, that I did not impute to him the holding such a doctrine. But this gentleman, in the warmth of his antipathy, stigmatizes his opponents with the name of Pharisees: leaving it to be inferred that he, for his part, belongs to another and more honourable sect—the Sadducees. Surely he must be aware that the latter were not reckoned "devout."

What, let me seriously ask the reader,

are the doctrines, promulgated by Dr. Elliotson, whose rejection, on the part of his professional brethren, shows a "want of modern knowledge," and which he assumes they ought to accept at his hands with submissive reverence? They are—that the existence of the soul is an idle fable; that when the body dies the mind ceases; that a piece of clay, a pot-herb, and a man, alike matter, differ only in the component elements of each being differently combined and arranged; and that we are acquainted with nothing besides matter, the principle which *apprehends* being identical, as to nature, with *all the things* which it apprehends! If this be modern knowledge, I prefer, for me and mine, *that* that is more ancient.

But, some will be ready to exclaim, such an hypothesis is too absurd to do harm, there being little risk of such *illogical* views obtaining any considerable currency; for that, even should the young student, unhappily, be tempted to angle for knowledge in these turbid and shallow waters, he will speedily discover how unprofitable is the labour, and turn to more wholesome streams. It may be so. But who does not know how very imperfect the preliminary education is in the case of a great proportion of our students of medicine—how poorly prepared they are for thinking correctly on abstruse subjects—and how apt to be caught by specious novelties (which, indeed, are *not novel*) when announced from the professorial chair with boldness, and with strong expressions of contempt for the opinions of the multitude. On this account it is that I see no harm, but much good, in an occasional "studied display" in favour of fundamental, irrefragable truths, even at the hazard of a charge of "hypocrisy" and "malice." At parting, I will remind this eminent physician that though nothing is so bad as hypocrisy, there are other vices of the mind productive to society of more extensive injury: one is the vice of an *insatiable egotism*, particularly when associated with an eager curiosity, a bustling activity, and slender reasoning powers.

Yours respectfully,

JOHN ROBERTON.

Manchester, Nov. 28, 1837.

I beg to observe that I will not be drawn into a controversy respecting the contents of this letter. My maturely-

weighed sentiments on life and mind are to be found in the little work before referred to, "Critical Remarks on certain recently published Opinions on Life and Mind," 12mo. Longman and Co. 1836. When the arguments in that work have been fairly answered, it will then be for me to consider how far a reply may be necessary.

SOME ACCOUNT OF MESMERISM.

BY BARON DU POTET DE SENNEVOY.

[Concluded from page 423.]

On Somnambulism.

It was at Busancy, near Poissons, that somnambulism originally presented itself with all its wonders. The Marquis de Puysegur was the first who thought of interrogating patients thrown by magnetisation into a kind of sleep. They replied without awaking, and the report of this astonishing circumstance soon spread abroad. People hastened from all parts to witness so singular a phenomenon.

The first account of these facts appeared in 1784: it was by a M. Cloquet, receiver of finance. "Attracted, like others, to this spectacle, I went prepared to be a calm and impartial observer, firmly resolved to be on my guard against the illusions of novelty and of wonder; firmly resolved both to look and to listen well."

M. Cloquet, after having described the proceedings employed by M. de Puysegur for acting upon the patients, and having related various scenes of magnetisation, adds—"The consummation of this state (the magnetic state) is an appearance of sleep, during which the physical faculties seem to be suspended, but to the advantage of the intellectual faculties. The eyes of the subject are closed: his sense of hearing is null; he wakes only at the sight of the master (*dumaitre*). No one should touch the patient during a crisis, not even the chair on which he is seated; it would cause him much suffering and convulsions, which the master only can calm.

"These patients, during the crisis, possess an extraordinary (*surnaturel*) power, by which, on touching a patient presented to them, on passing their hand even over the clothes, they feel

which is the affected viscus—the suffering part; they point it out, and indicate pretty nearly the suitable remedies.

"One singularity not less remarkable than all that I have just disclosed is, that these sleepers, who during four hours have touched patients, have reasoned with them, remember nothing, absolutely nothing, after the master has thought proper to disenchant them—to restore them to their natural state. The time that has elapsed between their entering into the crisis and that of their coming out of it, is as it were null. The master has the power, not only, as I have already said, of making himself heard by these somnambulists, but I have frequently seen him, observing him all the time with the utmost vigilance—I have seen him point his finger from a distance to individuals while in the crisis, and in a state of spasmodic sleep, and make them follow him wherever he chose; or send them from him, either to their own homes, or to different places which he designed, without telling them,—the somnambulists, it should be remembered, having their eyes the whole time completely closed. I have forgotten to mention, that the intelligence of these patients is singularly susceptible. If, at distances by no means inconsiderable, conversation is held offensive to propriety, they hear it as it were internally, their minds are disagreeably affected by it, they complain of it, and inform the master of the circumstance; and this has several times occasioned scenes of confusion to ill-witted jesters (*pour les mauvais plaisants*), who indulged, at M. de Puysegur's residence, in inconsiderate and misplaced sarcasms. In order to awaken the somnambulists, the master has only to pass his fingers over their eyes."

M. de Puysegur, whose philanthropy has led him to occupy himself with magnetism, hastened to impart his discovery to persons who, like himself, took interest in this subject. Wherever somnambulism could be produced, the admiration inspired by this strange phenomenon was so great, that those who presented it were consulted as oracles, and the enthusiasm of those who witnessed such scenes knew no limits.

By degrees, however, people became familiarised with this state, and reflection caused it to be better appreciated. Yet after forty years this discovery has lost nothing of its importance; it has

been combated; efforts have been made to prove that it does not exist. Negative facts, it is true, have been brought forward, which have caused its existence to be doubted.

Passing by many historians who have spoken of somnambulism, we reach our own epoch, and shall cite living authors, who may be consulted respecting the merit of their own assertions. The first summary is by the Comte de Redern, a distinguished man of science, who gave great attention to magnetism.

"The body is more erect than in the waking state; there is a marked acceleration of the pulse, and an augmentation of irritability in the nervous system; the touch, taste, and smell, have become more delicate; the sense of hearing is affected only by sounds proceeding from the bodies with which the somnambulist happens to be in direct or indirect relation, that is to say, which are in communication through the vital fluid, from having been touched by him and his magnetiser. His eyes are closed, and have no longer the power of vision; but he has a kind of sight which may be called internal, that of the organisation of his own body, of that of his magnetiser, and of the persons with whom he is placed in relation; he perceives the different parts of them, but in succession only, and according as he directs his attention to them; he distinguishes their structure, form, and colour: he has sometimes the faculty of perceiving external objects by a peculiar kind of sight: they appear to him more luminous, more brilliant, than in the waking state. He experiences a painful reaction of the sufferings of the persons with whom he is in relation; he perceives their diseases, foresees their crises, has a perception of the suitable remedies, and not unfrequently that of the medicinal properties of substances presented to him. His imagination has a tendency to exaltation; he is jealous, full of vanity and self-love, and disposed to make use of little artifices to give himself importance. His will is not inactive, but it is easily influenced by the magnetiser. Very striking contradictions are observable between his ordinary opinions and those in his state of somnambulism; he condemns his own actions, and sometimes speaks of himself as he would of a third person quite a stranger to him. He expresses himself better, has more

esprit, has greater powers of combinations, possesses more reason, more morality, than in his waking condition, all the ideas of which are present to him. When the somnambulist returns to the waking state, he has entirely forgotten all that he had said, done, and heard, during the fit of somnambulism, &c."

Let us now attend to further details on the faculties attributed to somnambulists.

"When magnetism produces somnambulism (says M. Husson,) the individual in that state acquires a prodigious extension of the power of sensation. Several of his exterior organs are, so to speak, put to sleep, especially those of sight and hearing, and all the operations dependent on them are performed internally.

"The somnambulist has his eyes closed; he neither sees with his eyes nor hears with his ears: yet he sees and hears better than a waking person. He sees and hears only those with whom he is in relation. He sees only that at which he looks; and he usually looks at those objects only to which his attention is directed. He is submissive to the will of his magnetiser in all things which cannot injure himself, and in all that does not oppose his own ideas of justice and truth. He feels the will of his magnetiser. He sees, or rather he has a perception of the interior of his own body, and of that of others; but he usually remarks those parts only which are not in the natural state, and which disturb the harmony of it. He recalls to his memory things which he had forgotten in his waking state. He has previsions and *présentations*, which may be erroneous in several circumstances, and which are limited in their extent. He expresses himself with surprising facility. He is not free from vanity; his self-improvement is progressive (*il se perfectionne de lui-même*) for a certain time if guided with discretion, but if ill directed he goes astray. When returned to his natural condition he entirely loses the recollection of all the sensations and ideas he had during his state of somnambulism, so that these two states are as entirely strangers to one another, as if the somnambulist and the waking man were two different persons."

M. Husson adds, "Recent observers affirm, that in this state of somnam-

bulism, of which we have just analytically exposed the principal phenomena, the magnetised persons have a lucidity which gives them positive ideas on the nature of their diseases, on the manner in which persons put in relation with them are affected, and of the mode of treatment to be employed in both cases. If it is assuredly true, as it is asserted to have been observed in 1820, at the Hôtel Dieu, at Paris, that during this singular phenomenon sensibility is so entirely deadened that the somnambulists could be cauterised; if it is equally true, as it is affirmed was seen at La Salpêtrière, in 1821, that the somnambulists possess such a degree of prevision, that women, well known, and treated for a length of time for epilepsy, were able to predict, twenty days previously, the day, the hour, the minute, when the next epileptic attack would come on, and that in fact it did so come on; finally, if it is equally acknowledged that this singular faculty can be employed with advantage in medical practice, there can be no manner of doubt that, in this point of view alone, it deserves the attention and the examination of the Academy."

When this summary was read at the Academy of Medicine, M. Husson was its president. If what he announced to exist had not presented itself to his eyes with all the characters of truth, would he not have shrunk from such language, and so far from soliciting the Academy to make the proposed examination, would he not have designated magnetisers as cheats and impostors? But as we have said, mesmerism was no longer in the hands of a few physicians only, and some scientific men. Many amongst them practised it, and to give even an abridgment of all their labours would require several volumes. To the summary which I have just transcribed I could have added those of M. Deleuze upon the same faculties, of M. Chardel on the same subject, and of Dr. Foissac, the physician, who excited the Academy to the examination, and went to great lengths in his assertions. I could tell that which I have seen developed in more than 300 somniloquists, and quote numerous foreign authors who have written on magnetism. But to what purpose should I prolong the recital, since such phenomena may be produced daily? Once more, magnetisers do not ask that persons should

believe in the reality of their statements, but only desire that they should examine fairly. An examination is, indeed, brought against them, in which all the facts are negative. Can four or five men, who have studied, for no great length of time, two magnetised subjects, prevail against thousands of observations and observers? Prove to us, say they, the wonderful phenomena of lucidity, and we will believe in them; explain to us how the eye and the ear can be supplied by other organs, and we will become your partisans. I desire nothing better than to endeavour to resolve this problem; for however objectionable it may be to speak of seeing without the aid of the eyes, I firmly adopt, in its full extent, the fact it is intended to express. As to the law according to which it is produced, I have not yet arrived at a full and positive conclusion.

I shall enter upon the phenomenon of sight (so called) without the intervention of the eyes. My examples will be numerous, and all authentic. As to the explanation of the facts, if it should appear incomplete, I will endeavour to satisfy, as far as may be in my power, the doubts proposed to me. Before I conclude, allow me to state my regret that, on the first discovery of animal magnetism, words were not created well calculated to express the effects arising from the proceedings employed by Mesmer; for the state of which I have just given a description cannot be rendered intelligible by the word sleep. The vision of somnambulists is not exercised by their eyes, it is another mode of perception, and which cannot be rendered by the word *seeing*. The action also of one individual upon another is no more magnetic than electric, and thence sprang innumerable errors that have furnished a text for many disputes, which would have been avoided, had the singular phenomena arising from the employment of a new agent received more distinctive names. But the mischief is done; it would now be very difficult to make use of other terms than those which the magnetisers have adopted. For the rest, the discovery is made; that is the essential point; it will not be lost; time will mature it, and like the rivulet, which does not become limpid till after it has flowed through the sand, and there deposited its sedi-

ment, so magnetism will make its way through criticism and contradiction; and thus purified, will, in time, appear in all the brilliancy of which so noble a discovery is susceptible.

Philanthropy, the desire of being useful to a suffering fellow-being, have no doubt caused the power of magnetism to be exaggerated; but this power does exist; it is indubitable. It is the part of the physician to study it without prejudice; it is for the physiologist to assign to it its just limits. The direct influence of this new agent upon the nervous system would lead at once to the belief that its action would be efficacious in nervous diseases generally; that hysteria, hypochondriasis, melancholia, catalepsy, epilepsy, might derive, as they have in reality derived, the most salutary influences from it. Spasmodic affections in general, a multitude of pains, some species of deafness, and paralysis, perhaps would experience some kind of modification from magnetism. In these various affections, the nervous system being principally injured, and magnetism especially influencing this system, it is easy to conceive that results might be obtained worthy of attention. Thus it is amongst these diseases that the partisans of magnetism affirm that they have had the most surprising success. It would render this article much too long were we to quote examples, but all works upon magnetism are full of them. No panacea exists, nor do we pretend that magnetism is one. Thus, if it is useful in some circumstances, there is reason to fear that it may be injurious in others.

The nature of its action should be carefully studied, to ascertain whether it is exciting, debilitating, or sedative. If we can rigorously determine this physiological action, we may then proceed philosophically; we may fix the cases in which it may be employed with advantage—we may become useful; at least, we shall cease to do mischief. But will the power of magnetism be limited to the diseases of the nervous system? We know that the brain extends its empire over all our organs, over all the parts of our bodies. This governing organ being by this means profoundly modified, may it not in its turn operate some beneficial change in a suffering part? By suspending pain, will not a first benefit be produced? Pain being

suspended, will not the afflux (*Puppel*) of the fluids, which is its consequence, be also suspended? will not the materials of congestion, irritation, engorgement, which these fluids bring with them, and which augment the local evil because the effect augments the cause, then cease to accumulate (*d'arriver*); and would not the ulterior progress of the disease be in this manner obstructed, and its resolution facilitated? Let us suppose only pain to be suspended, and this effect is incontestable, and we already see that the results are immense: what would be the case if physiological experiments should prove incontrovertibly that magnetism renders absorption more active?

Thus, in acute diseases, magnetism may produce beneficial effects. I ought, however, to call your attention to the circumstance, that if in the healthy state nature alone knows her own weights and measures, and if the harmonious course prescribed by infinite wisdom presents itself to our observation, the case is not the same in some acute states, where nature in a disturbed state seems to abandon the individual to chance. It would then be dangerous for you to rely entirely upon magnetism; you should join with it some active medicine, capable of arresting or of diminishing the existing disturbance; for it is only then that the materials of repair which you employ can be used with advantage by the conservative powers of nature; in the contrary case they may rather increase the evil. What I have just said is not applicable to syncopal diseases, diseases that can only be compared to death. It is on such especially that we may expect beneficial effects from magnetism. These diseases consist in a sudden weakening, in a greater or less degree, of the vital action, and are most commonly caused by some moral affection, such as joy, fear, surprise, grief, the antipathy of the senses, and above all of the imagination, towards certain objects.

In such diseases some unknown organs still retain sensibility; they serve as a last entrenchment for life. It is in this retreat that the magnetic fluid would probably penetrate to re-animate nature, and supply the stimulus required to awaken it, with more certainty than any of the known agents.

Zealous for the good of mankind, we have undertaken the defence of magnetism, because we are convinced that no

discovery could produce such important results; and this not only because it is a means of curing some of the diseases which afflict our race, but because from the knowledge of this agent flow new principles, which will infallibly emancipate us from a host of ancient errors, which have no other foundation than antiquity, and ignorance of some laws of nature.

[We have found it impossible to complete the article in the present number, but shall insert what remains of it next week.—ED. GAZ.]

MEDICAL GAZETTE.

Saturday, December 16, 1837.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

ON THE PRACTICAL TEACHING OF MEDICINE.

HAVING lately read with great satisfaction Mr. Whewell's work "On the Principles of English University Education," it will not, we hope, be out of place, if we lay before our readers some of the very valuable matter which it contains, using a few of the author's more important announcements in the manner of texts, which we shall illustrate by remarks that may be useful in regard to the subject of medical education. From a gentleman of talent so extraordinary, and of experience so extensive, as Mr. Whewell, any recommendation, indeed, on the subject of education, cannot but be deemed most valuable, not only in regard to those members of our profession who are more immediately concerned in University education, but to the much greater number, to whom, educated elsewhere, the same general principles to which he alludes will apply.

In the first part of his work Mr. W. points out the essential difference be-

tween the two chief modes of teaching at present pursued, in one of which a lecturer imparts to his audience the doctrines of some branch of study, the pupils being merely listeners, and never required to take any active part, or to apply, in the presence of their teacher, the knowledge thus acquired; while in the other, the pupils not merely listen, but do something themselves; they solve problems enunciated to them, while in classics they translate or compose. The former may be called *speculative*, the latter *practical*, teaching. The first is the mode generally adopted in the Colleges; the last, that pursued by the University professors.

Having pointed out the classes of subjects to which each of these systems is particularly applicable, he considers the general effect which each, when widely adopted, has had, and briefly but lucidly shews, that practical teaching (especially as pursued in mathematics) is very far to be preferred, in the discipline which it exercises over the intellect, and the healthful condition of the mind which it induces, by storing it with distinct fundamental ideas. From historical evidence it is proved that it has had the most marked and beneficial influence on the progress of civilization; that so long as practical teaching was adopted, the degree of civilization increased, and the progress of science and art was rapid; but that when speculative teaching was pursued, a result the very reverse followed. The nature of the subject taught of course corresponded with the mode of tuition—subjects of the class of mathematics and inductive philosophy coinciding with the practical, and those of more abstract philosophy with the speculative mode. The practical and mathematical education prevailed in the time of Plato; and at that period the greatest scientific discoveries of the

ancient world were made by Hipparchus and Archimedes. Soon after, the speculative study of philosophy prevailed, and from that time science was almost at a stand-still; it had even fallen below the height it had attained, and the intellectual world grew darker and darker, till the religious orders introduced a system of practical and mathematical instruction among themselves, and then the most rapid progress again commenced; and where the same system has been continued, the most exalted state of civilization, and the highest attainments of science, are, in the present day, reached. In one country, Germany, where the speculative mode of teaching *philosophy* has been resumed, they have been forming system after system, without seeming to be aware that in many sciences their professors are a century behind those of the more advanced parts of Europe.

The "great experiment" of history and accurate observation, have, in short, clearly shown the benefits of practical teaching, on the progress of science and civilization, and on the moral and intellectual condition of the taught: let us see how far this fact can be made useful in that branch of education with which we are most immediately concerned.

Mr. Whewell could nowhere have found a more marked individual instance of the truth of that which he proves generally, than is to be seen in the history of the medical sciences. Look to what period of it we may, we find those leaving the most valuable results of their labours, who cultivated it most completely as a science of accurate observation, and least as one of mere philosophy; and in succeeding years we find the impress which their teaching made on the minds of their pupils commemorated in the increased rapidity and progress of the science. It is but a short time since we made this remark,

when speaking of the state of medicine in England, France, and Germany, and we may here point to the striking difference of repute in which men, probably of nearly equal talent, are now deservedly held, according as they pursued their studies in one or other of these directions. Take, for example, Boerhaave, Stahl, and Van Helmont, on the philosophical side, and Harvey, Sydenham, and Haller on the practical, and it will be seen that while the facts elicited by the latter are now the most familiar, most clear and fundamental, of the science, the systems of the former are never mentioned except by those who now most unnecessarily take the trouble to refute them. Or to come to later times, compare Cullen with John Hunter: the system of the former long since superaded, while the facts of the latter become every day more valuable as they are more completely illustrated. The school of Cullen, even now, is scarcely recognised, and few would choose to acknowledge themselves supporters of his opinions, or followers of his mode of study; while, though hardly any of the actual pupils of Hunter are now left, he is still the model which every student is urged to imitate, and his reputation daily increases. It is a happy thing that at present we can scarcely be said to have a system of medicine in vogue, and seeing how futile have been the attempts hitherto made, and how signally men of very exalted genius have failed, it is to be hoped that none will again lose their time and labour in framing one;—centuries must still elapse, before sufficient distinct and fundamental facts can be accumulated to form any basis stable enough to bear so complex and so lofty an elevation as that must be which will include all the laws of such varied actions as medical science has to deal with.

For the sake of the science, therefore, practical study and teaching should by

all means be pursued, and the same spirit should prevail in the education of all, whether they are destined in after-life to be merely practitioners, or independent and scientific students of their profession. There can be little doubt that if the system of practical instruction could be introduced into medical schools, its tendency would be highly beneficial; though, of course, it would only be applicable to a part of the subjects usually taught there. Medical and surgical lectures must always remain as they are, consisting of enunciations by the teacher of the doctrines of his science according to the most received opinions of his day, and of such illustrations as he may see fit to employ. But such need not be the mode of teaching anatomy, or at least of all parts of it; in it, consisting almost entirely, as it does, of descriptions of visible forms and arrangements, which it is important for the student to remember well, no plan could be more likely to secure accurate and distinct ideas in his mind, than that he should be made to demonstrate his knowledge with the subject before him to his teacher, and to the class around. In some schools this is occasionally resorted to, in weekly examinations; but the demonstrated subjects are very limited, and little more is done than in questions and answers, in imitation of the ultimate examinations for which a competent preparation is at present the main and often the sole end of education. The system is far more generally pursued by the private teachers; but by them the subjects taught are carefully and expressly limited to those *required* by the examiners, and even these are taught in so superficial and hasty a manner, that they obtain not the slightest hold on the student's mind; and he deems that he has received all he paid for, if he has seemed to know on the necessary evening that which he ought to know in every hour of his life.

The course of anatomical demonstrations, which is of comparatively recent introduction, has of late become (whatever its origin might have been) nothing less than a second or supplementary course of anatomical lectures, in which the subjects are not always such as admit of visible demonstration, and are treated of in accidental arrangement. It is altogether a matter of speculation whether the student, who "has attended diligently" both of these courses for a lengthened period, has profited by them in the smallest degree. We know that instances continually occur where pupils who have been present at three or four hundred such lectures, have remained utterly unable to tell one bone from another when they were shewn them together; and it is not long since a candidate, who passed at the College of Surgeons, repeated accurately a demonstration of the scapula, but when asked to point out the superior costa, put his finger on the base. Now, in a study which may and ought to be practical, and which, except for its practical applications, is equally useless and uninteresting, these things ought never to occur, and the idleness of such students as would be content with their ignorance, should be met by more vigilant measures.

An improvement would undoubtedly be effected by making both the studies and the examinations more practical. We are not anxious to advocate any fundamental change in the system of the schools, for we look with satisfaction on the improvements which late years have seen rapidly introduced into them; but we think it well worthy the attention of teachers to consider whether the present subordinate course of lectures might not be made a *bonâ fide* course of practical anatomy. Each student might be called on in turn to dissect and demonstrate some muscle, or other part, while others stood

around; or it might be made the general practice in the dissecting-rooms, for the teachers not merely to direct the dissections, and assist in removing the difficulties of the students, but to call on them to demonstrate the parts in the study of which they were at the time engaged. No one who has for any time observed the degrees of knowledge of practical anatomy which students obtain during their attendance on lectures and dissecting, can be ignorant that the amount which they possess is in general utterly disproportioned to the time expended on it; and we believe that this depends, in great measure, on the want of more practical teaching.

Not long since, we pointed out the comparative inutility of chemistry and botany, as at present taught. The knowledge which students are expected to obtain of them is even more speculative than of anatomy; for they are never called upon to put any part of what they learn into practice, or to take any active part in the study of these branches of education, as they do in that of anatomy by dissecting. Much of the theoretical part of both these subjects might well be dispensed with, if the merest elements of their practice could be taught.

A practical study of the practice of medicine and surgery it would be difficult to enforce in our hospitals, without infringing in some measure upon the comforts and safety of the patients; but it would not be difficult to make the examinations more practical. We do not, indeed, despair of seeing the time when part of the examination shall be conducted at the bed-side of a patient, as it now is in France; where, indeed, it forms the only part in which their educational system is at all superior to our own. But in reference to the subject of examinations, there are some remarks in Mr. Whewell's work which deserve a separate consideration.

We need scarcely add, that a system

of practical teaching would remove the objection, that as students may attend in lecture-rooms without attending to what is said, the attendance might be given up altogether. Not that this objection is of any great force, for it would be difficult to prove that, if excused from lectures, the student would be better employed—as for example, in reading the works of better teachers, which, it is said, are open to him. We suspect the instances are very few where the inattentive at lectures are attentive to private study; and though attention cannot be enforced where attendance is, the student has at least some chance of learning afforded him: but in practical teaching, attendance and attention must be coincident, and we can scarcely see how the most ingeniously idle could evade the acquisition of knowledge.

MR. SAMUEL COOPER AND
MR WAKLEY.

Our readers will have perceived, from the correspondence inserted in our last number, that Mr. Wakley sent a friend to Mr. Samuel Cooper, to demand an explanation in consequence of certain expressions contained in his lecture, published the preceding week. Now the lamentable want of discretion and good taste displayed on this occasion, by one enjoying the reputation, and holding the prominent station of Mr. Cooper, is too mortifying a subject for us to discuss; but we cannot let the affair drop, after having assumed its present aspect, without adverting to the very unreasonable and absurd line of conduct adopted by Mr. Wakley.

It is matter of notoriety, universally felt, acknowledged, and acted upon, in the medical profession, that the Editor of the *Lancet*, by the indiscriminate abusive and often libellous nature of his attacks upon individuals, has earned for his journal such a place in public estima-

ion as to preclude every one, without a single exception, of the many whom he has assailed, from calling him to any account, unless that which is yielded in a court of law. This is the simple and undeniable statement of a well-known fact. But the very circumstances which have obtained for the Editor of the *Lancet* this peculiar species of immunity, have, as a necessary and obvious consequence, deprived him of all right to expect that any of those who, in self-defence, answer his attacks, should consent to afford him "satisfaction," merely because such retaliation may have proved unpalatable to him.

The only difference between the present and most other cases, is, that Mr. Cooper, on being attacked, has chosen to reply, and that, in our humble judgment, not in a manner such as his friends could have desired. Nevertheless, if it be admitted that consistency, and a regard for what he owes to himself and his professional brethren, did not peremptorily require that Mr. Cooper should decline the challenge, then would the Editor of the *Lancet* be placed in an entirely new position, and such as would render it imperative on all those whom he has calumniated to call him to account forthwith; in which case, we apprehend that the life of the honourable member for Finsbury would be held but an indifferent speculation by an insurance company, even in these days of hungry competition.

Since the above was written, Mr. Cooper has sent us another address to his pupils, which we have not, under all the circumstances, felt at liberty to withhold. It appears that he did not regard the message from Mr. Wakley as a demand of satisfaction, and implies that if he were to receive a challenge from him, he would accept it! While we have read these statements with unfeigned astonishment, they have only

served to impress us more strongly with the correctness of the view of the question we had previously taken, and which remains altogether unchanged.

P.S.—As this sheet was passing the press a letter was received, which will be found at p. 478, and to which we refer our readers, without any other observation than that they will find the termination of this affair by no means the least extraordinary, or least amusing, part of the whole.

CLINICAL LECTURE

ON

ENCYSTED TUMORS OF THE EYELIDS—ON PENETRATING WOUNDS OF THE EYE—ON SYPHILITIC IRITIS—AND STRUMOUS OPHTHALMIA.

By W. LAWRENCE, F.R.S.

Encysted Tumors of the Eyelids, containing Hair.

A FEW days ago I removed a small tumor, in the case of a young child, from the neighbourhood of the external canthus. It was about the size of a horse-bean, forming a colourless elevation, with the integuments covering it loosely, so that they could be pinched up into a fold over the swelling, which was more fixed below. It was placed immediately behind, and a little above the junction of the lids; and was said, by the mother, to have been there from the time of birth. She stated that it was increasing, and for this reason she wished that it should be removed.

In performing the operation, it was found that the tumor, which from external examination might have been supposed to be simply subcutaneous, was covered also by the orbicularis palpebrarum, and that it adhered closely to the external angular process of the frontal bone. It consisted of a thin but compact cyst, with a whitish glistening surface, and it contained a fatty matter, resembling soft suet, with an intermixture of short darkish hairs, principally in small bundles on the surface of the fat.

Such tumors are not unfrequent in infants and young children, occupying the situation just described. I believe them to be congenital; at least the statement of the mother generally leads to this inference. Sometimes they are stationary:

in that case, if the swelling is small, there is no necessity for operation, as it is perfectly indolent. I am acquainted with a gentleman who has had through life a rather larger growth of this kind: it causes an unnatural fulness near the extreme angle of the eye, not amounting to deformity, and has never been attended with the slightest uneasiness. The affection, as in the case just described, is a cyst containing fat, which is sometimes of oily consistence, sometimes firmer. I have always found short hairs mixed with it in various proportions. Is this admixture of hairs, which resemble those of the eyebrow in length, to be regarded as an exemplification of the principle so frequently observed in adventitious structures, viz. that they resemble in nature that of the textures in which they grow, or that of parts in their immediate vicinity? It is placed under the orbicularis, and adheres more or less firmly to the bone. You must bear in mind the two latter circumstances in operating; make a larger incision than the size of the swelling would seem to require; and pay especial attention to the complete removal of the cyst from the bone.

If a portion of the cyst is left, the wound will not close, and such an occurrence is very annoying to the patient, and considered discreditable to the operator. I saw a young lady, in whom such a tumor as those I have described had been removed from the root of the nose, at the interval between the two eyebrows. She was a handsome person, and had submitted to the operation for the removal of what she deemed a blemish, though it must have been very slight, as the tumor was inconsiderable. She was much worse off after the operation than before; for the wound did not heal, at least it sometimes scabbed over, and sometimes discharged. A probe introduced into the opening went down apparently to the bone. Having learnt the nature of the swelling, and that the operator had experienced unexpected difficulty in separating it from the bone, I concluded that a bit of the cyst had been left behind, and proposed an incision to ascertain that point, which was readily consented to. I found, closely adhering to the frontal bone, a small strip of the cyst, conspicuous by its white glistening surface, and having a few short hairs on it: this was easily removed, and a firm cicatrix was soon secured.

I once saw a small growth of similar nature, but with an external aperture large enough to admit an ordinary dressing probe, on the bridge of the nose. It was congenital; and the opening sometimes

produced a kind of greasy discharge. A probe passed in about a third of an inch. Various applications had been made to the part ineffectually. I slit it open, and found a smooth shining membrane with small hairs upon it, almost imbedded in the ossa nasi. It was difficult to dissect it out completely; but the removal was accomplished, and the part healed soundly.

Penetrating Wound of the Sclerotica, with Prolapsus (?) of the Iris.

A child, about five years old, was brought to the hospital, as an out-patient, a week ago, having received a severe blow on the right eye with a stick. The sclerotica was ruptured near the margin of the cornea, the wound being about one-eighth of an inch in length. The corresponding portion of the iris had disappeared, so that the pupil, opposite to the wound in the sclerotica, was continued to the circumference of the cornea. The conjunctiva was slightly elevated, as if by a protrusion of the missing part of the iris. The accident had occurred three or four days previously, and nothing had been done for it. There was no inflammation or pain of the eye: the pupil was clear, the iris natural, except in the points already mentioned, and vision seemed unaffected. The case required nothing further than care, with a little medicine and cold lotion. We saw the child since, the eye remaining in the state already described, and ascertained clearly that vision was unimpaired.

Penetrating wounds of the globe seldom terminate so favourably as in this case. They generally produce, more especially if they should be lacerated, as in this patient, serious inflammation, which involves the internal tunics, and is thus likely to destroy or injure sight. To prevent or to lessen this kind of mischief, active antiphlogistic means should be resorted to immediately after the accident, or as soon as the slightest indications of inflammation are observed. Again, a blow on the eye, without producing any wound or visible injury, may impair or destroy sight, by causing concussion of the retina. I use the word concussion here, as in injuries of the head, to denote a species of injury not produced by violence directly applied to the part, and of which indeed we do not know the exact nature, although it is capable of producing the most serious effects. I lately saw a young gentleman, in whom complete amaurosis had ensued from a blow in the eye, not followed by any visible injury.

When the sclerotica is wounded, there is commonly an excessive partial dilatation of the pupil opposite to the injury,

which may proceed, as in this case, to actual disappearance of the pupillary margin. This must be ascribed to injury of the corresponding ciliary nerves. Such wounds are frequently attended with effusion of blood into the anterior chamber, behind the iris, or in both situations. This indicates that the violence has been serious; and wound or rupture of the sclerotica, combined with such effusions, generally terminates in loss of vision, either by concussion of the retina, or by inflammation of the internal tunics coming on slowly after the accident, and terminating in atrophy of the globe.

I remember, however, another case of complete recovery after a penetrating wound of the sclerotica, which I mention to you, because such favourable results, although rare, may prevent us from pronouncing too alarming a prognosis. A boy at school, ten years old, received a blow on the eye, near the external angle, from an arrow, with a pointed nail fixed to its end: it was thrown towards him, and did not strike the globe with great force. He was immediately brought to me in a chaise, from a distance of fifteen miles, where the accident had happened. The master, who accompanied him, informed me that he examined the eye immediately after the accident, that he found the pupil greatly dilated, and that the boy could not see. There was a wound of the sclerotica, a short distance behind the cornea, shaped like a leech-bite, but larger: the pupil was round, clear, and larger than that of the opposite eye. I was pleased to find that the patient could see, though imperfectly; and I was unwilling at that moment to make the trials necessary for ascertaining the exact amount of vision. I directed leeches, cold cloths to the eye, aperient medicines, low diet, and rest in bed, strong light being excluded from the room. I saw the patient again in ten days, when the eye was, as it had been in the interval, free from all inflammatory redness; the iris, the pupil, and the motions of the former, were perfectly natural, and vision was unimpaired. The recovery in this case was permanent; the injury of the sclerotica being still visible. Wounds of this structure do not unite, as we see in the punctures made in couching.

Iritis combined with Scaly Syphilitic Eruption.

I have seen iritis occurring in conjunction with various forms of syphilitic eruption. If asked with which of these it is most frequently conjoined, I should have said the scaly; although Mr. Carmichael, whose experience has been so extensive, has represented it as almost confined to what he denominates the papular form of venereal disease. I mentioned to you in a former lecture a case of acute syphi-

litic iritis, with scaly eruption, and ulceration of the fauces. There was general discoloration of the iris, with a mass of lymph effused near the pupillary margin; contraction and irregularity of the pupil, with vision so much impaired, that the patient could not distinguish even capital letters. The treatment consisted, as I then mentioned to you, in abstraction of blood by cupping on the temple to sixteen ounces, and the administration, every six hours, of two grains of calomel, with one-third of a grain of opium. Subsequently the moistened extract of belladonna has been applied on the brow daily. The mercury has acted considerably on the system, producing pyalism; and the influence on the ophthalmic affection, and the other symptoms, has been proportionably decisive and rapid. In seven days the effused lymph is nearly absorbed, the iris has regained its natural colour, the external redness has nearly disappeared, and the patient can read small print; the adhesions of the iris have not given way, and the organ has not perfectly recovered, although the mercury has been discontinued, and will, probably, not be resumed. The eruption has faded, and the throat is recovered. The antivenereal powers of mercury seem to me to be shown most unequivocally in ulcerations of the throat and mouth; for although the remedy produces, as it did in this case, inflammation and ulceration of the gums, it cures the syphilitic ulceration of the contiguous membrane, thus appearing in the double light of bane and antidote, in reference to two parts of one continuous membranous surface.

W. Pratt was admitted May 25, with gonorrhoea, scaly eruption, superficial ulcerations of the fauces, and pains in the limbs. On account of the latter, which were severe, hyaliodate of potash, in the dose of 5 grains, three times daily, was administered in the compound decoction of sarsaparilla. It acted with its usual good effects; and the patient felt himself so much relieved, that he left the hospital, by his own desire, on June 14. He returned on the 21st with acute iritis of the right eye. There was a zone of pink redness in the sclerotica round the cornea; the iris was discoloured, dull, and dark throughout: the pupillary margin, and the lesser circle, being covered by a fur of dull brownish red lymph. The pupil was irregular, vision greatly impaired, and there was great pain in the frontal region, particularly during the night, completely preventing rest. Twenty ounces of blood were taken from the temples by cupping: two grains of calomel, and $\frac{1}{4}$ grain of opium, were given every six hours. On the 23rd, twelve leeches were applied round the eye: and now (June 26) recovery

is proceeding rapidly, under a decided but not excessive, mercurial influence.

In — Richardson, we have another example of iritis with scaly eruption. There was general discoloration of the iris, without any effusion of lymph in distinct masses—condylomata, as some of the German writers have called them. Although these effusions are seldom seen in the adult; except in syphilitic iritis, they do not always take place; perhaps they are not met with in the majority of cases. The pain in the frontal region was very severe, particularly at night, and we employed for its relief frictions of mercurial ointment and opium on the part, six grains of the former with two of the latter, which seldom fail to relieve this particular symptom. The treatment was the same, in other respects, as in the two preceding cases; and this patient is recovering favourably.

Thus you see that we have in the hospital at the same time three cases of syphilitic iritis accompanying the scaly form of eruption.

Strumous Ophthalmia.

Mr. Lawrence next adverted to two cases of this complaint, which had been some time in the hospital, and were now completely recovered under a mode of treatment which he generally finds successful. The most striking symptom of the complaint, intolerance of light, existed in both to its greatest extent; indeed it might rather be called total inability to bear the light in any shape, for these children lay in bed under the clothes, either with the face resting on the bed, or the hands pressed on the eyes. The face was red and excoriated from the pressure and from the scalding tears, while the physiognomy had the peculiar expression produced by the spasmodic closure of the eyelids, and the combined contraction of all the surrounding muscles, for the purpose of shutting out the light. To get a clear view of the globe was impracticable; but the eyes, as far as they could be examined, presented very little appearance of disorder. In these strumous subjects the occurrence of disease in a new part relieves that which was previously suffering. In imitation of this natural process, the tartar-emetic ointment was rubbed on the nape in both patients, so as to produce and maintain a considerable irritation; the sulphate of quinine was administered internally; the bowels were regulated by small doses of rhubarb; animal diet was allowed, when the appetite indicated the necessity for it; and the suffering organs were occasionally fomented with tepid water. Under this treatment both cases have recovered: the children can now open their eyes and bear the light as well as any body, and we find that no un-

favourable change has occurred in the affected parts. The patients are at the same time improved in general health. In one of them, the pustular eruption caused by the ointment spread over the body, with considerable but temporary constitutional disturbance.

THE BAYONET WOUND CASE.

To the Editor of the Medical Gazette.

Sir,

WHEN a man, who is avowedly a *public* journalist, freely abuses another individual, who happens also to hold a *public* employment, urging that this public employment is fair game, he of all other men should learn to bear with temperance the mortification and exposure to which his own public transactions, and aggression on others in their public capacities, may subject him. With this single remark, I request that you will insert the annexed clinical lecture in your journal. It was delivered this morning in the theatre of University College Hospital, to a great concourse of gentlemen.—I am, sir,

Your obedient servant,

SAMUEL COOPER.

Woburn Place,
Dec. 12, 1837.

GENTLEMEN,—Ever since I have acted as one of the surgeons of this hospital, I have faithfully endeavoured to elicit from the various diseases and accidents brought into it, all the practical instruction which they seemed capable of affording. I have always communicated to you such information in the most sincere and unreserved manner, disdaining to conceal, as some other parties in the profession do, any mistake which may have been committed, or any unfortunate result; and, indeed, rather preferring to give clinical lectures on unsuccessful and difficult cases, than on others. In this respect, perhaps, you may notice a difference between me and others; but I incline to this course on principle, believing that it is at least as important to trace and study the impediments to cure, as it is to dwell upon cases in which there are no remarkable obstacles to success. In this spirit, I began my clinical lectures this session with observations on three cases which ended fatally, perhaps not, however, through any egregious blunder on my part. But let me inform the writer of a well-known disgraceful journal, that, if such mistake had really happened, I should only be upon a par in this respect with some of his *infallible* continental surgeons, who have actually been elected by *concours*.

Had I the disposition, or (to use a term employed by himself) the *instinct* of this dealer in abuse, I might amuse the scandal-loving part of his readers with an exaggerated history of some of the occurrences referred to; but this task I willingly leave for him to perform, whose *instinct* would, indeed, richly qualify him for the business, were it not for the sake of the concourse itself, that little pet, which he loves, I suspect, much more cordially, than he will soon have reason to do some of his greater ones.

One of the unfortunate cases, forming the subject of my first clinical lecture this session, was that of the man Chaplin, who died of a bayonet wound, and who remained under the care of one of the house-surgeons, a regularly qualified resident surgeon, during the night of his admission, for this plain and simple reason, that I received no information that there was any immediate occasion for my interference.

In the lecture on Punctured Wounds, delivered in the surgical course over the way, I took the opportunity, the other night, of exposing some misrepresentations of the particulars of this case, as resorted to by the editor of the above mentioned inglorious publication, and resorted to, not, perhaps, exactly for the gratification of his own *instinct*, but, as is suspected, in the service of a party behind the curtain, who possibly may make his *debut* in due time.

Gentlemen—Amongst other topics in that lecture, I fearlessly declared my views of the base character and objects of the *Lancet*, and commented upon the gross ignorance of pathology and practical surgery displayed by its editor. If any gentlemen now present were absent from that lecture, I earnestly recommend them to read the sketch of it, as given in the MEDICAL GAZETTE of Saturday, the 2nd of December. It constitutes, indeed, an illuminated transparency of the bold and apparently wilful misrepresentations, for which the *Lancet* is more renowned than for any thing else that I know of, save and excepting the profound ignorance always manifested in it of practical surgery.

Notwithstanding the bayonet kind of wound, which such public exposure would be sure to inflict on any defamatory writer furnished with nerves as well as a brain, I did not venture so far as to hope that the editor of the aforesaid unprincipled work, who, in that capacity, has been for years habituated to greater exposures than this recent one, would be sensible of the lesion. In fact, my strictures were intended rather for the benefit of my pupils and others, than offered with the expectation of producing any impression on the editor of the *Lancet*, nice as he is about his *instincts*.

It seems, however, that I was wrong in my calculation; for on Monday, Dec. 4th, a stranger, calling himself a friend of Mr. Wakley's, and mounted on horseback, accosted me in the street. My first observation was, that I did not wish to hold any kind of communication with such a person as Mr. Wakley, direct or indirect. A short conversation, however, took place. The stranger said, that if I would allow him he could explain to me that I had attacked that individual's private character. "Perhaps," he added, "*you have spoken of him only in his public capacity, as editor of the Lancet.*" "Certainly," I replied, "and with respect to Mr. Wakley's private character, as I know nothing about it, I leave the world to form its own judgment of it. If Mr. Wakley fancies that his private character has been attacked, I recommend him to try the point in a court of justice." "Oh, very well!" rejoined my equestrian visitor, and off he galloped.

It is not true, therefore, as insinuated by the latter, in a note in the MEDICAL GAZETTE, that I ever received a challenge from Mr. Wakley, which I had declined to accept. What I should do were such challenge to arrive, remains to be seen; and my class already know what I would do. Indeed, supposing the editor of the notorious journal should venture to propose to me *gunpowder*, instead of *law or pepper*, which he has since been employing so freely, as the means of settling differences, there would be one vast temptation influencing me to accept the invitation, namely, that possibly the experiment which he may be thinking of making with our bodies, might really give the profession an opportunity of ascertaining most unequivocally, whether an extravasation of three or four pints of blood in the abdomen, and a wound of the intestinal canal, in two or three places, would produce pain in the epigastrium, and a disturbance of the stomach. All the doubt, still hanging over this knotty question might thus be removed; and here I speak more especially of the doubt, in relation to this particular individual, my aggressor, whose stomach is supposed to be much less delicate than that of any common mortal. By this time, I flatter myself that he has cooled, and even got rid of most of that harmless kind of ammunition with which he has chosen to pepper me, in return for which, however, I make no apology for treating him with a little mustard and goose.

Gentlemen, I had truly a great desire to invite him to hear this lecture, with a full guarantee of all becoming respect for his person during his attendance amongst us. I was anxious to pay him this compliment, because it is my inten-

tion this morning to explain to you a little more particularly, and on *higher authority than my own*, the grounds which I have for declaring the editor of the disgusting journal, which soils every body that touches it, to be only a *shallow pretender to medical knowledge*.

I pass over the question about the actual quantity of blood effused in the abdominal cavity of James Chaplin, merely remarking again, that *the true quantity was demonstrated to the eyes of at least 200 good and honest men*, some of them learned professors, and that the record of the quantity in the hospital book was made, not by me, an *interested party*, as is hinted with respect to all hospital surgeons, but by others, who had no interest in the statement whatsoever. Ah! Finsbury Thomas, I am sorry for thee; but I cannot pass over the next point so quickly, and depend upon it, that *unless thou canst squeeze thyself out of this part of the scrape*, as ingeniously as thou hast plotted to *squeeze something out of the Whigs*, thou art done for in this affair! Thomas! I have told thee flatly, that *thou art grossly ignorant of practical surgery and pathology*, and I stated in my address some proofs of the fact. *Thou art not, Thomas, even acquainted with the post-mortem appearances, which serve to denote the difference between a fatal inflammation of the bowels, arising from a strangulated hernia, and another inflammation of the same parts, proceeding from a penetrating wound, extracrusation, and other causes!* I rejoice that thou art not my pupil; and believe me when I say, that I would rather meet thee as a coroner, than an instructor in surgery.

This editor still wishes to make his readers suppose that the man did not die of peritonitis, excited by an extravasation of three or four pints of blood in the belly, and lesion of the intestines in two places, but of strangulation of the knuckle of intestine, and not of inflammation at all.

Now, gentlemen, although this empty pretender to surgical knowledge is conceited enough to think, that he will be able to improve me in this branch of science before he has dismissed me, I shall be rather sceptical about it, not only till he has *triumphed in a concours himself!* but obtained better information than he now seems to possess of any part of our noble profession, in which I rejoice to think he is not a real practitioner, but a sheer meddler—a person who, if I remember rightly, solemnly *abjured it several years ago!*

In order that you may perceive the strong light thrown on the case of James Chaplin by the *post-mortem appearances*, I will not repeat my own description of those which result from strangulated intestine, *where this is the cause of death*; but, gentlemen, I will adduce, in confirmation

of the truth of that description, the highest authority on this, as well as on various other important questions relating to surgery.

"The intestine [protruded]," says Sir Astley Cooper, "*is of a chocolate brown, with here and there a black spot, which easily breaks down on being touched with the finger. A coat of coagulable lymph, of the same colour as the intestine, may be peeled from its surface. At the particular part where the intestine is strangulated, it is either ulcerated through, or readily pulled asunder under slight pressure. The inflammation which takes place in strangulated hernia is different from almost every other species. In most other cases it is produced by an unusual quantity of blood sent by the arteries of the part, which become enlarged; but still the blood returns freely to the heart, and the colour of the inflamed part is that of arterial blood.*"

"Whilst, in hernia, the inflammation is caused by a stop being put to the return of blood through the veins, which produces a great accumulation of this fluid, and a change of its colour from the arterial to the venous hue. On dissection three or four convolutions of intestine are found lying across the abdomen, so enormously distended as to exclude the other viscera from view, and agglutinated slightly together by an effusion of adhesive matter. These distended convolutions consist of the portion of intestine immediately above the seat of stricture, and are their state of extreme distension in part to a collection of feculent matter, but chiefly to a secretion of air into the cavity of the intestine. On the contrary, the portion of intestine below the stricture is remarkably contracted in diameter, and free from any appearances of inflammation."

Such are the effects of strangulated intestine, as seen in persons who die of it, according to this description given by the greatest practical surgeon of the age, and by one of the first surgical pathologists of modern times. In James Chaplin, will any spectator of the dissection, *who has a local habitation and a name*, say that any of these characteristic appearances presented themselves? Were the bowels above the protrusion distended with air, or intestinal matter? The distension which may now be seen was produced with the blow-pipe, by Mr. Tayloe, after tying the bowel with the two pieces of string in it. Was the piece of bowel, when disengaged, found altered in the way described? Were the bowels above the protrusion the principal seat of inflammation? Were those below it remarkably contracted? None of these things were exemplified; on the contrary, had not the inflammation the arterial hue, and was it not most violent where the extravasated blood lay?

The coloured casts and preparations on the table, taken from nature, illustrate every point which it is here desirable to explain. But if these were not convincing enough, the animals on the table, a dog and cat, which were purposely destroyed yesterday by strangulating their intestines, would make an impression never to be forgotten. It does not follow, that because a piece of bowel had insinuated itself into the wound at some period after its reduction in the morning, that it had any material influence on the progress of the case. The appearances of the protruded bowel, and of the abdominal contents, tend to prove that the stricture was not of long duration.

Now the practical suggestions which I deduced from a review of this case, and explained in this theatre last month, the Editor of the notorious work had fancied would serve his cause. But remember, Thomas, that one of them, viz. the advice about operating, where the bowel is only suspected, *not known with certainty*, to protrude, is given with the express condition, "*that the case be unaccompanied by other fatal mischief.*" If the patient were dying of other mischief, no surgeon of common sense, always excepting the Editor of the Lancet, would think in a doubtful case, or indeed in any case, of tormenting a dying man by a useless operation. He would no more think of doing this, than of amputating a limb for a diseased joint, when the patient was sinking under disease of the lungs, or other vital organ.

Gentlemen, this miserable editorial judge of surgery, whose censure is rather an honour, and praise at least valueless, compliments me on the "care and precision" with which the treatment and complications of penetrating wounds of the abdomen are explained in my clinical observations; but hints, that the information, which I gave you on these subjects, was "concocted from my Dictionary, just as the Dictionary itself had been concocted from the writings of the *illustrious dead.*" Unfortunately, however, poor Thomas is here out again; for the particular views, to which he alludes, are not in the Dictionary, nor in any other publication. As, after the foregoing explanation, they will no longer suit him, he will now, perhaps, honour them with his reprobation.

As for the *illustrious dead*, I fear, Thomas, that thou hast no chance thyself of getting amongst them. Thy glory, as Editor of the Lancet, will be very transient, and thy only chance of immortality will depend upon thy retaining everlastingly the notoriety which it hath obtained for thee in this sublunary world.—But, gentlemen, to sum up.

1. The reason of my not having seen the patient directly after his admission, is, that *I was never asked to do so.*

2. That the protrusion, or swelling, whatever it might be, was reduced by me in the morning, as soon as I was informed of the existence of a swelling; and this was so much the case, that we were thinking of applying a compress.

3. That the statement about the man not having been visited by any surgeon of the hospital, considering that *I visited him thrice in the course of the twenty four hours* during which he was in the hospital, must be pronounced to be very bold editorial mendacity.

4. That the statement that *only a little blood* was effused in the abdominal cavity, when the quantity estimated, not by me, but many others, was from *three to four pints*, must be referred to the same head.

5. That the assertion that the man died from the effects of the strangulated state of the knuckle of intestine, and not of inflammation, is a proof that the party making it does not possess any acquaintance with surgical pathology.

6. That as the protruded bowel had suffered none of the changes constantly exemplified in cases of death from strangulated hernia, the inference is, that it had not been long strangulated.

7. That an operation for reducing the bowel, when the swelling was found to have returned in the evening, would have been unjustifiable, first, *because the patient was rapidly dying from other fatal mischief*, and *because the nature of the swelling was, in some degree, doubtful.*

8. That the occasional vomiting was no proof of hernia, as *the extravasation of three or four pints of blood, a wound of the bowels in two places, and peritonitis from these causes, would inevitably be attended with this symptom.*

9. That, for reasons explained in this lecture, since no purgatives were given, and the man had one feculent motion in the short time while he lived, no constipation can well be said to have been manifested.

10. After all the abuse lavished upon me, be it observed, that *my assailant has not been able to show, that there was the slightest chance of the man being saved by any thing which was not done.*

11. That from the accidental condition of the protruded piece of bowel, the wounded state of it would not have been visible, if the skin had been divided, and therefore it must certainly have been pushed back into the abdomen, so as to have occasioned the risk of intestinal effusion, in addition to that of the copious extravasation of blood. Would the man have been then in an improved state?

SECOND MESSAGE TO MR. COOPER.

To the Editor of the Medical Gazette.

SIR,

ON finding that two letters had been inserted in your journal of Saturday the 9th, intimating that I had received a challenge from Mr. Wakley, and declined to meet him, I took the earliest opportunity of publicly contradicting this representation in the hearing of about three hundred gentlemen, who attended my surgical lecture on Monday evening, the 11th instant. On Tuesday last, I found the same insinuation repeated in the *Morning Herald*, to the editor of which I transmitted a statement of facts.

In consequence of this, Captain W. Burt, and another gentleman, both on behalf of Mr. Wakley, called upon me yesterday morning, the 14th, when the Captain acknowledged my account, as published in the *Morning Herald* of Thursday last, and repeated, I believe, in nearly the same terms, in the clinical lecture sent to you on Tuesday the 12th instant, to be substantially correct. I then said, that I should adhere to that statement, and that if Mr. Wakley were dissatisfied with it, I was ready to meet him that afternoon. Captain Burt replied, that Mr. Wakley only required me to say, that I had not directed my observations against Mr. W.'s private character. As this had been already done in our first interview, and also in the letter published by me in the *Herald*, I had no difficulty in agreeing to this proposal. Captain Burt, and the other gentleman, then expressed themselves satisfied.

I wish it, then, to be understood, that whatever expressions may have been used by me in defending myself in this affair, are intended to relate solely to Mr. Wakley in his public capacity, as the responsible, but perhaps not the acting, editor of the *Lancet*.

Your obedient servant,
SAMUEL COOPER.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Dec. 12, 1837.

THE PRESIDENT IN THE CHAIR.

Abstract of a Report of Twenty-one Cases of Cholera that occurred in the Seamen's Hospital Ship Dreadnought, between the 8th and 28th of October, 1837. By GEO. BUDD, Physician, and GEO. BUSK, Surgeon of the Dreadnought.

The paper commences with a narrative of

the details of six of the cases in question, which prove in the clearest manner the identity of the disease with spasmodic cholera, as it appeared in 1832. To these two cases are subjoined, in consequence of some remarkable circumstances attending them. In one of them the patient was, at the time of attack of cholera, the subject of typhoid fever, and in him the symptoms, though unequivocal, were less violent than in most of the others, affording, perhaps, an example of the simultaneous influence of two poisons. The subject of the sixteenth case had been previously twice attacked with cholera, at Calcutta, in 1831 and 1833, on each of which occasions he had been treated by frictions, brandy, and opium. Of the twenty-one cases that occurred, twelve terminated fatally, the rate of mortality being greatest in the persons first attacked.

The organs of digestion, examined after death, presented appearances which varied as the patients died at a period more or less remote from the attack. This difference was no less observable in the external characters of the intestines, (which, in the rapidly fatal cases, presented a rosy hue, that disappeared in the protracted examples of disease,) than in the morbid appearances within. In the duodenum the solitary glands were very conspicuous, in the greatest abundance near the pylorus, and never extending into the jejunum. The glands of Payer, and those of Brunner, were much developed in all cases, but chiefly so in those cases that proved rapidly fatal. Generally there was increased vascularity of the mucous membrane of the intestines, giving rise in some cases to a purple colour near the termination of the ileum. In three cases, one of which proved fatal in less than seven hours, there were small black specks at the extremity of the villi. In those who survived the attack more than thirty six hours, the contents of the intestines were usually tinged with bile. The mucous membrane of the large intestines was in most cases pale throughout, being observed to be vascular in some of the protracted cases only. The lungs presented no appearances of disease in those cases which proved fatal within thirty-six hours; while of six cases in which the patients lived forty-five hours, four presented appearances of pneumonia: in two of these, who lived ninety-six, and one hundred and thirty-eight hours, parts of both lungs were found hepatized. In all the cases in which evidence of pneumonia was found on dissection, the symptoms had been latent, confirmatory of an observation made by Mr. Jackson, in his Report of Cholera in Paris in 1832. The gall-bladder in every case was distended with bile. The bladder

was empty in those who died in the stage of collapse, but contained a small quantity of urine in some of the others.

That the disease could not be attributed to any general atmospheric condition, the authors contend, 1st, because all the cases occurred in persons previously in the ship; 2dly, because no cases occurred on board the *Iphigenia*, which is moored under the stern of the *Dreadnought*; and 3dly, because no cases occurred in Greenwich Hospital, which is subjected to nearly the same atmospheric influence. The supposition that it was imported by infection from foreign parts, the authors consider to be highly improbable, from the very long period of incubation which, on that supposition, must be admitted; in some instances as long as thirty days. The authors also adduce the most satisfactory reasons for believing that the disease was not propagated by infection from one patient to another. The influence on which it depended seemed to act with an intensity which was variable, but generally greater in the lower decks; and in almost all cases its effects were first manifested during the night. The subsequent observations of the authors tend to show that the origin of the disease could neither be attributed to defective ventilation, to a crowded state of the ship, to the condition of the hold, nor to the food of the patients; the scale of diet being more liberal than those of the London hospitals, in consideration of the previous habits of the seamen who are its inmates. The disease did not attack the debilitated principally, but the most rapidly fatal cases happened in the medical ward, where cholera generally occurred as a complication of some visceral disease, and in patients previously reduced in strength.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

Fifth Meeting, December 2, 1837.

DR. GUY IN THE CHAIR.

A PAPER was read by Mr. HIFF—

On the Difficulty of Diagnosis in the commencement of Malignant Diseases in the Abdomen; illustrated by a Case.

The principal feature of disease observed in the patient was severe pain, extending from the hip-joint half way down the leg; this was at first thought to be simple neuralgia. The abdomen, however, subsequently enlarged, and a tumor appeared on the left inguinal region.

Sir A. COOPER expressed it as his opinion that it was an extravasation of blood

beneath the iliac fascia. The patient gradually sank, and post-mortem examination shewed a tumor as large as an uterus in the sixth month of utero gestation, occupying the inguinal, iliac, and hypochondriac regions of the left side. The tumor contained a grumous fluid inclosed in a firm unyielding capsule. The greater part of the swelling consisted of brain-like matter, and was easily broken down by pressure. The left iliacus and psoas muscles were partly absorbed and destroyed, and the venter of the ilium was ulcerated.

Great difference of opinion existed between the members present as to the possibility of malignant disease commencing from an effused clot of blood. This point was argued by Dr. Hughes, and Messrs. Bently, Bird, Molloy, &c.

Mr. HILTON said that he thought it highly probable that the disease had commenced from the periosteum of the ilium. This opinion was in close accordance with that of Sir Benjamin Brodie, as explained by Mr. Hiff.

Dr. HUGHES and Mr. BIRD related cases of malignant disease, in which there had been great difficulty in diagnosis. In both cases the kidney was affected with fungoid disease, and the urine was stated to be natural. Dr. Hughes said that fungoid disease in young persons was not essentially combined with a peculiar cachectic appearance. He was of opinion that malignant disease, when near the surface, was generally the result of violence. This latter opinion was opposed by Mr. Roderick.

On the motion of Dr. Hughes, seconded by Mr. Bird, a vote of thanks to Mr. Hiff was unanimously carried, and the meeting adjourned.

At the next meeting, C. Aston Key, Esq. in the Chair, Mr. Molloy will read *Some Observations on certain Cerebral Affections.*

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Mr. SCOTT, Surgeon.

Mr. HAMILTON, Assistant-Surgeon.

Nov.	Sex.	Age.	Case.
28.	M.	21	Lacerated hand.
	M.	47	Lacerated arm (a).
	M.	22	Injured foot.
29.	M.	23	Contused chest.
	M.	35	Injured back.
	M.	20	Compound fracture of the leg (b.)
	F.	4	Burn (died Nov. 30.)
	M.	5	Burn.
	F.	10	Burn (died Dec. 3.)
	F.	3	Burn (died Dec. 5.)

Nov.	Sex.	Age.	Case.
30.	M.	30	Fractured radius.
	M.	45	Contused head and chest.
	M.	18	Injured head.
Dec.			
1.	M.	14	Contused hip.
	M.	25	Injured pelvis.
	F.	67	Fractured humerus.
	F.	20	Erysipelas of the head and face.
	F.	56	Injured head and mortified toe.
2.	M.	21	Lacerated scalp.
3.	M.	47	Fractured patella.
	M.	25	Fractured fibula.
4.	M.	19	Injured side.
	F.	65	Fractured radius, and contused head.
	M.	39	Fractured fibula.
	M.	15	Injured head, erysipelas.

In-patients..... 25
Out-patients..... 38

Total during the week .. 63

(a.) This patient was admitted with an extensive lacerated wound of the left forearm, extending only through the integuments down to the fascia, accompanied with great swelling and contusion of the whole extremity. On the second day after admission mortification commenced around the wound, and has passed for some distance up and down the arm. The case has been treated with ammonia, opium, and wine, and a line of separation between the dead and living parts is now becoming well defined. The accident was caused by a heavy cask rolling on the limb.

(b.) In this case the man's leg was caught between the two sides of a draw-bridge just as it was closing, the tibia being crushed just above the inner ankle, and the soft parts extensively lacerated; a large spicula of bone, about an inch and a half in length, was removed; there was considerable arterial hemorrhage for some time, but it was arrested by compresses of lint. The case is doing well.

Omitted last week—

Increase of Burials, as compared with the preceding week .. 3002

In consequence of this being the last Weekly Bill which will be included in the General Bill of the present year, many of the parish clerks, who had neglected to make their returns in due order, have now reported their deficiencies, from which cause may be attributed the great increase which appears in the Christenings and Burials.

Since the new Registration Act came into operation, the office of Searcher has, in several parishes been discontinued; it has not, therefore, in these parishes, been possible to ascertain the diseases of which many of the persons have died; and, in such cases, the numbers reported are inserted under the head of Unknown Causes.

NOTICES TO CORRESPONDENTS.

We cannot insert the letter of Mr. Edward Heran.

The case communicated by Mr. S—ll does not appear to us of sufficient interest for publication.

It is not stated at what hospital the case of "Fungoid Degeneration of the Right Kidney" was treated. The case ought to be abbreviated. If our correspondent will attach his name to the paper, it shall be inserted.

The "Observations on the Mucous Membrane," by Mr. S., of Barnsley, are not sufficiently practical for our pages.

"The Homoeopathist from actual experience" must adduce stronger facts than any contained in his letter of Dec. 7th.

As Mr. Coles affixed his name to his paper, we do not think it would be quite fair to publish an anonymous answer to it: "M.," of Dec. 8th, will therefore excuse us.

Numerous other correspondents, the receipt of whose papers have not been acknowledged, will find them in our next number.

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine.

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE IV.

Confirmative and Infirmative Facts. — Fallaciousness of Evidence. — Fallaciousness of Direct Evidence; of Circumstantial Evidence. — Cases in illustration. — Misdecision sometimes the inevitable consequence of Ignorance; sometimes subsequently removed by Science. — Induction as to Punishment. — Doctrine of Livingstone, of Bentham, and of Paley, on the Punishment of Death.

Confirmative and infirmative facts.—Every fact, the accumulation of which tends to render the existence of the principal fact probable, is termed a confirmative fact. Every fact which tends to weaken, or to render infirm, the probative force of another fact, is termed an infirmative fact. There is no confirmative fact which may not be attended with its opposing infirmative supposition. In the case of Donellan, one of the confirmative facts was his secret practice of distillation; the corresponding infirmative supposition was, that the distillation might have been carried on for the purpose of obtaining rose-water, or of procuring some other product of distillation; and great efforts were made on the trial to give to the circumstance this very colour.

If either a confirmative or an infirmative fact be overlooked, the consequence, it is obvious, may be fatal to one or other of the direct ends of justice. If the circumstance overlooked be a confirmative

fact, the wrong-doer may escape punishment; if an infirmative fact, an individual who is not a wrong-doer may be subjected to all the penalties of guilt.

Fallaciousness of evidence.—I have already stated the properties which give to a mass of evidence its highest degree of probative force, which constitute its perfect trustworthiness, correctness, and completeness. How difficult it is to secure these two properties, how completely the judgment may be deceived even in a case in which these properties appear to be obtained in the highest degree of perfection, numerous instances on record, in which individuals really innocent have sunk under the load of imputation heaped upon them by fallacious evidence, but too fully testify.

Fallaciousness of direct evidence.—Sense itself may be deceived—that is, at least, possible; and being possible, it follows that direct evidence itself may be fallacious. Deception of this kind is certainly rare. Many things called deceptions of the senses are really false inferences drawn from a true testimony, delivered by the senses. Sense seldom deceives, but reason often errs; the impression made upon the eye and the ear is in general correct, but the induction drawn from the impression is often rash and false.

The story of the traveller and the innkeeper (Bradford), to which I have already adverted, may be considered as affording a case the very next remove from one of direct evidence. The innkeeper (Bradford) had come to the knowledge that his guest was well provided with money; he had determined, at least, on robbery; he had gone to the traveller's chamber for the purpose of accomplishing his purpose; but he had been anticipated by another traveller, with whom Bradford had had no communication, and who had contrived to perpetrate the murder, and to escape unseen with the booty. Bradford, discovered in the very chamber of the murdered man,

with the very weapon in his hand with which it was manifest that the mortal wound had been inflicted, what inference more natural, more ready to occur to every mind, than that the innkeeper was the murderer? He was universally believed to be so; the evidence that he had perpetrated the crime appeared irresistible; he was convicted and executed; yet he was really guilty only of the crime of intending to commit a robbery; there was no evidence whatever that he even intended to commit murder. The actual murderer escaped unsuspected, and on his death-bed confessed the fact.

Fallaciousness of circumstantial evidence.—It has been said that circumstantial evidence is more trustworthy than direct; that circumstances cannot lie. There are circumstances which cannot lie—namely, circumstances which connect the inference with the fact so closely as to render the induction absolutely necessary and unavoidable: as when a witness deposes that he actually saw a man run his sword through the body of his victim. Any circumstance short of this—any circumstance which leaves the conclusion in any the slightest degree contingent, may lie, and has lied. If a witness swear that he saw the prisoner draw a reeking sword from the side of a dead man, even in that case the conclusion that the prisoner was the murderer of the deceased is not absolutely necessary and unavoidable, and therefore may be false. This act of the prisoner might have been the friendly act of an innocent man, who had accidentally passed that way after the murder was committed. Even if it were the prisoner's own sword, it might have been snatched from his side and plunged into the body of the deceased by some one who had escaped; or the deceased might have borrowed the sword from the prisoner, and plunged it into his own body.

Cases in illustration.—Many appalling accounts are on record of the fallaciousness of circumstantial evidence—of the false decision which has been the result, and of the consequent infliction of horrible injustice. One case, having a fortunate issue, is curious. September 11, 1772, came on, at the sessions in the Old Bailey, the trial of one Mall, a barber's apprentice, for robbing Mrs. Ryan, of Portland street, on the high-way, on the 17th June last. The witnesses swore positively to the identity of the lad, and the whole court imagined him guilty. He said nothing in his defence but that he was innocent, and that his evidences would prove it. His evidences were the books of the court, to which reference being made, it appeared that on the day and hour when the rob-

bery was sworn to be committed, the lad was on his trial at the bar where he then stood for another robbery, in which he was likewise unfortunate enough to be mistaken for the person who committed it; on which he was honourably acquitted.

A remarkable instance of the deceptive circumstances by which it is possible for an innocent person to be surrounded and overwhelmed, is afforded by the melancholy case of Le Brun, the domestic servant of the widow Mazel, whose story I adverted to in the first lecture, and respecting which I stated that five sorts of professional persons were consulted. All the suspicious circumstances in which this poor lad was involved, had been preconcerted—all of them had been arranged by a companion of his, the real murderer, who had contrived to obtain a portion of his hair, to steal from him his knife, to purloin a cravat, and to get into his possession for a short time the key of the shop, from an impression of which, in wax, he procured a false key.

With the story of the aged Calas all Europe resounded at the time the event took place. This old man was a merchant of Toulouse; he was 70 years of age. He was greatly respected for his probity; but in the bigoted age and country in which it was his misfortune to live, he was bitterly hated by many as a protestant. He had a son, 28 years of age, robust, of a melancholy turn of mind, a student of the law. On account of his being a protestant, difficulties were thrown in the way of this young man in obtaining his license to practise his profession. Imagining these difficulties to be insuperable, his mind became extremely irritable and desponding, and he formed the determination to put an end to his existence. This resolution he effected by hanging himself, having fastened the cord to a billet of wood placed on the folding doors which led from his father's shop to the store-room. Two hours afterwards he was found lifeless. The father removed the cord from the body, and, as far as the confusion of mind into which he was plunged permitted, he obliterated or changed some of the appearances about the body, and other circumjacent objects. Here was forgery of real evidence. On his examination he denied some of the facts evidentiary that the death was not natural; he concealed some of the facts evidentiary that death was produced by strangulation. To what end these aberrations from the strict line of truth? The concealment of crime? No; for on the part of the accused there was none. The object was to save the reputation of his departed child, and thereby the reputation of the family, from the igno-

miny which, had the direct truth been known, would, in that age of ignorance and bigotry, have been stamped upon it.

The people, stimulated by religious prejudice, carried the dead body to the town-house, where it was the next day examined by two medical men, who, without viewing the cord, or examining the place where the death had been effected, declared that the young man had been strangled. The father was condemned to be broken on the wheel; the sentence was carried into execution; and the victim expired with the most ferrent and solemn protestations of his innocence.

Reflection, when too late, returned. It was now recollected that the son had been of a melancholy turn of mind; that no noise had been heard in the house when the deed must have been done; that his clothes were not in the least ruffled; that only a single mark was produced by the cord; that this mark was in the situation which indicated suspension; and, in addition to all these circumstances, it was remembered that the dress proper for the dead was found lying on the counter, close to the spot where the suspension took place. Voltaire espoused the cause of the injured family. The case was carried up to the Council of State, who reversed the judgment of the inferior tribunal, and vindicated the memory of John Calas; but alas! the tribunal had pronounced and executed an irreversible decree, and no earthly power could render compensation to the injured.

Misdecision sometimes the inevitable consequence of ignorance—ignorance which science subsequently removes.—Sometimes misconception, and consequent misdecision, is the inevitable result, not so much of the fallaciousness of evidence, as of the want of knowledge necessary to the true understanding of a particular article of evidence. There may be placed fully and directly before the eye, a circumstance demonstrative of an essential error: nevertheless, into that error the mind must inevitably fall, because it is destitute of the knowledge requisite to enable it to perceive the true character of that circumstance. In such a case, the desire to avoid error, however earnest—the endeavour to avoid it, however strenuously put forth, in the most minute and laborious investigation of all the ascertained circumstances, together with the exercise of the most cautious and strictly logical reasoning concerning them, can be of no avail. Additional knowledge is the only thing that can be of avail. At length science affords that additional knowledge, and then the error becoming manifest, the avoidance in all time to come of misconception and conse-

quent misdecision, in relation to that particular case, is easy; but the avoidance of misdecision may still not be possible in relation to every other subject whatever, of which experience and science have yet to render the knowledge of the human mind perfect.

That wrong conviction, followed by judicial murder, the consequence of misdecision, rendered inevitable by this want of knowledge, has taken place, is beyond all question. There is reason to believe that an instance of it occurred recently.

“A man of the name of Gilchrist, some time ago, was condemned and executed at Glasgow. He and his wife lived in an irregular rambling sort of way, getting drunk sometimes for days together. On one occasion, after their return home in the evening, the people who lived on the floor above them heard a noise like that of two persons struggling, and soon afterwards a rattling or gurgling, and moaning, as of one choking or bleeding to death. They so strongly suspected that all was not right, that they called down to Gilchrist, through the floor, that they were afraid he was killing his wife. In no long time they were alarmed by the smell of fire, and the filling of the house with smoke; upon which they went down to Gilchrist's apartment and demanded admission. After some delay he admitted them, and in doing so appeared to them to have come out of an inner room, where he said he had been asleep in bed. On letting them in he stumbled over the body of his wife, who lay in the outer apartment quite dead, kneeling before a chair, and very much burnt. The prisoner was accused of having murdered her, and burnt the body to conceal the manner of her death: he, on the other hand, alleged that he had gone to bed tired, and knew nothing of what had befallen her until he was awakened; and that he presmied her clothes had caught fire while she was intoxicated, and that she was thus burnt to death.”

What remained of the body was examined by medical men; but their report was merely, that the body was so much burnt that nothing could be learnt from it as to the cause of death. The man was hanged, to the last vehemently and solemnly denying that he was guilty.

There is the strongest ground for supposing that the medical report, in affirming “that the body was so much burnt that nothing could be learnt from it as to the cause of death” was incorrect. Nothing could be learnt from it with the knowledge which these medical examiners possessed; nor perhaps with the knowledge which any medical man possessed at that time.

But that this very body exhibited appearances capable of demonstrating the true cause of death, had the real character of these appearances been understood, is rendered in the highest degree probable by the result of an inquiry to which a subsequent case gave rise.

The wife of a man was apparently burnt to death under circumstances exactly similar to the preceding. "The prisoner and his wife lived together on bad terms. On the night of her death the woman had returned home at a late hour, after having lighted a candle and got some whisky at a neighbour's house. At this time certainly the husband was in bed; but, some time afterwards, there was heard a considerable noise, like that of struggling, and of chairs pushed up and down the room. Not very long after, the neighbours were alarmed by a strong smell of fire proceeding from the prisoner's apartments. They therefore knocked at his door for admission, but in vain; all the noise they could make did not bring him to the door. At last a man forced his way in, by breaking the window of the outer room, and, on entering, found the room full of smoke, and observed something burning red in a corner, over which he instantly threw a pitcher of water:—it was the body of the woman burning on the hearth. Several persons now entered the inner room; they found the prisoner either asleep or feigning to be so. On being roused and told of his wife's death, he expressed neither surprise nor sorrow, but coolly demanded by what authority the people had broken into his house." The presumptions were strong against him; they were completely removed by the result of a scientific investigation suggested by certain appearances on the dead body. The burns on those parts of the body which were not reduced to a cinder exhibited peculiar characters which appeared to the medical examiners to indicate that the burning had taken place during life. This idea led to the institution of a series of experiments with a view to ascertain whether a part of the body burnt during life, and a part burnt after the extinction of life, present the same or different appearances; and if different, whether the differences are definite and constant. The result of this inquiry was the discovery of the means of determining with indubitable precision, in every case in which the whole of the body is not reduced to a cinder, whether the body were alive or dead when burnt.

In the present case, on examining the face and extremities (the parts of the body which were not burnt to a cinder) "we found (says the late Dr. Duncan) what we

were unanimous in considering to be incontestible proof that the woman had been burnt to death—that she had been set fire to while alive, and had died in consequence of the burning. There was every mark of vital reaction; some spots merely red and inflamed, others scorched to a hard transparent crust, but surrounded with distinct redness, and a great many blisters filled with lymph, perfectly different from those produced on the dead body, which are not filled with a fluid, but with air or vapour. In short, we found appearances exactly similar to those of fire on a living body; and therefore we reported, as our unanimous opinion, that the deceased was burnt to death."

But for the light shed upon the true nature of this case by science, coming at the very moment it was needed to the aid of justice, there cannot be a doubt that the fate of this man would have been the same as that of Gilchrist; that he would have been put to death on evidence in his case now certainly known to be fallacious, as Gilchrist had been put to death on evidence, in all probability, equally fallacious.

Induction as to punishment.—To infer from these and similar cases which demonstrate the fallaciousness of circumstantial evidence, that such evidence is not to be trusted, would be a false induction. Neither in a court of justice nor in the ordinary affairs of life could we proceed a single step without placing trust in it. That it may mislead is an infirmity inherent in its nature which cannot be cured. One consequence, however, inevitably follows from this infirmity in the nature of evidence. *The punishment annexed to a crime, the proof of the commission of which rests on circumstantial evidence, ought in no case to be of a nature which is irremediable, which admits not of compensation, should proof arise that he who has been pronounced guilty, is really innocent.* The injustice when it happens is so dreadful, that the risk of it ought on no consideration to be incurred. This is an argument against the punishment of death which may supersede all others. It is alone sufficient to outweigh every advantage which any one has ever supposed to result from the employment of death as an instrument of punishment, and is absolutely unanswerable and irresistible.

Doctrine of Livingston on the punishment of Death.—How solemn and profound was the conviction of this truth on the mind of the great American legislator, the illustrious Livingston, who on being empowered by the House of Representatives of the State of Louisiana to prepare for that State a Penal Code, in his first Report to

the Legislative Assembly thus speaks of the punishment of death: "I approached the inquiry into the nature and effect of this punishment with the awe becoming a man who felt, most deeply, his liability to err, and the necessity of forming a correct opinion on a point so interesting to the justice of the country, the life of its citizens, and the character of its laws. I strove to clear my understanding from all prejudices which education, or early impressions, might have created, and to produce a frame of mind fitted for the investigation of truth, and the impartial examination of the arguments on this great question. After the best use that my faculties would enable me to make of all the sources of knowledge on this subject within my reach, after long reflection, and not until I had canvassed every argument that could suggest itself to my mind, I came to the conclusion, that the punishment of death should find no place in the code which you have directed me to present.

"In coming to a resolution on this solemn subject, we must not forget a principle, established on the soundest reason, that other things being equal, that punishment should be preferred which gives us the means of correcting any false judgment to which passion, indifference, false testimony, or deceiving appearances, may have given rise. Error, from these or other causes, is sometimes inevitable, its operation is instantaneous, and its fatal effects in the punishment of death follow without delay; but time is required for its correction: we retrace our steps with difficulty; it is mortifying to acknowledge that we have been unjust, and during the time requisite for the discovery of the truth, for its operation on our unwilling minds, for the interposition of that power which alone can stop the execution of the law, its stroke falls, and the innocent victim dies. What would not then the jurors who convicted; the judges who condemned; the mistaken witness who testified to his guilt; what would not the whole community who saw his dying agonies, who heard at that solemn moment his fruitless asseverations of innocence; what would they not all give, to have yet within their reach the means of repairing the wrongs they had witnessed or inflicted?

"Instances of this kind are not unfrequent, many of them are on record; several have taken place in our own day, and a very remarkable example which was given but a few years since, in one of the northern states, shows, in a striking manner, the danger of those punishments which cannot be recalled or compensated, even though the innocence of the sufferer is rendered clear to demonstration. A few such instances in a century are suffi-

cient to counteract the best effects that could be derived from example. There is no spectacle that takes such hold on the feelings, as that of an innocent man suffering by an unjust sentence; one such example is remembered, when twenty of merited punishment are forgotten: the best passions take part against the laws, and arraign their operation as iniquitous and inhuman.

"To see a human being in the full enjoyment of all the faculties of his mind, and all the energies of his body; his vital powers attacked by no disease; injured by no accident; the pulse beating high with youth and health; to see him doomed by the cool calculation of his fellow-men, to certain destruction, which no courage can repel, no art or persuasion avert; to see a mortal distribute the most awful dispensations of the Deity, usurp his attributes, and fix, by his own decree, an inevitable limit to that existence which Almighty power alone can give, and which its sentence alone should destroy, must give rise to solemn reflections, which the imposing spectacle of a human sacrifice naturally produces, until its frequent recurrence renders the mind insensible to the impression."

Doctrine of Bentham.—While such sound and humane views determine and guide the sanctions of the law in other countries, it is painful and humiliating to think, that still, in the impressive language of Bentham—"Death is the English judge's universal remedy: higher he cannot screw up the exertions of blind barbarity. To this point the labour of every session adds; at this a stop is made, because there is nothing beyond it.

"It is the part of the same man, the same natural and implacable enemy of justice, on the one hand to keep watch and ward in favour of the murderer, charging him not to let drop any the least hint from which justice may receive assistance, not to say any thing by which his guilt may be brought to light—and on the other hand to be no less active in his exertions to extend the demesnes of death. To the profit of cold barbarity he thus adds the praise of tenderness. The manly dictates of public utility are sacrificed to the cant of hypocritical or childish sentimentalism. The excess of the punishment becomes a sufficient warrant for not executing it. Extending the demesnes of death, he thus extends the range of his own despotism; of that preposterous state of things by which, every year, the lives of men, by dozens and by scores, are laid at the feet of every English judge."

Doctrine of Paley.—It is this preposterous state of things which is advocated as the best possible, or at least as the best

which is likely to be practicable, by Paley, whose work is the text-book of moral and political philosophy, taught in our universities, where most of our legislators and judges are educated. "By the number of statutes creating capital offences," says this writer, "it (the English law) sweeps into the net every crime which, under any possible circumstance, may merit the punishment of death. But when the execution of this sentence comes to be deliberated upon, a small proportion of each class are singled out, the general character, or the peculiar aggravations of whose crimes render them fit examples of public justice. By this expedient few actually suffer death, whilst the dread and danger of it hang over the crimes of many." "The wisdom and humanity of this design furnish a just excuse for the multiplicity of capital offences, which the laws of England are accused of creating beyond those of other countries. The charge of cruelty is answered by observing, that these laws were never meant to be carried into indiscriminate execution; the legislature, when it establishes its last and highest sanctions, trusts to the benignity of the crown to relax their severity."

But the direct effect of the system thus advocated is, to take away the *certainty* of punishment which all jurists admit, Paley among the rest, to be the most effectual means of preventing the commission of offences. "The *certainty* of punishment," says Paley, in the very chapter from which the above passage is taken, "is of more consequence than the severity. Criminals do not so much flatter themselves with the lenity of the sentence as with the hope of escaping. They are not so apt to compare what they gain by the crime with what they may suffer from the punishment, as to encourage themselves with the chance of concealment or flight. For which reason, a vigilant magistracy, an accurate police, a proper distribution of force and intelligence, together with due rewards for the discovery and apprehension of malefactors, and an undeviating impartiality in carrying the laws into execution, contribute more to the restraint and suppression of crimes than any violent exacerbations of punishment."

Bentham assigns as the reason why the English law and the English judges stop at the infliction of death, that there is nothing beyond it. If there had been any thing beyond it, and if the law and the judges had eagerly availed themselves, as they would certainly have done, of that something more beyond death, it is plain that Paley would have justified the principle and the practice. "If," he says, "a mode

of execution could be devised, which would augment the horror of the punishment, without offending or impairing the public sensibility by cruel or unseemly exhibitions of death, it might add something to the efficacy of the example, and, by being reserved for a few atrocious crimes, might also enlarge the scale of punishment, AN ADDITION TO WHICH SEEMS WANTING; for, as the matter remains at present, you hang a malefactor for a simple robbery, and can do no more to the villain who has poisoned his father. *Somewhat of the sort we have been describing, was the proposal, not long since suggested, of casting murderers into a den of wild beasts, where they would perish in a manner dreadful to the imagination, yet concealed from the view!*"

The frequency of capital punishments in this country, according to Paley, owes its necessity to three causes—much liberty, great cities, and the want of a punishment short of death. The evils arising from all these sources, according to him, can only be counteracted by adding to the number of capital punishments. "The uncertainty of punishment must be compensated by the severity. The ease with which crimes are committed or concealed, must be counteracted by additional penalties and increased terrors. Thus the statute of James I., relative to the murder of bastard children, which ordains that the concealment of the birth should be deemed incontestible proof of the charge, though a harsh law, was well calculated to put a stop to the crime."

The grand argument in favour of the infliction of capital punishment is the terror of the example. "If," continues Paley, "there be any thing that shakes the soul of a confirmed villain, it is the expectation of approaching death." The dreadful suffering endured by a criminal about to undergo execution, which suffering must be known to and is commonly witnessed by his confederates in crime, and which is necessarily brought home, in a greater or less degree, to the imagination of all addicted to the same guilty courses, must, it is presumed, if there be any thing that can do so, shake the soul of the most confirmed villains. The answer to such representations, and to the argument in justification of the punishment of death founded thereon, is the evidence given before a Committee of the House of Commons appointed to inquire into the effects of Capital Punishment. One of the witnesses examined before this Committee, a solicitor, who had practised for more than twenty years in the criminal courts, makes the following statement:—

"In the course of my practice, I have found that the punishment of death has no

terror upon a common thief; indeed, it is much more the subject of ridicule among them, than of serious deliberation. The certain approach of an ignominious death does not seem to operate upon them; for, after the warrant has come down, I have seen them treat it with levity. I once saw a man, for whom I had been concerned, the day before his execution, and on offering him condolence, and expressing my concern at his situation, he replied, with an air of indifference, 'players at bowls must expect rubbers;' and this man I heard say, 'that it was only a few minutes, a kick and a struggle, and all was over.' The fate of one set of culprits, in some instances, had no effect even on those who were next to be reported for execution; they play at ball and pass their jokes as if nothing was the matter. I have seen the last separation of persons about to be executed; there was nothing of solemnity about it, and it was more like the parting for a country journey than taking their last farewell. I mention these things, to show what little fear common thieves entertain of capital punishment, and that so far from being arrested in their wicked courses by the distant possibility of its infliction, they are not even intimidated by its certainty."

Another witness, a magistrate of the capital, being asked, whether he thought that capital punishment had much tendency to deter criminals from the commission of offences, answered, "I do not. I believe it is well known to those who are conversant with criminal associations in this town, that criminals live and act in gangs and confederacies, and that the execution of one or more of their body seldom has a tendency to dissolve the confederacy, or to deter the remaining associates from the continuance of their former pursuits. Instances have occurred within my own jurisdiction to confirm me in this opinion. During one sitting, as a magistrate, three persons were brought before me for uttering forged notes. During the investigation, I discovered that these notes were obtained from a room in which the body of a person named Wheller (executed on the preceding day for the same offence) then lay, and that the notes in question were delivered for circulation by a woman with whom he had been living. This is (he adds) a strong case; but I have no doubt that it is but one of very many others."

The Ordinary of Newgate, a witness perhaps better qualified than any other to give information on this subject, being asked, "Have you made any observations as to the effect of the sentence of death upon the prisoners?" answers, "It seems scarcely to have any effect upon them; the

generality of people under sentence of death are thinking, or doing rather, anything than preparing for their latter end." Being interrogated as to the effect produced by capital executions on the minds of the people, he answers, "I think, shock and horror at the moment, upon the inexperienced and the young; but immediately after the scene is closed, forgetfulness altogether of it, leaving no impression on the young and inexperienced. The old and experienced thief says, the chances have gone against the man who has suffered; that it is of no consequence; that it is what was to be expected; making no serious impression on the mind. I have had occasion to go into the press-yard within an hour and a half after an execution, and I have there found them amusing themselves, playing at ball or marbles, and appearing precisely as if nothing had happened."

Some of the investigations in which Paley engaged led him to pay considerable attention to the subject of evidence. He was well acquainted with that infirmity inherent in its nature, against the consequences of which, false judgment and wrongful punishment, no degree of human sagacity and caution can obtain security. Yet fully aware of this, he was capable of writing as follows:—"I apprehend much harm to have been done to the community by the overstrained scrupulousness, or weak timidity, of juries, which demands often such proof of a prisoner's guilt as the nature and secrecy of his crime scarce possibly admit of; and which holds it the part of a *safe* conscience not to condemn any man whilst there exists the minutest possibility of his innocence. Any story they may happen to have heard or read, whether real or feigned, in which courts of justice have been misled by presumptions of guilt, is enough in their minds to found an acquittal upon, where positive proof is wanting. I do not mean that juries should indulge conjectures, should magnify suspicions into proofs, or even that they should weigh probabilities in *gold scales*; but when the preponderation of evidence is so manifest as to persuade every private understanding of the prisoner's guilt; when it furnishes the degree of credibility upon which men decide and act in all other doubts, and which experience hath shewn that they may decide and act upon with sufficient safety; to reject such proof, from an insinuation of uncertainty that belongs to all human affairs, and from a general dread lest the charge of innocent blood should lie at their doors, is a conduct which, however natural to a mind studious of its own quiet, is authorised by no considerations of rectitude or utility. It counteracts the

care, and damps the activity of government: it holds out public encouragement to villany, by confessing the impossibility of bringing villains to justice; and that species of encouragement which, as hath been just now observed, the minds of such men are most apt to entertain and dwell upon.

"There are two popular maxims, which seem to have a considerable influence in producing the injudicious acquittals of which we complain. One is:—'That circumstantial evidence falls short of positive proof.' This assertion, in the unqualified sense in which it is applied, is not true. A concurrence of well-authenticated circumstances composes a stronger ground of assurance than positive testimony, unconfirmed by circumstances, usually affords. Circumstances cannot lie. The conclusion also which results from them, though deduced by only probable inference, is commonly more to be relied upon than the veracity of an unsupported solitary witness. The danger of being deceived is less; the actual instances of deception are fewer in the one case than the other. What is called positive proof in criminal matters, as where a man swears to the person of the prisoner, and that he actually saw him commit the crime with which he is charged, may be founded in the mistake or perjury of a single witness. Such mistakes, and such perjuries, are not without many examples; whereas, to impose upon a court of justice, a chain of circumstantial evidence in support of a fabricated accusation requires such a number of false witnesses as seldom meet together; an union, also, of skill and wickedness which is still more rare; and after all, this species of proof lies much more open to discussion, and is more likely, if false, to be contradicted, or to betray itself by some unforeseen inconsistency, than that direct proof, which being confined within the knowledge of a single person, which appealing to, or standing connected with, no external or collateral circumstances, is incapable by its very simplicity of being confronted with opposite probabilities.

"The other maxim which deserves a similar examination is this:—'That it is better that ten guilty persons escape than that one innocent man should suffer.' If by saying it is *better*, he meant that it is more for the public advantage, the proposition, I think, cannot be maintained. The security of civil life, which is essential to the value and the enjoyment of every blessing it contains, and the interruption of which is followed by universal misery and confusion, is protected chiefly by the dread of punishment. The misfortune of an individual (*for such may the sufferers, or*

EVEN THE DEATH, of an innocent person be called, when they are occasioned by no evil intention) cannot be placed in competition with this object. I do not contend that the life or safety of the meanest subject ought in any case to be knowingly sacrificed; no principle of judicature, no end of punishment, can ever require that. But when certain rules of adjudication must be pursued, when certain degrees of credibility must be accepted, in order to reach the crimes with which the public are infested, courts of justice should not be deterred from the application of these rules by every suspicion of danger, or by the mere possibility of confounding the innocent with the guilty. They ought rather to reflect, that he who falls by a mistaken sentence may be considered as falling for his country, whilst he suffers under the operation of those rules by the general effect and tendency of which the welfare of the community is maintained and upholden."

According, then, to the express statement of this authority, direct evidence itself may be fallacious. "What is called positive proof in criminal matters, as where a man swears to the person of the prisoner, and that he actually saw him commit the crime with which he is charged, may be founded on the mistake or perjury of a single witness. Such mistakes, and such perjuries, are not without many examples."

In regard to circumstantial evidence, according to this same authority, proof sufficient to warrant conviction is obtained, when the preponderance of evidence is so manifest as to persuade every private understanding of the prisoner's guilt; when it furnishes the degree of credibility upon which men decide and act in all other doubts, and which experience hath shewn that they may decide and act upon with sufficient safety. But universal experience testifies, that with this degree of evidence misdecision does take place, and that not unfrequently: this is not denied by Paley! Nevertheless, he argues that in all these cases the punishment of death—a punishment in its own nature irreversible and irremediable—may be justly inflicted, on the ground that those who fall by a mistaken sentence are unfortunate individuals, who may be considered as having fallen for their country.

Without doubt "certain rules of adjudication must be pursued, certain degrees of credibility must be accepted, in order to reach the crimes with which the public are infested; and therefore the courts of justice should not be deterred from the application of these rules by every suspicion of danger, or by the mere possibility of confounding the innocent with the guilty;"

but it is equally true, that no punishment ought to be inflicted on any criminal, however apparently complete the evidence of his guilt, which punishment, when once carried into execution, is absolutely irrevocable and irreversible, and which consequently admits not of the possibility of compensation for unmerited suffering, when the proof of innocence is established.

But, indeed, in the whole argument of Paley on this subject, there is involved every possible vice which can attach to legislation, and to the mode of the administration of the law. While there is an acknowledged chance of misdecision, a sanction is imposed which, in the case of misdecision, inflicts the most dreadful injustice that can have place between man and man, without the possibility of reversal or compensation.

Moreover, this dreadful and irrevocable sanction is attached to numerous offences; not, it is admitted, because those offences are in their own nature more atrocious than others to which it is not attached, but merely because they are more easy to be committed, and more difficult to be prevented.

Nay, this dreadful and irrevocable sanction is attached to many offences chiefly as a threat, there being no intention actually to carry it into indiscriminate execution. But in order to render the exercise of this discrimination possible, there must necessarily be lodged somewhere a power either to suspend the law, or to enforce its execution. This power is actually lodged with the administrators of the law. It follows that, in regard to this whole class of cases, the real law is not the statute, but the will of the administrator of the law. But the will of the administrator of the law is changeable; the sanction of the law is peremptory and unchangeable. The encouragement necessarily given to crime, by removing the punishment of it from the unchangeable to the changeable, it is attempted to counteract, partly by the reiteration and extension of the menace, and partly by the occasional seizure of an individual, not more criminal than the hundreds who escape, who is put to death.

In this manner the law, rendered at once hard, partial, and uncertain, generates in the criminal the hardness that leads to recklessness and violence, while at the very same time it encourages in him the hope of escaping with impunity.

Gentlemen, I make no apology for bringing before your view, on the present occasion, such considerations as these. You cannot perform the momentous and difficult duties which will devolve upon you, in a manner conducive to the public

welfare, or satisfactory to your own conscience, if you possess in any degree an enlightened conscience, unless you keep constantly in view the consequences which must result from the evidence you give in a court of justice.

And I take another ground. You will go forth into the world with minds enlightened and humanized by science, and having especially (for you must have grievously failed to derive from your *peculiar* studies their noblest profit, if you have not) a purer and more correct knowledge of human nature, than is common in the cultivators of other professions. The result cannot but be a deep conviction in your own minds—a conviction which I trust you will contribute largely to diffuse among other minds—a conviction of two truths which mankind have been slow to learn, but which are as certain as any mental, and therefore as any physical law, truths which ought to form the basis of all penal enactments, and to guide the imposition of all penal sanctions: first, that justice is not vindictive, but corrective; and, secondly, that an incomparably greater influence is to be exercised over human dispositions and actions, the evil no less than the good, by mildness, firmness, and benevolence, than by hardness, harshness, and implacability.

ON THE COMPOSITION AND ABSORPTION OF PUS.

BY M. BONNET,

Surgeon to the Hôtel-Dieu, at Lyons.

[Concluded from p. 454.]

SECT. V.—On the Absorption of Pus.

I DISTINGUISH the absorption of pus which has not been in contact with the atmosphere, from that which has. I have shown above, that the former contains no principles but those which are present in healthy blood; the latter may hold in solution an active poison—the hydrosulphate of ammonia.

(a.) *On the absorption of pus which has not been in contact with the atmosphere.*—With reference to its absorption, I distinguish in pus, first, the parts which dissolve in water; secondly, those which form an emulsion with albumen; thirdly, those which are undissolved and merely suspended.

The first are re-absorbed the most easily; their *ensemble* constitutes the serous part of pus, and, like all serous fluids, they can easily, under given conditions, re-enter the circulation: thus, when col-

jections supposed to be purulent are partly re-absorbed, they always contain a large proportion of serum—such as those of the pleura, the peritoneum, the articular synoviae, and cold abscesses. In the last, as every one knows, the serous parts predominate; and in the pus of the pleuræ, or of the articular synoviae, they are in a still greater proportion. If, for example, we place upon a filter the pus produced by an acute or chronic pleurisy, we see more than two thirds pass through in the state of a serum as limpid as that which swims upon the clot in the blood of a healthy man. This is by no means surprising, for in serous and synovial membranes, the product of purulent secretion is mingled in the same cavity with the serous exhalation.

When the serous part of the pus has been re-absorbed, the abscess, after having diminished for some time, remains stationary; and if it is then opened, we find upon its parietes clots, or filamentous masses, whitish and insoluble, which I cannot compare to anything so well as to those which remain upon the filter when pus has been placed upon it for some time, and a part of the serum has filtered through. These are the parts which, in consequence of their insolubility, have not been capable of being taken up by the absorbent vessels, or rather of being imbibed by the tissues.

The fatty matters which form an emulsion with the albumen of pus, seem to me to be absorbed with difficulty, and even to hinder the absorption of the serum. When they are abundant, they almost entirely prevent filtration, as may be seen in the creamy pus, which, when placed upon the filter, allows but a few drops to pass through. Now I do not believe that I am advancing a paradox, when I maintain that every substance which is difficult to filter is also absorbed with difficulty: this general proposition is derived naturally from M. Magendie's experiments on the imbibition of tissues; and hence it appears why creamy pus, that is, pus containing a large quantity of emulsive fatty matter, which is difficult to be filtered, is so rarely absorbed, that I cannot venture to affirm the possibility of the case.

As to the parts of pus which we have considered as consisting of fibrin, they do not dissolve in water, cannot be imbibed, and are evidently the most difficult to be re-absorbed; it is not surprising, therefore, that they are found on the surface of cold abscesses, when a part of the pus of those abscesses has re-entered the circulation.

We can now understand that if the immediate principles of pus which has not been in contact with the atmosphere are carried into the blood, either in whole or in part, they need not disturb its functions.

This absorption may seem frightful as long as we do not know the composition of pus, and consider it as a peculiar and hurtful substance; but our fears must cease as soon as we comprehend the relations of its composition to that of the blood, and see that its absorption is merely the restoring to the blood the serum and fatty matters which had been separated from it. Hence we see why the diminution of an effusion, supposed to be purulent, causes no more bad symptoms than if it were a dropsy; and we shall attach less importance to finding pus in the blood, a problem which it has often been attempted to solve by chemical analysis, without perceiving that it could not be done.

If pus, indeed, contained some immediate principles peculiar to itself, as urea and the yellow colouring matter are to urine and the bile, it might be possible to recognise it in the blood; but it consists of those immediate principles only which belong to the fluid which forms it, in its normal state; and hence the mixture of pus with the blood can only alter it by changing the proportion of its elements. When we find this change, how can we be sure that it arises from the absorption of pus? To arrive at this certainty it would be requisite to know all the varieties that can be produced in the proportions of the immediate principles of the blood, by other causes besides absorption—a knowledge which we have not attained, and which perhaps is unattainable.

(b.) *On the absorption of pus which has been in contact with the atmosphere.*—Pus which has been exposed to the atmosphere contains, when it is fetid, hydrosulphate of ammonia, with an excess of the alkali; and this salt necessarily accompanies the pus when it is absorbed, or even if its serum is absorbed alone; and a septic poison, which can be recognised by accurate methods, is thus introduced into the blood.

For ages writers have spoken of the absorption of putrid matters, and of the putrefaction of pus; but as they did not specify in what this putrefaction consists, and what are the new elements which it develops, it was impossible to trace these substances in the blood, where, moreover, the attempt to examine them by any known method, such as reagents, chemical analysis, and the microscope, would have been useless. But now that I demonstrate that the fætor and the alteration of putrefied pus depend upon the hydrosulphate of ammonia, and that I point out a certain method of discovering its presence, namely, the exposing to its vapours the test-papers which indicate the presence of sulphuretted hydrogen and ammonia, the solution of the problem becomes easy, and it is seen that if pus

altered by putrefaction gets into the blood, it can be discovered there. This I have done; but as I have not long thought of applying to the blood the method of discovery which I have employed for two years in the study of pus, I am in possession of only one well-established fact on the absorption of the hydrosulphate of ammonia, its presence in the blood, and its excretion by the urine. But this fact is sufficient to establish the possibility of the phenomenon; and the method being once shewn to be useful, will be capable of many applications.

CASE.—A man, aged 43, had the upper part of his foot and the lower part of his right leg severely contused by the wheel of a heavy carriage; all the subcutaneous cellular tissue of these parts became gangrenous, and the skin itself mortified over the malleolus externus, and the superior part of the tarsus, in irregular patches of about two inches square. On the sixteenth day the gangrene was well defined, and the cutaneous eschars were detached, but those of the cellular tissue were still partly adhering: the pus which ran from this vast abscess was filled with gas of an insupportable fetor, and gave a black colour to diachylon plaster, and to compresses dipped in the lead wash. Its alkalinity was well marked; it immediately restored the blue colour of litmus reddened by an acid, and when a rod, dipped in hydrochloric acid, was brought near the surface of the sore, white vapours were disengaged, copious and very thick. I put some in a phial, and on placing litmus paper reddened by an acid, at its mouth, its blue colour gradually returned, and then grew weaker on exposure to the atmosphere. These tests demonstrated the presence of free ammonia.

Continuing my experiments, I put two ounces of the pus in a phial, and then placed upon its mouth the test-papers for sulphuretted hydrogen. The solutions of lead, copper, and mercury, became of a very deep black; those of antimony, reddish; those of oxide of arsenic, yellow; and a salt of the tritoxide of iron, of a rusty colour; but, except this last change, which unquestionably depended upon free ammonia, they all demonstrated the presence of sulphuretted hydrogen. Moreover, the disengagement of this gas was quicker and more copious when I heated the pus in a water bath, or added a little sulphuric acid.

Meanwhile the patient, who, during the first days of his illness, had merely had an inflammatory fever, now laboured under the most serious symptoms, as soon as the sores were thus overflowing with fetid pus; on the tenth day he was seized with

rigors, which, after having lasted an hour, were followed by fevers, with extreme acceleration of the pulse, and abundant sweats. These febrile attacks were repeated until the fourteenth day, sometimes in the morning and sometimes in the evening. At a later period they were no longer preceded by a sensation of cold, but were merely characterized by fever and sweating. These fits were accompanied by a very fetid diarrhœa; the loss of strength became extreme, and the face of a paleness slightly tinged with yellow.

I had examined the pus on the sixteenth day, when it contained a large proportion of hydrosulphate of ammonia; and as the symptoms of the attack exactly resembled those of the absorption of pus, it was natural to suppose that the hydrosulphate of ammonia had entered the blood. I then ordered a small bleeding on the seventeenth day. The house-surgeon reported that the blood, on issuing from the vein, was more fluid than usual, and of a colour resembling the lees of wine. When I examined it, two hours afterwards, it had separated into serum and clot; the surface of the latter had become red by exposure to the atmosphere, and its physical appearances were quite regular. I repeated the same experiments on the blood as on the pus, and with the same results. The serum quickly restored the blue colour of litmus reddened by an acid; and its vapour, when disengaged by a slight increase of temperature, produced the same effect on the test-paper. Lastly, when the blood was not heated, and a rod dipped in hydrochloric acid was brought near its surface, white and thick vapours were disengaged in abundance. This blood, therefore, like the pus, contained free ammonia.

I first tried to find sulphuretted hydrogen by placing the serum in a phial, heating it in a water-bath, and exposing to its vapour papers dipped in solutions of lead, tartar emetic, and white oxide of arsenic. No change resulted; but when I made my experiments upon the clot mixed with the serum, that is to say, upon the whole blood, its vapour acted upon the test-papers in the manner characteristic of sulphuretted hydrogen, just like the vapour of the pus. As it was thus shown that the hydrosulphate of ammonia was present in the blood of this patient, I was naturally led to suppose that this salt might be found in all the secretions, and particularly in the urine. I accordingly collected some on the day following that on which I examined the blood. It was perfectly clear, of the natural colour, but a little paler, and deposited no sediment after being suffered to stand for two hours. It was very alkaline, which was

obvious either by dipping litmus paper reddened by an acid into it, or by exposing this paper to its vapour. This vapour, disengaged by a slight elevation of temperature, indicated, when tested in the usual way, the presence of sulphuretted hydrogen; so that it was evident that the hydrosulphate of ammonia absorbed from the surface of the gangrenous sore became mixed with the blood, and ran off in part by the urine. It is to be remarked, that although the urine was not albuminous, the tests for hydrosulphuric acid did not show that it was present.

The existence of hydrosulphate of ammonia in the urine, made me imagine that this salt might also be found in the perspiration. Unfortunately, I did not attempt to find it until the twenty-second day of the disease: at this period the sweats had ceased, and I had no other way of examining the perspiration but by applying turmeric and litmus paper to the skin; but the slips of paper became displaced during the night, so that I could not find them; and on the following days, whether from want of alkalinity, or from the quantity of perspiration being insufficient, no change of colour took place.

It was about this period (on the twenty-third day) that the eschars of the cellular tissue were completely detached; the sore began to be covered with healthy granulations; the pus gradually became less foetid and less alkaline; the urine recovered its acidity, and the febrile paroxysms ceased. The patient suffered from nothing but constant quickness of the pulse, extreme weakness, and diarrhoea, which diminished in foetus as the suppuration grew less. Six weeks passed away in this progressive improvement; the patient's appetite returned, and he took nourishment, but his strength could not be renovated; he continued dreadfully pale, and always lay upon his back. Eschars formed upon the sacrum; the diarrhoea returned, and the patient sank, without any particular symptom, rather less than three months after his accident. On examination, we found no structural disease in any of the thoracic or abdominal viscera; there was very little blood in the veins, and no fibrous clots in the aorta. The heart and the pulmonary arteries were completely empty. The large abscesses which had occupied all the subcutaneous cellular tissue of the foot, and of the inferior part of the injured leg, had entirely closed; the cicatrization of the sores was almost completed, and without doubt the cure would have been perfect, if the exhaustion and prostration of his strength had not carried off the patient by a truly exsanguine death.

The treatment which I adopted was the usual one. To get rid of the foetid pus, I

opened the abscesses freely; I made a considerable number of counter-openings, and used frequent injections with the chloride of lime; I removed, as soon as possible, the cellular tissue when it became gangrenous within; I gave *negus* (*limonade vineuse*) when I found that there was hydrochlorate of ammonia in the blood; and I administered the preparations of cinchona when the symptoms of exhaustion succeeded those attending the absorption of putrid matter.

If the surgical art is able to do much in this kind of absorption, it is chiefly in the way of prevention, by diminishing the secretion of pus, and preventing its contact with the atmosphere. Immediate reunion assists in attaining this object in operations; and it is to be accomplished, when large abscesses are opened, by making the incision under the skin to the affected parts. This method, to which I have been led by my scientific researches, is destined, as I hope, to exercise as beneficial an influence upon the treatment of large abscesses, as immediate reunion upon that of recent sores.

However this may be, when we have not been able to prevent the putrefaction of pus, and the injurious principles resulting from its putrefaction have been absorbed, can the demonstration of their presence in the blood lead to any useful application? I doubt it. We might imagine that it would be well to excite the urinary secretion, as it might serve as an outlet to the hydrosulphate of ammonia; and that it would be right to try to neutralize the excess of ammonia in the blood by acids, and to decompose the sulphuretted hydrogen by the chlorides, or neutralize it by the salts of lead, which might form an insoluble sulphuret; but unquestionably it would be a strange mistake to attribute any real efficacy to any of these means. Even chemically no one of them decomposes, or completely neutralizes, the hydrosulphate of ammonia when it is dissolved in serum; and even if this decomposition or neutralization took place, there is no proof that the blood would thereby regain its natural state. The following experiments, moreover, may serve to clear up this question.

At a time when I supposed that, in the diseases called putrid, the blood contained hydrosulphate of ammonia, without my having yet been able to detect it, I thought that if the blood found in the bodies of those who die of typhus fever, or of absorption of pus, owed its colour (which remains black after exposure to the atmosphere), its fluidity, and its want of coagulum, to its mixture with hydrosulphate of ammonia, I could give the same characteristics to ordinary blood by mixing it, as

soon as it was drawn from a vein, with hydrosulphate of ammonia. In order to verify this supposition, in bleedings performed on persons suffering under slight indispositions, I let the blood partly into dry vessels, and partly into vessels containing hydrosulphate of ammonia, or solutions of sulphuretted hydrogen. The blood mixed with either of these solutions (which were in the proportion of one-fourth or one-fifth of its volume), preserved its venous colour whatever was the length of time that I left it exposed to the air, and also remained liquid; while the blood of the same patients, received into dry vessels, became red and separated into serum and clot. Now if the blood mixed with hydrosulphate of ammonia had all the physical characters of that which is found in the bodies of those who have died of typhus fever, or absorption of pus, it was in vain that I aided acetic acid, or subcarbonate of lead, or chloride of lead; it neither recovered its power of becoming red, nor that of separating into serum and clot—a result which tends to shew, if it does not strictly prove, that the depravation of the blood is too great to be removed by the addition of substances which decompose, or partly neutralise, the hydrosulphate of ammonia; and hence we learn, that in the treatment of diseases capable of forming these putrid principles, it is in the *prevention* of their formation that art must be employed; and it is from such an attempt that really useful results are to be hoped for.

From the moment that I detected hydrosulphate of ammonia in the blood and urine of the patient whose history I have given, I have thought of searching for it in the same fluids, and by the same methods, in patients suffering from malignant typhus, or from purulent absorption following either an operation or the opening of a large abscess.

Hitherto, however, I have not had any favourable opportunity for prosecuting my inquiries. I wanted cases of typhus fever which had arrived at the stage in which there is fœtid suppuration from ulcers in the bowels, or cases of absorption of pus, indicated by paroxysms of fever, preceded by rigors, and followed by sweating; but though I have not had any opportunity of seeing these serious diseases for some time, they are frequent enough to allow any industrious man, taking advantage of the method of which I have laid down the rules and shewn the application, to ascertain what part is played by the hydrosulphate of ammonia in the changes which take place in the blood, the urine, and the sweat, of the patients who are affected by these diseases, including in general all those patients who labour under the symp-

toms which are called putrid. As it is always easy to examine the urine, and since, to judge by the case I have narrated, if the hydrosulphate of ammonia is in the blood, it is probable that it will also be in the urine, we ought always to begin by the examination of the latter fluid. We must first see whether it has lost its acidity and become alkaline; and if it has, we must then employ the tests which detect free ammonia; and then, after heating the urine, we must observe whether its vapour contains sulphuretted hydrogen. If the vapour causes no change in slips of paper dipped in solutions of lead, tartar emetic, and arsenic, we must then try if we cannot disengage sulphuretted hydrogen by the addition of sulphuric acid. I have examined in this manner the urine of several patients whose suppuration was fœtid, ammoniacal, &c. without any signs of absorption being present. As upon examination I neither found free ammonia nor sulphuretted hydrogen, I proceeded no farther; but had I found these substances in the urine, I should have extended my researches into the sweat and the blood; into the sweat, by applying turmeric, litmus, and acetate of lead test-papers to the axilla and the front of the chest; and to the blood, by examining its vapour by the method of which I have now repeatedly given the details.

My researches into the composition of pus, and the chemical reason of its varieties, have led me to some pathological facts, which are merely useful as they contribute to our comprehension of morbid phenomena: but the proof which I obtained of the existence of the hydrosulphate of ammonia in pus which has undergone putrefaction, brought me to more practical and useful applications. Knowing that the decomposition of pus cannot take place without the contact of the atmosphere, that indispensable agent in every kind of putrefaction, I thought right to study, as so many others have done, the best means of preventing this contact. My first plan was to make an incision into the parietes of abscesses under water,* and I did so in two cases where they were in the elbow and the

* Five years ago, M. Messiat, well-known for his investigations into empyema, when talking with me about the dangerous sequelæ of the extraction of foreign bodies from the knee-joint, which are generally attributed to the action of the air, proposed to extract them under water. At the time that Monro insisted so much upon the dangerous action of the atmosphere after operations, Aitken proposed to perform the Cæsarean operation in a bath. The air, however, is not of itself an irritant, but it is indispensable to putrefaction; its entrance into large abscesses is dangerous, not that it directly inflames their parietes, but because it allows of the putrefaction of the pus contained within them.

knee. In the former case I left the joint for several days in the water contained in the small vessel in which the operation had been performed; in the latter I followed a different plan.

The patient being placed in a bath, and his knee kept under the water, but near its surface, I made an incision an inch in length into the spot where the fluctuation was most perceptible; when the pus had escaped, I pierced the middle of the lips of the wound under water with a pin, and joined them by the twisted suture. This opening of the abscesses in the two patients was not followed by any bad symptom; but the pus soon returned, and rendered fresh incisions necessary. I then reflected that as the exit of the pus contained in an abscess diminished the pressure upon its parietes, and this diminution of pressure favoured the afflux of blood, it was necessary, when the pus had been discharged, to make a permanent compression, in order to prevent or retard its reproduction. I therefore covered the knees of the first two patients whom I next operated on, and afterwards those of three others whose abscesses I also opened under water, with strips of diachylon plaster so disposed as to form Scultet's bandage. Two of these patients, who were much relieved by these means, having unfortunately got up, I saw that I had given them too much liberty, and being convinced that the destruction of the cartilages which always follows abscess of the joints would not allow motion to be re-established, and that anchylosis was the most favourable result that could be expected, I resolved to treat knee joints, which had been the seat of open abscesses, like fractures, and accordingly to place them in the usual apparatus; but since the patient found it difficult to bear the constrained position, and I was afraid that lying on the back too long might cause sloughing of the sacrum, I suspended the apparatus, by fastening cords to the two extremities of the lateral splints. Thus taking my researches into the dangers arising from the putrefaction of pus as a starting point, I devised and put into execution, in cases of chronic abscess of the knee-joint, a method of treatment which consists,

First, in letting out the pus, the diseased joint being placed under water, and uniting the wound thus made, by the first intention, and also under water.

Secondly, in compressing the parts immediately by means of strips of diachylon plaster.

Thirdly, in keeping the bones of the thigh and the leg extended and fixed by means of a fracture apparatus, until anchylosis is produced.

Fourthly, in suspending this apparatus so as to allow the patient to move the trunk without allowing any motion of the bones which we wish to have anchylosed.

It is impossible for me at present to give the result of this complex method, because the original plan having been put into execution not more than three months ago, I do not as yet possess any complete case, and the additional means which have advanced this method to the point which I have just explained, being never still, cases which are merely begun would not allow my readers to judge of the plan with all its advantages. Moreover, in order to explain the method of treating abscesses of the joints, it would be necessary to set forth the pathological anatomy of white swellings, with the diagnosis of their several varieties, and the interpretation of the phenomena which they offer. I reserve for another period the publication of my labours in this field; but my reason for detailing the method of treatment which I employ in abscesses of the joints, was to show that the scientific investigations which form the basis of this essay have not been without a result; I wished also to fix the date of a method which I believe will improve the treatment of a very serious disease which most obstinately resists our ordinary means. I now do what I did in the preceding years for the solution of urinary calculi, and the radical cure of herniæ. A few days of fortunate meditation are sufficient to invent a method: whole years are necessary to develop it practically, and to pass upon it a judgment founded on experience*.

REMARKS

ON

THE NATURE AND TREATMENT

OF THE

DIFFERENT FORMS OF PORRIGO.

By WALTER DICK, M.D.

Formerly House Surgeon to the Glasgow Royal Infirmary.

[Continued from p. 419.]

Of Porrigo primarily affecting the Pilius Cysts, and Structure secreting the Hair—comprehending Porrigo Furfurans, and Porrigo Scutulata.

WE agree with Mr. Plumbe in believing that porrigo furfurans, and porrigo scutulata, are not two distinct diseases, but varieties merely of one and the same disease. In this country, they

* From the *Gazette Médicale*.

both receive the popular name of "Ringworm." We shall, therefore, describe them together; and we cannot do this better than in the words of Mr. Plumbe, who has described ringworm of the scalp, as occurring in this country, more faithfully than, perhaps, any other author*.

"The attention," says Mr. P., "is first attracted to the disease by the *falling off* of the hair of the part; there is little attendant itching, and no apparent fluid secretion on the spot. Sometimes, but not always, the patches are of a pretty regularly circular form, the margin being clearly defined, and exhibiting a line of scurf considerably thicker than that in the centre. In the centre of the spots the skin is scurfy, and the air thinned and easily extracted by the finger and thumb. What remains of it is unhealthy in appearance, some hairs being thin and delicate, others being the remains or stumps of those which have been broken or dropped off. There is a *downy or towy-looking substance* just rising above, and mixing with the scurf, evidently formed by feeble attempts at the production of new hair. Two, three, or more of these spots, varying in dimensions, are usually discovered on examining the head more particularly; and when the hair has been removed by shaving, they exhibit a red and slightly inflamed appearance. Several others, in an incipient state, will be discovered in different parts. The latter may be known before the hair begins to fall off, when they exhibit nothing beyond the appearance of a small discolouration about the size of a spangle; the hue is of a yellowish red, somewhat resembling the bran of the darker coloured wheat; others, a little larger, have decidedly assumed the ringed form.

"At the commencement of the disease, and for some time after, spots, evidently of the same nature as the affection of the scalp, may be seen on different

parts of the body; but the former being usually protracted for a considerable time, these spots generally disappear before much improvement is effected on the scalp. To describe them more minutely would be to copy very nearly the account of the first form of *Herpes circinatus* of Bateman*."

Although Mr. Plumbe despises (perhaps too much) minuteness of distinction in cutaneous diseases, his descriptions are generally very accurate—evidently the result of sound observation and extensive experience. The above quotation contains an admirable delineation of the most striking features of "ringworm," as it usually occurs in this country; and its faithfulness will be at once recognised by those even the least conversant with the disease. *Porrigo furfurans*, as described above by Mr. Plumbe, does not, most frequently occur in adults, as is said to be the case with the form of the disease so called by Bateman; it is met with, almost invariably, in young subjects, from infancy to puberty.

Ringworm of the scalp is described by some of the French writers under the terms *teigne tondante*, and *porrigo tonsoria*; but they are in error in supposing that their *porrigo tonsoria* is the species described by Willan under the epithet *decalsans*. Any one who attentively reads their descriptions will, I think, agree with me in this opinion.

Willan and Bateman assert that *P. furfurans* and *P. scutulata* begin with *achores*; but, with Mr. Plumbe, we are inclined to think that these elementary lesions, when they do occur, are accidental, rather than primary or essential symptoms, being generally produced subsequently by irritating applications, or by the disease extending upwards, and affecting the sebaceous glands. In this latter way, *achores* (or, as the French call them, *favi*) are frequently produced, we believe, during the progress of the disease.

As the *furfuraceous* patches of ringworm enlarge, they not unfrequently exhibit a somewhat granular appearance, consisting, when examined through a lens, of minute vesicles, which either subside spontaneously, or burst, and their contents concrete into delicate incrustations or scales.

* *Furfuraceous porrigo* is one of the group of heterogeneous diseases described under the term, *Alopecia*, in the *Cyclopædia of Pract. Medicine*. But it is scarcely right to make (as the writer of the article alluded to has done) a separate disease of *alopecia*, which is but a symptom common to several eruptions which attack the scalp. Such an article as the one alluded to, we may be allowed to observe, shews the urgent necessity of investigating the pathology, and zealously striving to establish the *exact seats* of the different diseases of the skin. Till this is effected, it must be pretty obvious, we should think, that dermatology will continue in a very unsatisfactory state.

* Plumbe on Diseases of the Skin, 4th edit. p. 141.

In long-standing cases of ringworm, nearly the whole scalp is rendered bald, exhibiting only here and there a little towy-like hair; and the affected parts appear *mealy*, from being covered with scurf. This scurf consists partly of epidemic *debris*, and partly of squamous incrustations, formed by a secretion thrown out from the pilous cysts. In some cases the scurf seems to consist almost entirely of these latter thin incrustations, as any one may be convinced by attentive examination. They are seen surrounding the hairs at their exit from the skin; they resemble scales of bran, and are quite different in appearance from epidemic scurf.

The thick circular scabs, by many thought to be characteristic of *P. scutulata*, are never met with except as the effect of improper treatment, and inattention to cleanliness. Those who look upon such scabs as characteristic of ringworm, have been misled by confounding it with the variety of *P. lupinosa* described by Alibert under the term *faeus scutiformis*, and which we have called *porrigo lupinosa conferta*.

From *P. furfurans*, and *P. scutulata*, so generally commencing with furfureous patches, from which the hair falls off and becomes altered in texture, we are inclined to think that it would be proper to refer them both to the common term, *porrigo furfurans*, and expunge the term *P. scutulata* from the cutaneous nomenclature. Alibert also seems inclined to consider *P. scutulata*, or, as he calls it, *P. tonsoria*, closely allied to *P. furfurans*. After alluding to M. Mahon's opinion of the affinity of *P. scutulata* with *P. lupinosa*, he remarks:—"Je ne saurais adopter cette opinion; je pense, au contraire, qu'elle se rapproche davantage de la porrigne furfurace*."

The separation and altered appearance of the hair in ringworm (under which term we always include *P. furfurans* and *P. scutulata*) are sufficient, in our humble opinion, to lead to the belief that the parts nourishing and secreting the hair are those primarily affected in this disease. Mr. Plümbe and others, however, take a different view of the matter. "Much light," says Mr. P., "may be thrown on the pathology of this affection by reference

to the known effects of the severe forms of *scarlatina*, as well as other diseases attended by determination to the skin. In this disease (*scarlatina*), where excessive excitement of the part prevails through its course, its termination is attended by extensive exfoliations of the cuticle, and occasionally by the separation of the hair of the scalp; which two circumstances appear to depend on the same cause—the excessive action of the vessels of the cutes. The action of which those vessels partake which secrete the cuticle, produces a morbid increase of this structure; while the privation of blood which (during the continuation of the inflammatory state of the cutes) the structure secreting the hair sustains, cutting off its nourishment, it is observed to drop off, apparently by the roots, though, if examined, never having its rounded healthy bulbs. The same privation of nourishment which the structure secreting the hair suffers in the extended inflammation of *scarlatina*, is experienced in an aggravated degree in the smaller space which ringworm commonly makes its appearance on; and hence it is that the hair separates, in this disease, without the formation of pustules." He adds, "Ringworm may be defined to be inflammation of a specific character, affecting the solid structure of the cutis." The hairs, in his opinion, exert a very mischievous influence on the disease; and to their presence he ascribes the formation of pustules.

The above explanation of the nature and phenomena of ringworm is too hypothetical, and at the same time *mechanical*, I apprehend. The supposition that a hyperemic state of the skin can be so circumscribed and permanent, and operate in such a way as by derivation to deprive the hair bulbs of their due *quantum* of blood, is not, when properly considered, supported by any recognized law of pathology. We are also of opinion that the phenomena of *scarlatina* are altogether inapplicable to the elucidation of the disease in question. Indeed, it is very problematical whether the desquamation of the cuticle, after *scarlatina*, be the effect of the previously injected state of the cutis; for it occasionally succeeds *scarlatina anginosa* unattended by cutaneous efflorescence. Those who wish to find cases establishing this fact, may refer to a clinical lecture of Dr. Graves',

* Vide Monographie des Dermatoses, tom. i. p. 470.

published in the MEDICAL GAZETTE for March last.

That ringworm consists primarily of subacute inflammation of a specific character, affecting the pilous cysts and structure secreting the hair, we infer from the following circumstances:—

1st. The thin bran-like incrustations so frequently seen surrounding the roots of the hairs, and consisting evidently of a morbid secretion from the pilous cysts.

2d. The falling off of the hair from affected parts, and the towy, unhealthy appearance of what remain.

3d. In pulling out the hair from affected parts, we have sometimes brought the bulbs along with them; and these never presented their usual or normal appearance*.

We proceed to make a remark or two upon

Porrigo Decalvans.

The form of porrigo, called by Willan and Bateman decalvans, presents patches usually of a circular shape, completely deprived of hair—the scalp, at affected parts, appearing of natural colour, smooth and shining. There is no visible cutaneous lesion: the hairs appear to drop off from their roots. These bald patches sometimes attain a considerable size, but they commonly appear of about the size of a shilling or a half-crown-piece. Sometimes there is but a single patch; in other cases there are three, four, or more, on the same subject, as we ourselves have occasionally observed.

Mr. Plumbe thinks that *P. decalvans* cannot be deemed, strictly speaking, a disease. However, from its appearing in schools and families, where the other forms of porrigo prevail, we are warranted in viewing it as allied to them.

From the phenomena of the affection, one would be led to suppose that the principle which produced it acted upon the organs secreting the hair in such a manner as to produce a temporary atrophied or inactive state of them. But its true nature, it must be confessed, is very much in the dark. We see it often continue for a very long time, and afterwards, either spontaneously, or during the application of stimulant liniments,

see, get well—the hair sprouting up, strong, healthy-like, over the previously bald patches.

Causes of Porrigo.—Porrigo is a disease to which, in some form or other, persons of all ages are subject; but it attacks chiefly the young, and from the frequency of its occurrence it is justly deemed the bane of youth. The forms of it most frequently met with in this country are porrigo furfurans and porrigo scutulata, which, as we stated above, are essentially one and the same disease, and designated by the common people, ringworm. In France, judging from the Hospital Reports, *P. lupinosa* seems to be the most common form. *P. decalvans* is the least frequent form, and indeed in this country is comparatively seldom seen.

Although all the forms of porrigo may arise spontaneously in those who are badly fed, and inattentive to cleanliness, yet it may be safely affirmed that it is by contagion they are most commonly produced. And it is a well-established fact, that all the forms which we have above described may be produced from one and the same contagious principle. It has been frequently observed that when a case of porrigo appears in a family, if rigid seclusion of the infected subject be not immediately adopted, the disease spreads, and not unfrequently in other forms than the one first developed. At schools, boys frequently contract the disease by wearing the caps of others affected with it; and in boarding-schools, it is sometimes communicated to several of the pupils by means of combs and towels, before the contaminating source is discovered.

However clearly the contagious nature of the different forms of porrigo is established, it is equally certain that the disease is not communicable to all subjects; and that for its transmission by contagion, certain conditions, as respects age, temperament, and state of the integuments, are requisite. We have seen ringworm attacking two or three subjects in the same family, almost at the same time, when the occurrence of the disease could not be traced to contagion. We have been led to believe that the disease, under these circumstances, originates from some dietetic irregularity, or from some article of food being of a bad quality.

From what we have observed, we are inclined to think that porrigo is not so

* I am inclined to think that the eruptive disease so common in dogs, and technically called "red mange," is closely allied in its nature to the disease the pathology of which we have just been discussing.

contagious as many suppose.* Alibert lately seemed inclined to deny, nearly in toto, its contagious nature. The ingenious Baron, however, was rather changeable in his opinions—it is not long since he was as extreme on the other side of the question.

[To be continued.]

SOME ACCOUNT OF MESMERISM.

By BARON DU POTET DE SENNEVOY.

[Concluded from page 423.]

Somnambulist Phenomena.—*Vision (so called) without the intervention of the Eyes.*

WHEN only a few men relate astonishing effects, which they affirm to have themselves produced, their testimony may be contested, and it may be believed that they are in error; especially if these effects are of an order superior to the usual phenomena of nature. Those doubts acquire still greater weight when, having been desirous to show and prove these facts, they have failed in their endeavours. But if these identical facts have been attested by individuals of the highest honour; if thousands of persons again assure us that they have themselves verified them; it is then only fair to believe that some obstacle exists which prevents them from being elicited according to our wish, and that it is very probable that nature may not always obey our desires, more especially when those desires oppose the laws which she has established. To call men charlatans because they are so unfortunate as not to succeed in some delicate experiment, is to forget that the most skilful professors of chemistry and physics, operating on inorganic bodies, and which are consequently uniform in their action, are at any moment liable to fail in their experiments without any one having a right on that account to deny what they have advanced, since it is generally known that extraneous causes, causes often very trifling, may destroy or disturb the conditions necessary to success.

* We have more than once endeavoured to contract the disease, and hitherto without success. But, probably, some may say, (perhaps with truth,) had I been more anxious to contract the disease, I might have been more successful in the experiment.

I am entirely ignorant of the law which regulates the production of the phenomena of somnambulist vision; but I know perfectly well what it is that in certain cases prevents their manifestation. It has been my fate, also, not to be always successful, and I have studied the causes of my failure. The following is the explanation.

When I operated on a somnambulist in silence and *recueillement*, and that I had around me only inoffensive persons who were ignorant of that which was about to be produced, or who awaited it without suspecting my motives, I was calm and tranquil; the action of my own being (*de mon être*) upon the somnambulist, was almost as regular as that of a machine, and what passed in the somnambulist was equally so. Nature then manifested herself unconstrained, and the resulting phenomena had a peculiar character, and almost always satisfactory.

But it was otherwise when my desire of convincing persons who doubted my statements induced me to permit them to be present at my experiments. These persons very soon acted upon me by their incredulity, often expressed by cutting words or sarcastic smiles. I ceased from that moment to be calm and composed; my mind became extremely agitated; my heart beat violently: it was when in this state that I was required, commanded, to justify my assertions. Unwilling to recede I continued the task, and pride prevented me from listening to the voice of wisdom. What was the result? The being whom I magnetised, and who had no cause of disturbance, for he was often ignorant of what would occur during his sleep, no longer went to sleep in the same manner. Sudden starts were observable; his cheeks flushed; his heart beat like my own; and although he might fall into somnambulism, I soon perceived that his sleep was not regular as before, and that my own excitement had thrown him into a similar state. It was in this condition that I urged him to obey, that I solicited him to give me proofs of his vision. He consented reluctantly; for he was aware that changes had taken place in his state; but finally he did consent, and we very soon had proof that his lucidity no longer existed, and that all his annunciations were illusory. My disturbance at this want of success

only added to the already existing difficulties, and rendered all my experiments negative.

Several lessons of this kind at length enlightened me, and I obtained the proof that I had discovered the cause of the non-success of these experiments, when, on repeating them in the presence of the same men, I had sufficient resolution to be unmoved by their remarks, and not to suffer myself to be demoralised by their contemptuous looks. Water, so transparent when calm and tranquil, no longer reflects objects when it is disturbed. The mirror is dimmed by a slight breath, and ceases to give a faithful image. If undue moisture is allowed to approach an electrical machine, the handle will be turned in vain; no electricity will be produced. These transient accidents having ceased, and calm being restored, order resumes its course, admirable phenomena are again presented; but those who have witnessed the disorder only, accuse you of falsehood, and your name is enrolled on the list of charlatans. What is to be done under these circumstances? To be silent, and to pity the men who force you to bend beneath their hasty decisions; to wait for time to enable you to triumph over them: for when men say no, respecting a fact, and Nature says yes, it is very certain that nature will eventually prevail.

Here are cases of vision without the aid of the eyes, attested by men of education. I have selected them from many others, because the greater number of those who witnessed them are living, and hold at this day a distinguished rank in the faculty of medicine at Paris, or in the scientific world.

M. Francœur, a distinguished mathematician, read in 1826, at the Philomathic Society, a paper containing very curious facts. Happening to be at Aix, in the society of some respectable physicians, especially Dr. Despine, head-physician of the establishment there, this latter related to him that he had witnessed for months the phenomenon of the transference of the senses, so singular, that M. Francœur thought it his duty, for the advancement of truth, to give an account of it to the Society.

In the first notice of this memoir, we read that the patient who is the subject

of it had the faculty of seeing, hearing, and smelling, by means of her fingers.

The second is much more remarkable. The observation was made on the daughter of M——, who possessed the esteem of the city of Grenoble, where he lived in retirement, and who was extremely afflicted by the illness of his daughter. He did all he could to conceal this illness, and would not permit any visits of curiosity. Among the different states exhibited by this invalid, and which Dr. Despine describes with great minuteness, he dwells particularly upon that of somnambulism.

"We have seen her select from a packet of more than thirty letters, that one amongst them which had been designated to her. She read on the dial-plate, and through the glass, the hour indicated by a watch. We have seen her write several letters; correct, on reading them over, the mistakes she had made; and recopy one of the letters word for word. During all these operations, a screen of thick pasteboard entirely intercepted every visual ray which could possibly have reached her eyes.

"The same phenomena took place at the soles of her feet, and on the epigastrium; and the patient seemed to feel a sensation of pain on being merely touched."

We find also some very circumstantial facts of vision without the aid of the eyes, in a curious memoir of Dr. Delpit upon two cases of nervous affections*.

"One of the patients read," says the author, "and read very distinctly, when her eyes were entirely closed to the light, by moving her fingers over the letters. I have made her read thus, either in full day-light or in the most profound obscurity, printed characters, opening the first book that came to hand, and sometimes written characters; giving her notes which I had prepared expressly before going to her residence. Was it only the sense of touch which then supplied that of sight? I know not; but I affirm that she read very fluently by passing her fingers over the letters."

This is certainly a very decided testimony, one rendered by a man to whom such facts presented themselves without his seeking them, without his having a suspicion of the possibility of their ex-

* *Bibliothèque Médicale*, t. 5^e, p. 308.

istence, and who, struck by their inconceivable singularity, took up the pen with the sole view of recording them.

Dr. Delpit, in some very short reflections annexed to these observations, appeals to the authority of several known authors, and in particular of M. Dumas. "Five years ago," says that celebrated author, "a young person from the department of l'Ardèche, having come to Montpellier to consult the physicians there respecting an hysterical affection, accompanied by catalepsy, presented an instance of a very strange phenomenon. She felt during the attacks such a concentration of sensibility towards the pre-cordial region, that the organs of the senses were as if entirely fixed there. She referred to her stomach all the sensations of sight, hearing, and smell, which were then no longer produced by the usual organs. This rare phenomenon, observed in a person very much calculated to inspire interest, was an object of attention to medical men, and of curiosity to the public.

"I am well aware," continues Dr. Delpit, "that facts of this kind, in opposition to all the laws of nature, ought not to obtain without difficulty, nor without restriction, the assent of sagacious minds fearing to be imposed upon; but if observations upon it are multiplied, if the most minute circumstances of each observation are scrupulously verified, the possibility of a phenomenon must then be acknowledged, which perhaps only appears so wonderful from the absence of many facts with which to compare it."

These cases are recent, and are of such a nature as to render deception respecting them impossible. Here are testimonies rendered by living authors, above all suspicion of imposture.

It would be very difficult to find the motives for such assertions, if the facts had not been evident. Besides, they are incessantly being renewed. The following is a notice published in the *Gazette de Santé*, of September, 1829. Hear what the editor of the journal says:—

"*Animal magnetism.*—There is at this present moment, in the wards of M. Fouquier, a patient in whom magnetism has developed curious, and sometimes incredible, phenomena. Without ranging ourselves amongst the lovers of the marvellous, it is a part of our duty

to pay some attention to facts when they are authentic. Now these which we are about to relate, having been observed simultaneously by a great number of persons, we think that we may offer them to our readers as deserving of their full confidence.

"A person called Pétronille Leclerc, 26 years of age, a sempstress, had been admitted into La Charité, to be treated for a cerebral affection, accompanied with spasms of an epileptic character: of a very nervous constitution, pale, exhausted by former sufferings, and excessively irritable. She had experienced, subsequently to a fit of anger, a turning upwards of the eye-balls, which had resisted all kinds of medical treatment. The idea occurred to M. Sibire, who attended her, to try the effect of magnetism. He made the first application of it on the 29th of August, and repeated it several times afterwards. Here are some of the most remarkable effects which were noted down, and some of which passed under our own eyes.

At the first sitting, the somnambulist gave several proofs of lucidity. The person who magnetised her presented some objects to her—such as a phial with its contents, some sugar, and bread, which she described perfectly, without seeing them. She had a bandage over her eyes. Besides, in order to answer the questions which were addressed to her, she turned to the opposite side, and buried her face in the pillow. Without being interrogated, she said to the person who held her hand, "You have a headache." This was true; but in order to test her knowledge, the pupil answered her that she was mistaken. "That is strange," resumed she; "I touched some one, then, that had a headache, for I felt it distinctly." She distinguished also different individuals who were present at the experiment, by some particularities in their clothes. One of the most remarkable circumstances is the following:—The magnetiser had retired, promising her that he would return about half-past five, to awaken her. He anticipated the hour of his return, and the somnambulist remarked to him that it was not half-past five. He replied that a letter which he had just received had obliged him to return to her. "Ah! yes," said she immediately, "it is that letter which you have

in your pocket-book, between a blue card and a yellow one." It was found to be exactly as she had stated it.

"A watch was placed behind the occiput, and she was asked what o'clock it was. 'Six minutes past four.' It was seven minutes past four."

The following is another extract, from *La Gazette Médicale de Paris*, October 2, 1832:—

"There is at present under consideration, at the hospital Della Vita, at Bologna, a very extraordinary phenomenon of animal magnetism. A patient in that hospital is seized every three days, at precisely eleven o'clock in the morning, with so violent a convulsion that he entirely loses the faculty of perceiving sensations; sight, hearing, smell, disappear completely; the organs of the senses no longer perform any function; both his hands are clenched so fast that it is impossible to open them; if force were employed, his fingers would infallibly be broken. Dr. Cini, however, son of the painter, who attends him, has discovered, after long and attentive observations, that the epigastrium, at the distance of about two fingers' length above the umbilicus, received, during the convulsive crisis, all the perceptions of the senses.

"If the patient is spoken to, the epigastrium being touched at the same time, he answers, and, if ordered, he opens his hands of himself. If any substance is placed upon the epigastrium, he describes its form, smell, quality, and colour. During the contact of the finger, the convulsion continually diminishes, and seems to disappear; but if the finger is placed upon the heart the convulsion is again produced, and lasts as long as the finger is kept in that situation. If a flute be played on, the epigastrium being touched at the same time, the patient hears the music; and when, without interrupting the performance on the instrument, the finger is removed for a moment from the epigastrium, carried towards the heart, and immediately brought back to the epigastrium, he asks why the music is suspended at intervals.

These experiments have been made in the presence of the professors and the students, and have excited extreme surprise."

In a very curious work, printed some years ago in Germany, some instances

of the same faculty are related, which do not appear to be less conclusive; and these instances are equally attested by good observers.

The author of the work of which we speak, himself an eye-witness of the facts contained in it, has joined to his own narration that of three distinguished physicians whom he had called in to the somnambulist; and these three accounts agree strikingly with his own. Here are some of the principal cases of sight, without the aid of the eyes.

The somnambulist sees a paper written by M. le Baron de Strombeck. She indicates that the writing contains two paragraphs, and how many lines are contained in each paragraph.

"I went to fetch the paper," adds the author; "I counted the lines, and I shuddered as I should have done at the sight of a spectre." The same individual saw, in M. Strombeck's chamber in an upper story, upon his desk, a proof-sheet from his printer, which he himself was not aware had been sent. She described the places of several objects situated behind her, and the position of which had been designedly deranged, unknown to her.

The patient named, to the minute, the hour shown by Dr. Smith's watch, which did not agree with any one of those in the apartment.

She said that Dr. Mercard had money about him in a long green-striped purse, of a kind which had long been out of fashion. This physician had only carried the purse about him for the last few days, and he affirmed that he had never taken it out of his pocket except in his own house.

If we open the work of Pététin *, we find phenomena exactly similar to these, and no longer observed in a single individual, but upon seven women, all falling into catalepsy.

One of these cataleptic persons distinguished, successively, several cards which had been slipped under the bed-clothes and placed upon her stomach. She told the hour marked by a watch inclosed in the hand of one person, and distinguished an ancient medal in the hand of another. On another day the same patient distinguished a letter placed under Pététin's waistcoat, then

* Voyez *Electricité Animal*, par le Dr. Pététin, Paris, 1808.

a purse which had been slipped there by an incredulous person: she also told the number of gold and silver coins in each side of the purse. Towards the conclusion of this last experiment, she gave notice that she was going to describe what was most remarkable in each person present, which in truth she did. She also perceived through a screen that M. Pététin had taken her husband's cloak instead of his own, and caused him to be informed of his error.

Another patient gave no less extraordinary proofs of vision without the aid of the eyes. Being experimented upon by several persons, she was able to distinguish a small piece of platina inclosed in a bit of paper, a ball of copper hidden in a handkerchief, a seal with three faces, held in the hand, and ascertain what was engraved upon them. On one of the faces was a motto, in Italian, in such small characters, that Pététin was obliged to give great attention in order to read it. The patient also described two books which were placed in the pocket of one of the spectators; finally, she read a prescription contained in a sealed paper, and named what it contained: one ounce of bark and a drachm of valerian.

Dr. Bertrand, who gives an account of the work of Pététin, makes the following reflections:

"If Pététin has not falsified, it must be frankly confessed that the patients whose history he has given us had the faculty of acquiring, without the help of the eyes, the knowledge of the form and colour of bodies; and if the facts which he affirms are not true, not only he himself must have falsified, but we are under the necessity of making the same supposition with respect to the relations of his patients, their friends, and the physicians, who were incredulous at first, and ended by declaring themselves convinced. Now I do not fear to say, that the agreement of so great a number of witnesses selected amongst enlightened people, who could have no interest in wishing to deceive; this agreement, I say, to attest, as facts, what were only insipid lies, would offer a most singular moral phenomenon: for the work of Pététin contains the history of seven somnambulists, who all presented the same phenomena; and consequently this marvellous agreement of witnesses to a useless and daring imposture must have been renewed seven

times: it is impossible to suppose this." I could add here to the facts contained in the Report to the Academy already mentioned, my own personal observations, and all those scattered in great numbers in all the works on magnetism; but not one of these observations would be more conclusive than that which I shall extract from the *Dictionnaire de Médecine*, printed at Paris in 1827; article, *Magnetism*.

After having spoken of somnambulist faculties in general, M. Rostan thus expresses himself:

"But if sight is abolished in its natural organ, I have fully demonstrated that it exists in several parts of the body. The following is an experiment which I have frequently repeated; it was made in the presence of M. Ferrus. I took my watch, and placed it three or four inches behind the occiput. I asked the somnambulist if she saw any thing? 'Certainly, I see something shining; it gives me pain.' Her countenance expressed uneasiness; ours must have expressed astonishment: we looked at each other, and M. Ferrus breaking silence, said to me, that since she saw something shining, she would no doubt tell what it was.

"'What is it that you see shining?' 'Ah! I do not know, I cannot tell you.' 'Look well.' 'Stay, it fatigues me—stay, it is a watch.' Fresh matter of surprise. 'But since she sees that it is a watch,' said M. Ferrus, 'she will doubtless be able to tell what o'clock it is?' 'Oh no, that is too difficult.' 'Pay attention, endeavour.' 'Stay, I am going to try. I may, perhaps, be able to tell the hour; but I shall never be able to see the minutes.' And after having tried with the greatest attention, said, 'It wants ten minutes to eight,' which was correct. M. Ferrus was desirous to repeat the experiment himself, and he did so with the same success. He made me turn the hands of his watch several times; we presented it to her without having looked at it. She made no mistake."

Much ingenuity has been expended in arguments to prove that man cannot thus act upon his fellow-man. Our opponents say to us—Explain how this lucidity is produced, and we will believe the possibility of it. Let those who put this question to us, explain how opium causes sleep; how they move their limbs. They themselves con-

ness, they do not know the limits of possibility, yet they deny the existence of a new fact, because their minds are not able to conceive it. They tell us the eye is made for seeing, the ear for hearing; we know it as well as they do; but we know also that the ear and the eye are but instruments, and that the principle which sees and hears is not the organ itself. That this principle is not able to transfer itself to some other part of the body is an opinion which is contradicted by facts, facts produced by other causes than animal magnetism. Both catalepsy and ecstasy, observed by so many able physicians, furnish the most complete and evident proof of this. It is to be hoped that the mystery which accompanies this phenomenon will soon be unveiled.

Let me be allowed, in concluding, to express one regret—that of seeing so many educated men content themselves with denegations, instead of investigating a subject which offers so vast a field for their observations. Let them condescend to make use of a power which they have within themselves. Their discussions will then become profitable, and humanity will return them thanks, for they will have contributed to enlighten its course.

MEDICAL GAZETTE.

Saturday, December 23, 1837.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

ON MEDICAL EXAMINATIONS.

IN our last notice of Mr. Whewell's work on the Principles of University Education, we introduced and commented on some of his observations on the subject of Practical Teaching. We proceed now, according to promise, to follow him into that of Examinations.

For various reasons, of which some are applicable to our case, he regards all compulsory examinations as "necessary evils," and this anomalous character

they certainly, in some degree, possess in medical education. They are necessary, and even indispensable, because it cannot be doubted that the public safety must be compromised if persons be admitted to superintend it, without its being in any way ascertained whether they are fitted for the discharge of the responsible duties they undertake. The destructive consequences so often resulting from the acts of unauthorised practitioners, prove at once the danger of admitting more with no testimony of qualification, and the utter inability of the public to form just opinions of the merits of those who, however different their qualifications, all profess the ability to render them service. It is, of course, a duty incumbent on the legislature to prevent unauthorised persons from thus imposing on the ignorance of the public, but while no laws exist against them which they cannot with ease evade, it must be the chief object both of examinations and education to guard the public against the incursions of those who, with an appearance of authority, might be doubly mischievous.

With some, examinations alone are deemed sufficient for the public protection; and the previous education, it is said, is of no importance, provided any person can satisfactorily prove to competent judges that he is fitted to undertake the care of patients. We need scarcely say, that in university education, where the subjects of examination admit of far more exactness in question and answer than in medicine, Mr. Whewell utterly repudiates such an idea. Such perfection of examinations is purely ideal, and the instances in which the plan is followed in medicine are themselves remarkable proofs of its being a bad one. To make this evident, we need only point to the very low degree of estimation in which those institutions are held, both by the public and by the profession, in which de-

degrees are conferred on persons whose education, if inquired into at all, is allowed to have been conducted at a distance, or to a very slight extent; for instances, we would refer to some of the German and Scotch universities,—mere refuges for the destitute.

This estimation of diplomas, in the present day, evidently depends much more on the degree of education which is required of the candidate previous to the examination, than on the severity of the examination itself. Whatever, indeed, may be the deficiencies of the certificate system, as it is called, the insufficiency of examinations becomes every day more clear. Besides, the class to whom it is said that compulsory education is burdensome, that of the natural geniuses is really too small in number to be legislated for, and when one *rara avis* does occur, he always shows how much better he would have been by a little discipline of education. In short, it is no less desirable than probable, that a proper compulsory education, and suitable compulsory examinations, may *together* be made the means of guarding the public against the perils of medicine.

We have already considered the former; let us proceed to the latter. That the examiners should possess honesty, judgment, and all the other qualifications required of those who are to be judges of questionable matters, needs no argument to prove; and that they should have a knowledge of the subject on which they examine, sufficient to enable them to form an accurate opinion of the degree of acquaintance with it which the candidate possesses, must be equally evident. But there is a question connected with this which has often been discussed by medical politicians, and which Mr. Whewell moots in reference to university examinations: it is, ought the same persons

to teach and examine in the same subject? The practice of our several boards of examiners would appear to answer this in the negative. But there is good reason to doubt whether this system be a wise one. Mr. Whewell justly says, "A man cannot conduct an examination well, unless he be quite master of his subject. If, instead of being an habitual study, in which he is familiar with all that has been done in its various forms, the subject be a portion of literature or science, which he takes up merely as an examiner, his acquaintance with it will probably be meagre, unconnected, and partial." He will not give the student an opportunity of showing the extent of his acquirements; he will not possess the knowledge contained in the most recent authorities, which are just those the student is most likely to have referred to, but will be inclined to question him on those few subjects which, of all he learned, have most faithfully abided by him. M. Bouillaud very candidly asked, when the subject was being discussed not long since in Paris, how he, or any hospital physician of like standing, could be expected to be capable of examining properly in anatomy or chemistry, which, though subjects of study in their pupillage, they had, of course, long since forgotten, while their minds had been engrossed in the objects of their present more immediate pursuits?

Full support to these opinions is furnished by the cases of some of our medical institutions. It is really quite lamentable to hear how easily the better class of students are able to detect the anatomical errors of their examiners at the Apothecaries' Hall; and we feel sure that the reputation of that establishment would be materially increased, if, so long as they think an examination in that subject essential, they would employ some professed anatomist for

the purpose. We mention this deficiency with the less hesitation, because it is really no imputation on the talents of any one to say that he has forgotten his anatomy, after a few years' absence from a personal study of it: it is, indeed, peculiarly characteristic of that science, that it may be easily lost in one half of the time which was necessary to acquire it; and we question whether it be possible for any one who is not continually engaged in examinations, or actual dissections, to retain for many years more than the broad outlines of it. There can be little doubt that it would be nearly the same with the Board at the College of Surgeons, if their practice was not in many parts essentially anatomical, and if many of them had not been in early life teachers of anatomy, so that they learned the principal portion of it so completely, that it forms still some of their most familiar knowledge. They wisely limit themselves to the subjects which they study for their professional practice, and hence their examination presents a remarkable contrast to the other, in the degree of repute in which it is held.

The principal, and indeed the only plausible objection, that we have ever heard made to the appointment of lecturers to be examiners in their own subjects, is, that they would be partial judges, to the advantage of their own, and the injury of others' pupils. A sufficient reason why a teacher should not examine his own pupil is, that the latter would be sure to know and favour the peculiar ideas which the former might entertain, and be almost as sure to choose for the subject of his questions; but we cannot think there is any good reason why teachers should not examine each other's pupils; and while the degree of rivalry which might thus be excited would be itself beneficial, we should not have the folly exhibited of

gentlemen endeavouring to judge of the proficiency of those better acquainted with the subject of examination than themselves.

A chief evil of medical examinations, as at present conducted, is that they fix a standard which all have to attain, and which it affords but little honour to surpass. If it could be that this standard should be such an one that none could pass without its being certain that he was fitted for practice, it would be well, and examinations might then be self-sufficient; but this, we have said, is unattainable. Yet it is to be lamented that, while to many the attainment of the average knowledge is the sole end of study, and while, when attained, there is still an uncertainty whether the candidate be really fit for practice, there should be so little present reward for those who, to make themselves truly competent for practice, exert a most laudable industry. We believe that the standard at present fixed is, as regards quantity, as high as can fairly be expected of the pupils, in the period during which they are expected to study. (We speak here of the College of Surgeons and the Apothecaries' Hall.) But we are sure some improvement might be made by altering the *quality* of the subjects required, by making them more practical.

In the examination at the College of Surgeons, this is, as we have said, a chief characteristic, and as the Board have been lately regularly improving their system at each change, we do not despair of seeing them require a demonstration on the dead subject of some parts of anatomy, and of the more frequent surgical operations. It may be true that they have already a standard which many whom they pass have but ill-attained, but they may rely on it, the desire of obtaining their diploma, whatever be the motive, is too great, in

most students, to let any moderate obstacle prevent them.

The examiners at Bridge-street might take a good place from those at Lincoln's Inn Fields, and seeing the repute the latter are held in, we wonder they are not jealous enough to imitate them.—We would recommend the passage quoted from Mr. Whewell, strongly to them; it points out the propriety of confining their examinations to practical medicine and pharmacy. As the apothecaries of the present day are much more in the habit of writing than of reading prescriptions, it would be well to test how a pupil could do that, by relating a case (a fresh supply being had for each night) and requiring him to prescribe, and even to dispense for it. With properly competent examiners on collateral subjects, and these, and a few other practical tests, we think they might easily put a stop to the practice of *getting up* in a month, a feat not unfrequently performed, by the assistance of very rough grinding, collections of drugs just like that of the examiners, and a view of the plants that are to be used on the particular night.

A word to the Council of the University of London, who evidently find that their situation is growing each day more difficult and responsible. It is so, principally because they were expected to do something new, and they now find few novelties in education are void of danger in experimenting with them. Let them look at the *present* condition, not at the future hypothetical prospects of analogous establishments,—those which have required little or no previous education, *all despised*—those which have required little or nothing else, *neglected*—those which, after a well-judged education, have informed the most practical examinations on practical subjects, *the most esteemed*. And let them read Mr. Whewell's most judicious work—it can be no disgrace to be taught

by such a man, and from every page of it they and all concerned in like pursuits may obtain ideas which no thinking will give them; for his knowledge is eminently practical, and the result of long experience.

SYMPTOMS OF STRANGULATED INTESTINE.

LATE BAYONET WOUND CASE.

To the Editor of the Medical Gazette.

SIR,

As some extraordinary doctrines have been lately enunciated by a well-known journal (I mean the *Lancet*), relative to the symptoms of a strangulated intestine, which, if allowed to pass without examination, may be regarded by some as being actually founded in truth, I would, if the inclosed communication* appears to be deserving of it, request its insertion into the pages of your valuable and extensively circulated periodical.—I remain, sir,

Your constant reader,

THOMAS MORTON.

2, Stanhope-street,
Hampstead Road, Dec. 20, 1837.

Gentlemen,—The object which I have in view, in bringing the subject of this paper before your notice, is to endeavour to show what are the symptoms of a strangulation of the small intestine which can serve as a means of diagnosis between that affection and some forms of peritonitis arising from other causes. I shall also endeavour to ascertain what are the symptoms of a strangulated intestine which may demand the surgical interference of the professional attendant, and which, when present, may leave no room for hesitation, or difference of opinion, as to the proper course that ought to be pursued in the treatment of the case.

I shall also consider it necessary to determine whether, in the case of a fatal termination, there are any morbid appearances on which we can rely *with certainty* as proofs of the existence, during the life of the individual, of strangulation of the intestine, and which, if found to exist, will warrant us in ascribing the death of the patient to the effects of strangulated intestine.

* On the Diagnostic Symptoms of Strangulation of the Small Intestine, and of Peritonitis arising from other causes, &c. Read before the Medical Society of University College, London, Friday, December 15, 1837.

On the other hand, should these morbid appearances be absent, it will be my aim to prove that we are not justified in attributing the death of the individual to strangulation of the intestine and its consequences, but to some other cause; and that he who persists in the expression of an opinion that the death did ensue from strangulation of the intestine, *knowing that these morbid appearances were absent*, lays himself open to the imputation of ignorance, or of being actuated by some improper motive.

Previously, however, to entering upon the consideration of these points, I deem it necessary to make a few observations relative to the meaning which I wish to be attached to certain terms, or expressions, which I shall have occasion to make use of; and by so doing, I trust I shall render myself less liable to be misunderstood.

1st. When I use the word *intestine*, I mean to refer only to some portion of the jejunum, or ileum.

2d. In using the expression *strangulated intestine*, I shall be understood to mean that condition of the bowel which, if *unrelieved*, must necessarily either destroy the patient in whom it occurs, or terminate in the destruction of the vitality of the portion of the bowel which is so constricted: and that where the patient's death shall have been produced by this cause, the portion of intestine which had been the seat of the strangulation shall be found *invariably* to present such remarkable and obvious changes in its appearance and structure, as cannot be overlooked, nor mistaken, in a post-mortem examination that is properly conducted.

3d. By the term *incarcerated intestine*, I would be understood to denote that state of the small intestine, which, when protruded from the cavity of the abdomen, and though firmly embraced by the borders of the opening in the tissues through which it escaped, shall not present any of those alterations of its appearance and structure, which have been already stated as *invariably* co-existent with, and demonstrative of, strangulation of the intestine.

I now proceed to determine what are the diagnostic symptoms, as occurring during life, which may serve to distinguish strangulation of the intestine from peritonitis arising from other causes; and to ascertain what are the circumstances, if any, which demand the interference of the surgeon for their relief.

It is almost superfluous for me to enumerate, in this place, the symptoms of strangulated intestine, for they are well known to all; yet, as I shall be obliged to establish a comparison between the symptoms of strangulated intestine and of peri-

tonitis induced by other causes, I feel myself obliged to mention them, in order that I may support the conclusions which I shall draw from such a comparison.

Thus, then, there is pain in the belly, with tenderness under pressure; desire, with inability, to evacuate the bowels; vomiting, first of the contents of the stomach, and then of the intestinal canal above the seat of the stricture. Generally, the matters vomited assume a bilious character as the case proceeds, and not unfrequently even a stercoraceous odour and appearance. In a later stage, the vomiting becomes more urgent and distressing. The constipation is complete; the pulse begins to fail, becoming feeble, irregular, and intermittent. The countenance is anxious, and haggard in its expression: cold and clammy perspirations ensue, and soon the scene is closed by the death of the wretched sufferer. Now there are two forms of strangulated intestine, and in both the symptoms and pathological conditions are the same; with one exception, however.

In one of these forms there is a circumstance present which is absent in the other, and it is to this circumstance that I request you will give your particular attention. The circumstance to which I allude is, the presence of a tumor externally, and which is connected with some portion of the abdomen. With the appearance of this tumor the symptoms of strangulation commenced, and it is upon the constriction of its contents that they depend.

This tumor is tense, firm, tender when compressed, and resists all attempts which may be made to reduce it by the taxis. There are changes which occur in the appearances of this tumor that are indicative of the condition of the parts that are contained within, for at first the tenderness is only slight, but as the strangulation of the intestine continues the tenderness becomes extreme. In the last stage, however, the tension and pain occasionally disappear.

The earlier of these symptoms are caused by the engorgement and inflammation of the strangulated bowel; the latter by the termination of the inflammation in the death, or gangrene, of the portion of bowel included within the constriction.

The time which is requisite for the development and succession of these symptoms is subject to considerable variation, but in the majority of cases it exceeds 48 hours, and is often prolonged to 4, 8, and even 10 days. In those cases that terminate before the lapse of 48 hours, the individuals have been seized, while in the enjoyment of full and vigorous health, no other circumstance concurring to diminish the intensity of the inflammation, or slacken the rapidity with which it

hurries through the several stages of its progress.

In the second form, where there is no external swelling, such as has been described to mark the first, it will be freely granted, I think, by all, that no operation is demanded on the part of the surgeon: therefore I am prepared to contend that unless the symptoms which exist, and which are referred to strangulation of the intestine, be not accompanied with an external tumor, originating from the abdomen, and which tumor can be shown by reference to the history of the case to be connected with the appearance of the symptoms, and also unless this tumor is firm, elastic, tender under pressure, and incapable of being reduced by the taxis, no operative proceeding ought to be recommended, or had recourse to, with the view of removing the supposed cause of the symptoms. And that although the rational symptoms observed are those which are usually caused by strangulation of the intestine, yet from the absence of this most essential diagnostic circumstance (the external swelling, firm, tender, and painful, and irreducible by the taxis), the surgeon is not called upon to operate; and so far is he from being liable to the charge of culpable neglect for not operating, that he deserves, and will obtain, the commendation of all competent judges, for the accuracy of his diagnosis, and his correct appreciation of the perfect inapplicability of the powers of his art. Let us now examine what are the morbid conditions of the intestine which are invariably found to be present where the strangulation of intestine has been the cause of death.

These pathological conditions are so remarkable in their appearance, and so universally constant in their presence, when strangulation has been the cause of death, that when *they* are absent, we are warranted in denying the truth of the assertion that strangulation was the cause of death.

On opening the abdomen, after death from this cause, there are usually all the evidences of extensive peritoneal inflammation, as evinced by the increased vascularity of the peritoneum covering both the intestines and the abdominal parietes. The extent of this must, no doubt, vary in different cases. The folds of the intestine are adherent to one another by recently effused coagulable lymph. Frequently, also, there is a copious secretion of serum, which may be clear and straw-coloured, or dark-coloured, from the presence of the colouring matter of the blood. It may be turbid, with flakes of lymph; it may partake more of the nature of pus than of serum.

But, gentlemen, these are, comparatively speaking, unimportant changes, and it is to the appearances which I am now to describe that I again request your attention.

It is the alteration which has been produced in the appearance and structure of the portion of intestine which has been strangulated, that you are to bear in mind. The colour of this part of the intestine is changed from its natural light grey tint to a dark red, or mulberry hue. The vessels are engorged with blood. Blood is extravasated into the tissues of the gut. The surface of the bowel is frequently dull from the presence of a layer of adhesive matter, by which it is glued to the adjacent surfaces. The folds of the strangulated portion are thus frequently adherent to one another, though not very firmly.

When gangrene has commenced, the colour is of a deeper cast, usually compared to a chocolate brown or port wine tint. In cases that are still farther advanced, there is a dirty grey and greenish appearance; and the coats of the bowel, which before were only thickened and but little softened, are now no longer able to resist the gentlest impression of the finger, for they give way as easily as paper that has been moistened in water.

Now no one will assert that these appearances are not sufficiently striking to be obvious to the most careless and unwilling observer; and I can venture to say, that no case has yet been known where strangulation of the intestine had produced death, and that these appearances were not found in the post-mortem examination. So invariably constant is their occurrence in such cases, that of themselves they are a sufficient and clear proof that the cause of death was the strangulation of the intestine, or at least had an important influence in the production of the fatal result. On the other hand, it must be observed, that when these appearances cannot be shown to exist, though even looked for more anxiously than usual, that it must be to some other cause that we ought to attribute the production of the symptoms and death of the patient. Indeed, were any one, *under such circumstances*, to assert that strangulation of the intestine had been the cause of the symptoms, and death, it would prove him to be equally regardless of truth, as destitute of character.

We are next to determine, whether a diagnosis can be established from a consideration of the symptoms, between strangulation of the intestine and peritonitis arising from other causes. This will be soon decided—for unless there is present an external tumor of the character previously described, the symptoms are frequently so exactly similar, that any attempt to establish a certain diagnosis must end in a failure, or succeed by chance. Thus the pain and tenderness of the belly, the vomiting, and all the other symptoms of strangulated intestine, are

very commonly observed in simple peritonitis, and many other affections. It must be, then, from a consideration of the history of the case, as well as of the symptoms, that the diagnosis, during life, ought to be founded.

One self-constituted authority has publicly declared *vomiting of bilious matters is to be held henceforth as sufficient proof of strangulated intestine*. But I need not surely attempt to refute a doctrine so absurd and utterly devoid of support. Suffice it to say, that I witnessed a case in the College Hospital of a strangulated hernia, which had existed for 23 hours, and in which the operation was obliged to be performed. The man was temporarily relieved, but sunk from peritonitis 41 hours after the performance of the operation. In the post-mortem examination of that case, the characteristic morbid changes in the intestine that had been strangulated were present to an unusual degree. At the time of the operation the bowel was extremely dark coloured, and the muscular and mucous coats were considered by Mr. Liston, who was present at the examination of the body, to have been divided by the tightness of the stricture in which it had been embraced. *And yet, gentlemen, that man did not vomit until after the operation had been performed*. In peritonitis arising from other causes, such as laceration of the bowels, wounds of the peritoneum, effusions of extraneous matters into the abdomen, &c., there are no special or particular symptoms which will serve as the foundation of a decided diagnosis. In such cases the surgeon must be guided, when delivering his opinion as to the cause of the symptoms, by the history of the case, particularly concerning the mode of its commencement and origin, and also, in no small degree, by his own experience, as afforded by previous cases which shall have occurred to him.

It is obvious that in such cases the surgeon has very little to offer in the way of operative proceeding; but that he must content himself with enjoining perfect rest, avoiding medicine, and regulating carefully the diet, making use of such other antiphlogistic measures as the symptoms may appear to him to demand. In such cases as these the patient almost always, if not invariably, dies from the peritonitis induced by the injuries he has sustained. He seldom lives more than 24 hours; frequently not twelve.

It will be remarked, that in these cases, when they are first seen by the surgeon, the patients are generally found in a state of extreme collapse and depression; but that if they survive a few hours, a transient reaction occurs, and which, I think, is with justice attributed to the commence-

ment of that peritoneal inflammation which will go on increasing until it produces the death of the sufferer.

After death, the real source of the symptoms will be readily ascertained; there is the increased vascular condition of the peritoneum, and which is accompanied by the same morbid changes as in simple peritonitis, but probably to a much greater extent and degree; the wound of the bowel, of the peritoneum, the presence of the extravasated matters, with their appropriate qualities, are now ascertained, for the first time, with certainty.

But there are none of these remarkable circumstances appearances that distinguish death caused by strangulation of the intestine.

Such, gentlemen, are the remarks which I have to offer to your notice upon the subject of the diagnosis between the symptoms of strangulated intestine, and of peritonitis arising from other causes; and I think you will consider me justified in deducing the following conclusions:—

1. That there is no difference in the rational symptoms of peritonitis, from constitutional and other causes, and of strangulated hernia, from which the diagnosis can be satisfactorily made, unless account be taken of the history of the case, or that there is an external tumor which is connected with the abdominal cavity, and which is firm, painful, and tender to the touch, and which resists the employment of the taxis.

2. That when a portion of intestine has become strangulated, and causes the death of the patient, we can have no difficulty in proving such to have been the case, from the morbid conditions which are invariably found to have been induced in the portion of the intestine that had been strangulated, and which conditions are so characteristic of their cause, as to admit of no doubt of the true nature of the case.

3. That when death has followed symptoms resembling those usually observed in cases of strangulated intestine, and those alterations in the colour and structure of the intestine, which have been described as characteristic of strangulation, are absent, we ought not to hesitate to refer the symptoms and death of the patient to some other cause, the effects of which will probably be sufficiently evident to enable us to ascertain its nature.

4. That an *incarcerated intestine* does not induce the same severity of the symptoms, nor is it accompanied by the same pathological changes, as strangulation of the intestine; and that the practice which ought to be pursued in the latter case is not demanded by the former.

5. That in cases of strangulated intestine, the only symptoms which can decide the surgeon to operate for the removal of the stricture is *the presence of an external*

tumor, originating from the abdomen, and which tumor is firm, tender under pressure, and the contents of which cannot be reduced into the abdomen by the taxis.

6. That if a case occur in which the other symptoms of strangulated intestine exist, yet if there is no external tumor, possessing the characters that have been described, to direct the surgeon where to perform his operation for the removal of the stricture, sufficient reason has been adduced that he is not called upon to interfere with his knife, but, on the contrary, were he to operate, he would expose himself to the just imputations of a culpable rashness and ignorance, or disregard, of the history of his art.

7. That in cases of wounds of the abdomen, accompanied by symptoms of effusion of extraneous matters, and lesions of the important viscera contained therein, where there is no external tumor which shall resist the taxis, the surgeon is warranted in referring the symptoms to such lesions, and to the peritonitis excited thereby; and that his treatment of the case, when guided by these principles, is rational, and consonant with the present state of our knowledge.

Such are the conclusions which I trust I am correct in deducing from the argument used; and I shall make only one practical application of them, and it is this:—

That if a case occur in which the abdomen shall have been wounded by a bayonet or other similar instrument, and that symptoms present themselves which may reasonably be attributed to extravasation into the abdomen of the contents of any of the organs contained within that cavity, and to the injury done to the peritoneum and intestine, and to the peritonitis consequent upon these injuries—if, moreover, there was no tumor apparent externally, which was tender to the touch, firm, and resisted the taxis when examined; and also, that after the death of the individual a post-mortem examination was conducted by competent authorities; and that this examination was both publicly and carefully instituted, and at which a wound of the intestine, copious extravasation of blood, and injury to the peritoneum in three different places, along with undeniable evidence of severe peritoneal inflammation, as evinced by the increased vascularity of the peritoneum, the effusion of coagulable lymph, and the tender cohesion of the folds of the intestines to one another, were found; and, above all, mark you, if a portion of intestine was found incarcerated in the bottom of the wound, but which did not present any of those limited changes of colour and structure which are pathognomonic of strangulated

intestine, then we can have no hesitation in declaring our conviction, that the death of the patient arose, not from strangulation of the intestine so incarcerated, but from the lesions done to the bowel and peritoneum, and to the presence of extravasated blood; and that these circumstances do fully, fairly, and without the possibility of contradiction, prove that the surgeon who treated such a case, without reference to strangulated intestine, to be free from the charges of ignorance and inattention that might be brought against him.

MR. S. COOPER AND MR. WAKLEY.

To the Editor of the Medical Gazette.

SIR,

A CORRESPONDENT of last week's *Lancet*, signing himself H. B., gives an incorrect statement of the proceedings of the meeting of medical students of University College, and would thereby lead his readers to draw an erroneous conclusion, and quite opposed to the real facts of the case, viz., that the students concurred in the justness of the strictures upon Mr. Cooper, whereas quite the contrary is the fact, and is sufficiently evidenced by what happened at and subsequently to that meeting, and which H. B. has taken sufficient care to suppress.

When the *Lancet* was denounced by one gentleman as a vile publication, doubtless referring to the low abuse for which it is pre-eminently distinguished, the concurrence of the students in this announcement was clearly indicated by the applause with which they greeted the speaker. Again, when Mr. Cooper entered his lecture-room subsequent to the meeting, the long-continued and enthusiastic cheers and acclamations of the students shewed plainly their feelings towards him, and contrasted strongly with the cordial and heartfelt manner in which three groans were proposed and given for his opponent.—I am, sir,

Your obedient servant,

A STUDENT OF UNIVERSITY COLLEGE.

Dec. 18, 1837.

THE CHARTER-HOUSE SQUARE
INFIRMARY.

To the Editor of the Medical Gazette.

SIR,

I READ this day, in the *Gazette* of the 8th ultimo, a paragraph, headed "Inde-

cent Mode of Advertising," which I presume would not have been inserted had you been aware that the management of the valuable charity, which you say "a surgeon in the City has contrived to establish," is intrusted to a committee of governors, as respectable and influential, to say the least, as that of any charitable institution in the metropolis. By the direction of this committee, the board in front of the premises, upon which is simply inscribed, "Infirmery for diseases of the Rectum, supported by voluntary contributions," was erected. The assertion, therefore, that "a surgeon in the city is annoying the inhabitants of the district, by refusing to remove the board, and even threatens to insert words which shall make it more offensive," must necessarily be, and in fact is, devoid of truth; the individual alluded to not having the power, even if he had the inclination, to carry any such threat into execution.

You surely, sir, cannot be aware of the custom that prevails in London and every other great city, when you assert that this manner of giving publicity to a charity "is an indecent mode of attracting attention," which you "never before heard of from any one who occupied the place of a regular practitioner"—yet those members of the profession, who gratuitously attend the various charitable institutions, the nature of which is made known "by the exposure of a board in front of the house," might, with equal justice, be accused of indecently advertising themselves. The fact is, the paragraph is altogether founded in error: I have, therefore, sent you these few lines, trusting to your impartiality for their insertion, and assured that you would not, knowingly, injure the character and talents of one of the most honourable and useful of its members.

I remain, sir,

Your obedient servant,

A GOVERNOR.

Dec. 2, 1837.

P. S. I inclose you my card for your private information, and I beg to add that though not practising, I am a licentiate of the Royal College of Surgeons, Ireland.

[Our correspondents object not to the erection of a board in front of the institution, but to the words upon that board, and in this objection we concur.—E. G.]

QUACKS AT TRURO.

To the Editor of the Medical Gazette.

SIR,

I beg leave to inclose, for your perusal, two hand-bills, issued by *Dr. Reynolds Fowler* and *Mr. M. Oliver*, two worthies recently settled in this town, as medical practitioners. These hand-bills have been industriously circulated throughout the town and neighbourhood, and the latter person has visited many patients and sent them medicines. Being desirous of knowing on what pretence these gentry had the impudence to proclaim themselves professors of the healing art, I called on them this morning, in company with another surgeon, when *Dr. Fowler* avowed that he had "no license nor diploma, but that he had been a practitioner since he was seven years of age! That the great body of those who had obtained licenses to practise were as ignorant as pigs, and that he defied either the authorities of the Hall or elsewhere, to prevent him from practising when and where he pleased. That he would hold a public disputation with any of the medical men in Truro on any subject, at three days, three weeks, or three months' notice." I called, also, on *Mr. Oliver*, in company with the same gentleman, and asked by what authority he had commenced practice in the town. He said he had been a practitioner before 1815; then said he gave advice gratuitously, and that he had never visited any patients; but that if persons came to him for advice he had a right to give them advice and medicines. On my intimating that I should inform the authorities at the Hall of his proceedings, he said, also, he did not care for them. Thus does quackery raise its unblushing front in the country; and the great practical question is, what power can be exerted to repress it? I leave this communication in your hands to use as you may see fit; and I shall feel much obliged if you will forward this letter to the proper officer of the Apothecaries' Company, to whom I shall be happy to forward any further details that may be necessary to enable them to deter such unworthy pretenders from deluding the public.—I remain, sir,

Your obedient servant,

S.

Truro, Dec. 12, 1837.

[The writer of the above gives his name. His letter, together with hand-bills alluded to, have been forwarded to the Secretary of the Society of Apothecaries.—*Ed. Gaz.*]

LIFE INSURANCE FEES.

To the Editor of the Medical Gazette.

SIR,

AGREEING most fully with you in the views expressed in the leading article of your journal of 18th instant, I trust you will allow me to suggest a mode by which your readers, who, I take it, constitute all the respectable practitioners of London, of all grades in the profession, may have an opportunity of expressing their determination respecting the point upon which we are at issue with insurance companies.

My proposition is this: let every physician, surgeon, and general practitioner, who is disposed to follow the example of the Leeds practitioners, send a note to the Editor of the MEDICAL GAZETTE, expressing his determination not to give an opinion to an insurance company, unless a fee be sent by the company along with the letter of consultation. In this way you, sir, will be enabled to form a list of those gentlemen who may have professional and public spirit enough to come to such a resolution; and such a list, if published in your pages, will soon find its way into the columns of the newspapers, and will prove to the public and to insurance companies that some union does exist among medical men.

For my own part, I cannot allow myself to doubt that, if you would announce your willingness to assent to such an arrangement, and to afford the necessary facility for it, a considerable number of our most influential men would come forward, and thus probably the question might be settled.—I am, sir,

Your obedient servant,

A PHYSICIAN.

November 25, 1837.

[If a considerable number were to send their names, we should readily publish them; but if otherwise, we should think it unfair towards the parties to do so.—*ED. GAZ.*]

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Dec. 21, 1837.

Joe Poppleton, Almondbury, Yorkshire. — Henry John Watkinson, High Town, near Leeds. — Charles Alexander Holcombe, Cosheston, Pembroke, South Wales. — Robert Cross, Wisbeach, Cambridgeshire. — Frederick William Mackenzie. — Thos. Ashell Henderson. — Jas. Boulton, Ponty Pool. — Wm. Joseph Lunn, Hull, Yorkshire. — W.

Hughes, Cheltenham. — Martin Mauger, Guernsey. — Joseph Warburton, Pateley Bridge. — Alfred Keyser. — Thomas Stringer Hatfull. — Frederick Maxwell Dinwoodie, Appleby, Westmoreland.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE X.

Examination of the Chest through the Vital Properties or Functions of its Organs. — Analysis of the General Symptoms (continued). — Expectoration: Explanation of the Act; Means of promoting it. — The Matter of Expectoration; its Nature and Value as a Sign. — Morbid Kinds: Mucous; Albuminous; Watery; Compound Varieties. — Signs derived from the Form and Weight of Sputa. — Pain: its Nature and Value as a Sign; its Varieties in the Chest, and their Causes. — Modes of testing the Sensibilities of the Chest.

THE expectoration is another symptom of thoracic disease, which must be considered as the result of vital as well as physical properties, and therefore I include it under the head of general diagnosis, although it sometimes approaches in character to a physical sign. Now you know that the word expectoration strictly means the act of expelling any thing from the chest; but by a figure of speech, it is also applied to the matter so expelled. We shall find that both the act and the matter of expectoration may present us signs of the condition of the pectoral organs.

If you consider the structure of the bronchial tree, you may perceive that natural breathing tends to prevent the accumulation of matters in its tubes, in spite of gravitation. The area of the smaller divisions of the bronchi is considerably greater than that of their trunks; and it may be represented as the divided base of a hollow cone or funnel, which is concentrated in the trunks, and lastly in the windpipe. Now the air, in the more sudden act of expiration, passes with greater rapidity and force as it converges into these trunks, and therefore tends to carry through them any superfluous matter that may be present on the bronchial surface. This will explain how the finer bronchial tubes of the most dependent parts of the lung are, in health, kept clear of any accumulation. Possibly the ciliary motions of the mucous membrane may, as MM. Purkinje and Valentini have surmised, tend to the same effect.

But it is the forcible acts of special expectoration, *hawking*, and coughing, that tend most effectually to clear the air-passages; and they do this by both increasing the force and fulness of the expiratory effort, and at the same time contracting the upper tubes and trachea, so that the air acts with greater force on any superfluous matter in them. The repeated closure of the glottis in coughing increases the expulsive effort by letting out the air in successive sudden jerks, which are more forcible than any continued act of expiration would be. We see this exemplified in cases where the operation of bronchotomy has been performed. The patient often cannot expectorate effectually as long as air can pass out from the artificial opening, and he is in danger of suffocation in consequence; but on closing this during the act of coughing, the force of the air can be directed in the natural way against the accumulated matter. By attention to this particular, suffocation

has been averted in more than one instance after this operation. In certain diseased conditions of the larynx, the patient cannot close the glottis; and hence also expectoration may be difficult, and the cough assumes a continuous unguidable character, which we might have added as another variety to those enumerated in the last lecture. This is what M. Trousseau calls a *belching* cough.

There is another element essential to the proper performance of the act of expectoration, the capacity to make such a full inspiration as shall carry the air in beyond the accumulating matter, so that it may on its forcible passage out again carry this matter before it. Hence you see why weakness, which prevents a sufficient inspiratory effort, or obstruction of the terminal and most expansible parts of the air-tubes, which renders this effort ineffectual, may stop the act of expectoration, and by permitting the accumulation of matter in the air-tubes, may speedily conduce to a fatal result. Inability to expectorate is the immediate cause of death in a great many cases of various diseases; in fact, it is a part of the article of death itself; and when you hear the rattle in the throat of the dying, you hear the sign of the accumulating barrier which is shutting out the breath of life. Sometimes, even at this stage, there are sensibilities enough in the system to feel the force of a stimulant which may excite the sinking powers to another struggle; expectoration is once more accomplished, and breath once more renewed; and where there is no irrecoverable alteration of structure, this act of expectoration may in some few instances turn the balance in favour of recovery. I need not tell you, then, how important it is to study the act of expectoration, and to acquaint ourselves with those means that may excite or promote it. I dare say that every one of you has seen an instance in which a patient has been snatched from the jaws of death by the timely administration of a diffusible stimulus, such as a warm aromatic draught, with carbonate of ammonia, together with such a change of posture and other circumstances as might most favour the expulsion of the matter that was suffocating him. A great deal may often be done in less urgent cases by attention to the posture of the patient. In most instances the act of expectoration is easiest in that posture in which the respiration is most free, which is commonly the semi-erect posture, but I have known some patients expectorate more freely when lying on one side; and I remember a phthisical patient who really appeared to be several times saved from suffocation by alternating his posture from lying down to sitting up in a

particular manner, suggested by a knowledge of the condition of the lungs in that case. When this expedient was neglected, the patient was so shaken with frightful fits of fruitless cough, and so oppressed with the accumulating matter, which they could not expel, that speedy suffocation seemed inevitable. In some cases, the act of expectoration may be favoured by another kind of action, in which the expiratory muscles are concerned, that of vomiting; and we shall find hereafter, that some emetics may exert an influence of an important nature on the bronchial tubes, besides this mechanical one.

The *matter of expectoration* frequently furnishes us with very instructive signs. It is the product of diseased action, and in its physical or chemical qualities it may inform us somewhat of the nature of that action, of the condition, and sometimes of the position, of the parts from which it comes. As, however, we have seen that the effort of expectoration is sometimes unsuccessful, so here you will find no matter of expectoration to judge of; and besides this, most children and some adults cannot spit out what they expectorate, but swallow it.

The basis of expectoration generally is the secretion of the mucous membrane of the air-tubes. This is naturally a transparent, colourless, slightly glutinous liquid, like thin mucilage. The chief animal matter which it contains is that called mucus, which seems to be a sort of imperfectly coagulated albumen; and the varieties of sputa presented by disease commonly depend on an unnatural condition or quantity of this animal matter. There is also saline matter, which may vary in quantity, and so may the proportion of water. Unfortunately, we know very little of the chemical differences in the various kinds of sputa; but their physical qualities have been sufficiently studied, to enable us to connect some of them with particular pathological conditions in a way that proves useful in diagnosis and practice.

The difference between mucus and albumen seems to consist in their physical condition, rather than in their chemical constitution. Mucus is a transparent glutinous matter, not coagulable by heat, as liquid albumen is, and not solid and opaque like coagulated albumen; but on ultimate analysis it is not found to differ from this principle. When, therefore, we see expectorated matter opaque and solid, or liquid and coagulable by heat, it loses the only distinguishing characters of mucus and is strictly albuminous*. For this

* Since these lectures were delivered, an excellent account of the chemical characters of different kinds of expectoration was read at the meeting of the British Association at Liverpool

reason, I propose the following general classification of expectorated matter:—

The matter of expectoration may be generally divided into the *mucous*, the *albuminous*, the *watery*, and the *compound* kinds.

1. *Mucous* expectoration is that most like the natural secretion, being transparent, colourless, and more or less viscid. It is the general result of simple acute inflammation of the mucous lining of the air-tubes, in which case it is increased in quantity, and particularly in viscosity; in fact, the glutinous character of the sputa, and the tenacity with which they stick together, and to the containing vessel, or fall out in a ropy mass, was described by Andral, and I think correctly, to be a mark and, in some degree, a measure of acute bronchitis. In the most intense forms of inflammation, and where the disease occupies the finer tubes, to the glutinous character of the mucus is added a frothiness, arising from the mixture of those air-bubbles in the tubes, which in their breaking cause the mucous and sub-mucous rhonchi. But the most intense bronchitis is that accompanying inflammation of the parenchyma; here you have the most viscid form of sputum, through which air driven produces the crepitant rhonchus; and the blood in the distended vessels of the engorged parenchyma communicating a little colouring matter to it, gives it that reddish or rusty tinge which is so characteristic of the sputa of peripneumony. The transparent or semi-transparent condition of these viscid sputa distinguishes them from the albuminous kind, into which, however, they pass in the advanced stages of all the more inflammatory affections of the bronchial membrane. The mucous expectoration has commonly a saltish taste, and with its saline matter is probably connected its irritating quality, so marked in the early stage of bronchitis.

2. The varieties of *albuminous* expectoration are pretty numerous, for I comprehend under this head the opaque kinds of sputa which have no remarkable viscosity, such as the purulent expectoration of chronic bronchitis, the fibrinous or polypous sputa of plastic bronchitis, and the more compound combinations of these with caseous and other matters, which are voided in the advanced stages of pulmonary phthisis. This class of sputa denotes an error of secretion, further than the mucous from the natural standard; but their production generally announces a decline

of inflammation from its most acute form. Probably, the very throwing off of so considerable a mass of animal matter is the means of relieving to a certain extent the inflamed vessels; for we frequently find the purulent or polypous expectoration in intense bronchitis attended by a remarkable diminution in the signs of local and general excitement*. But such an expectoration ceases to be a favourable sign when it *continues*, either with undiminished irritation, or with proofs of general weakness; for then a change is implied, either in the structure, or in the habitual action of the membrane, which, secreting pus instead of mucus, goes beyond the mere removal of a temporary congestion, and proves of itself a cause of irritation and exhaustion. I am not sure that I make myself intelligible, but as we shall revert to this subject in connexion with the pathology of bronchitis, I must dismiss it at present. I dare say you have heard much about the modes of distinguishing pus from mucus in the expectoration. On these formerly the diagnosis of pulmonary phthisis was supposed to depend. We now hold all these tests very cheap, not only because it is well known that pus may be produced without any ulceration or consumption of the lung, but also because these distinctions cannot be complete between matters that pass by insensible gradations into each other.

3. *Watery* expectoration is that kind in which a liquid of only slightly glutinous quality is coughed up in greater or less abundance. This appears to contain very little animal matter, and to be rather a diluted mucus than to have in it any thing peculiar. It is often covered with a froth, particularly when it is coughed up with much effort. This secretion I regard as the result of irritation, with a relaxed state of the vessels, rather than of inflammation; but it may occur as a consequence of this lesion, as well as of congestion or obstruction to the circulation of the blood in the lungs. It is the expectoration of what is called humid asthma and pituitous catarrh. Some persons of a relaxed habit have it during a common cold, or any form of bronchial inflammation. It sometimes tastes more salt than usual, and in this case it commonly causes a more incessant teasing cough.

4. Under the head *compound* expectoration, I class various combinations of the preceding kinds, which we meet with in almost every form of pectoral disease. They are either products of different parts, in distinct pathological conditions, al-

by Mr. Brett. He has found that the chief character of the sputa of bronchitis, pneumonia, and phthisis, lies in the presence of a variable quantity of albuminous matter, liquid or solid, which does not exist in natural bronchial mucus.

* A high authority on thoracic pathology, Dr. Stokes, in his late excellent work, takes a similar view of this subject.

though coughed up at the same time; or they may in some cases proceed from the same part in an intermediate pathological state, and capable of secreting different kinds of matter. An example of the latter is the opaque or muco-purulent expectoration of the latter stages of bronchitis, in which the opacity and colour of albuminous matter is apparent, whilst it is held together by a mucus of some tenacity. In the *concocted* sputa of declining acute bronchitis, the mucus predominates; whilst the loose albuminous matter is more abundant where the inflammation tends to pass into a chronic state. The sputa of chronic bronchitis, and in fact of most chronic diseases of the lungs and air-tubes, are almost always more or less mixed; for it generally happens that the different parts of the membranes and tissues are variously affected; and when, as in the advancing stages of phthisis, there is structural lesion or destruction of parts, there is the greater reason for a more heterogeneous kind of expectoration. In these cases, however, the albuminous kinds mostly predominate, in the form of muco-purulent, purulent, caseous, or tuberculous matter, and coagulable or fibrinous lymph, occasionally tinged or mixed with the colouring matter of the blood; these constitute the bulk of the expectoration of the consumptive. In catarrhal diseases of a chronic kind, we very commonly see very opposite forms of sputa expectorated together. Thus in a spitting-dish full of thin frothy watery expectoration, you will often find portions of tough and almost solid semi-transparent mucus, as if some parts of the tubes were throwing off the water, and others the animal matter, in a separate form. When we come to the subject of catarrh, we shall find that these opposite products do not imply an equally opposite pathological condition. After hæmoptysis, it is very common to see fibrinous concretions, together with purulent and mucous matter, all more or less tinged with blood. In other affections, it is not uncommon to see the sputa streaked with blood; and this sign is of less importance when the cough is violent, because it may then merely proceed from a slight abrasion caused by the force of this mechanical action. When, however, there is often blood present, without much force of cough, and especially if there be pus with it, we may suspect the presence of ulceration in some part of the air passages. The colouring matter of the blood, in an altered state, may also be combined with other forms of sputa. Thus, in scorbutic persons affected with humid catarrh, or bronchitis, the expectoration is a thin reddish-brown

liquid, like prune juice, or diluted treacle; and in the last stages of pulmonary disease, the colouring matter, from the final pulmonary congestion which precedes death, is seen in the dirty reddish-brown or greenish tinge of the purilagenous sputa.

You see, then, that the matter of expectoration will often inform us of the pathological condition of the lungs and their tubes; and its quantity or quality may sometimes suggest proper remedies. In some cases you may learn other things from it. Thus, when in consumption, tubercular matter, with portions of pulmonary tissue, are expectorated, the conclusion is obvious. You will also sometimes see the expectoration present physical signs of the state of the interior by its containing albuminous or compound matter, moulded into the shape of the tubes or cavities from which it comes. The large rounded flocculent muco-purulent sputa of advanced phthisis, are often such as could only accumulate in a cavity; and the tubular or vermicular albuminous matter which is coughed up in the plastic kind of bronchitis, sufficiently explains whence it comes, by its being an exact mould or cast of the bronchial tubes, sometimes in an arborescent form, from several of their divisions.

I must not omit to notice a test, which is erroneously used to determine the nature and source of sputa, whether they float or sink in water. Now the floating of a sputum merely depends on the number of air-bubbles retained in it, and although pus alone, or tuberculous matter alone, will not retain these bubbles, yet a small addition of tenacious mucus will enable them to do so. Again, although the sputa formed in ulcerous cavities are less likely to contain air and to float than those formed in the tubes, yet we not unfrequently find the concocted expectoration of acute bronchitis, which is formed exclusively in the large tubes, sink in water; whilst the mixed product of a vomica and the adjoining tubes, which has been churned together with air, floats. This *hydrostatic* test of expectoration is then a very inconclusive one; but it may be useful in sometimes causing a rough separation of the albuminous matters from those of a more viscid mucous kind.

I might occupy you with other details regarding the matter of expectoration; but I have said enough to illustrate how it may prove useful in diagnosis and practice. You will now, I think, perceive how much more valuable its indications may become when conjoined with the physical signs, by which you may often

detect the position, and measure the amount of the local disease, of which the matter expectorated is the product. We shall find many exemplifications of this position hereafter.

The only other morbid phenomenon connected specially with the modified vital properties of the organs of respiration is *pain*. Now you know that pain may arise either from an excessive impression on the nerves of sensation, or from an excessive sensibility of these nerves, to which common circumstances of position, motion, &c. then become painful. The latter is the more common cause of pain in internal diseases, but it is not unusual to find them combined, as when a tumor, or effused matter, presses on or stretches parts morbidly sensible. The most common causes of pain are inflammation, and those kinds of vascular excitement that are allied to it; this vascular excitement is generally attended, in the first instance at least, with an exaltation of the nervous function. But the nervous function may be *primarily* excited; and although the increased sensibility thus produced seldom lasts long without more or less stirring up the function of the vessels also, yet we may for a time have pains purely nervous, such as pleurodyne and pectoral neuralgia. Further, as inflammation is not the only cause of pain, so the pain present in inflammation is by no means an index of the extent of the inflammation, nor even of its situation. Most extensive inflammations have been known to occur, not only in the parenchyma of the lungs, but in the bronchial membrane and pleura also, without producing any pain; and it frequently happens in phthisis, that the pains chiefly complained of are low down in the sides, when the disease is almost entirely in the upper lobes of the lungs. So likewise in bronchitis and pneumonia, the pain is often confined to the sternal, lateral, or scapular regions, whilst the disease occupies other parts.

There are, nevertheless, some general characters with regard to pain, which may render it useful as a symptom of disease of the chest. It is commonly remarked, that the pain of parenchymatous and bronchial inflammations is dull and diffused, whilst that of inflammation involving the serous and fibrous membranes of the pleura and pericardium is of a sharp lancinating character. This is generally but not constantly true; and we may find it explained by the circumstance that the par vagum, which supplies the bronchi and lungs, is by no means so sensitive a nerve as the spinal intercostals, which are distributed on the pleura and pericardium.

For this reason, too, there is more apt to be acute pain when the costal pleura, or the coverings of the great vessels, are inflamed, than when the pulmonary pleura is the chief seat of disease. Observe a further distinction in the variations of these various kinds of pain, and you will be confirmed in the opinion that they belong to different orders of sensibility. The dull, heavy, or aching pain of bronchitis, or pneumonia, is generally pretty constant, although it is increased by full inspiration, exertion, or the breathing of cold air; yet even then it gives the feeling of soreness under the sternum, rather than of severe pain. It often resembles the pain of dyspepsia, which is probably seated in a branch of the same nerve, and is also usually referred to the sternum. The degrees of pleuritic pain, on the other hand, are sudden, extreme, and intolerable. If it be not felt in ordinary breathing, a long breath, or a cough, just sufficient to bring the membranes to a requisite degree of tension, causes that sharp stitch of the side—that sudden catch of the breath, that has been considered so characteristic of pleurisy. When it is constant, the patient is obliged to hold his side to diminish its severity, by restraining the motions; and thus placed in opposition to the sensation which prompts the act of respiration, this sharp pain may cause such a voluntary restraint of these acts as to bring the patient to the verge of asphyxia. It is under these circumstances that the breathing becomes partial, as I formerly described to you; and patients whom pain constrains to breathe only with the diaphragm, or with one side, will perform this supplementary respiration so well, that they are completely free from pain, although the inflammation is as acute and the membranes as tender as ever. Sometimes you may detect the latent tenderness by pressing between the ribs of the affected side; but you will be more likely to succeed if you restrain the supplementary respiration by pressing on the abdomen, or on the healthy side, and then desire the patient to cough, or to take a sudden long breath. If there be any exalted sensibility, or tenderness, it is pretty sure to be discovered by this means; and I have several times met with patients who denied having any uneasiness, or tenderness, yet they winced at the pain developed in this way.

As a general rule (not, however, without some exceptions), we may consider a fixed permanent pain, or a permanent tenderness, which you see depends on the same pathological cause, an indication of inflammation, or congestion, or some analogous condition of the vessels; and when present it deserves attention, not only as an object of treatment on its own

account, but also as an index, which, together with the pulse, cough, fever, and other general symptoms, shows the increase and diminution of the complaint, and the effects of remedies, even before these become manifest from the physical signs. Still, if we trust to it alone, it will negatively deceive us in those numerous cases of extensive disease in which it is absent, or scarcely complained of; and it will positively deceive us in those cases in which modified nervous sensibility, a mere neurosis, is the only or the chief disorder.

LECTURES

ON THE

ENTOZOA,

OR

INTERNAL PARASITES OF THE HUMAN BODY,

Being Part of a Course on Morbid Anatomy, delivered at the London Hospital,

By T. B. CURLING, Esq.

THE researches of naturalists have shewn that most species of animals are infested with various beings endowed with distinct vital properties or organizations—creatures that live and propagate their kind at the expense, and in the interior of other animals, which afford them a habitation, nutriment, and heat. And certainly, amongst the numerous accidental formations developed in the human body, there are none which merit more the attention of the physician and of the physiologist, than these organized but independent productions. They have been called, from the situation in which they are found, *Entozoa* (from *entos* within, and *ζῶον* animal), a name given to them by Rudolphi of Berlin, who has particularly investigated their organization. These animals, which have attracted but little attention in this country, are developed in various situations of the body, both in parts having communication with the external surface, as the alimentary canal, and in the interior of the best protected organs, as in the substance of the brain, liver, and muscle. It is necessary that the *Entozoa* should be distinguished from the *sporicius worms*; that is to say, from those living beings that are also found in the interior of animals, but which have evidently been introduced there from without. Thus, insects or other animals sometimes work their way into the skin, or become lodged in the nasal sinuses, and in the stomach or intestinal canal. At certain periods of

the year, the internal surface of the splenic portion of the stomach of the horse is often found covered with a number of small worms, commonly called *botts*, which adhere very closely to the mucous membrane, and cannot be detached without violence. Now these animals do not originate in the stomach, but the eggs from which they are produced being deposited about the shoulders and knees of the horse, come within reach of the tongue, and by this means are introduced into the body, where, after undergoing their first transformation, and becoming changed into larva, they leave the stomach, pass into the intestines, and quitting the body along with the fæces, undergo a further change in the open air from the form of a worm to that of the fly known to naturalists by the name of *æstrus communis*.

Entozoa have been found in nearly all classes of animals. Thus they have been discovered in birds, reptiles, and fishes, as well as in the mammalia. The invertebrata have likewise their entozoa, for it has been ascertained that they exist in the various species of insects. But what is still more wonderful, an immense concourse of minute parasites have been found infesting a small entozoon, the abode of which is the aqueous humour of the eye! In these lectures, however, I shall treat only of those entozoa which are found in the human body, and as many of them will no doubt come under your notice in practice, it is desirable that you should be able both to recognise them, and to treat the disorders to which they give rise.

The entozoa are found either upon free surface, in natural cavities, or in the parenchyma or substance of organs. The different species have their own peculiar localities. Thus some, as the *Ascaris lumbricoides* and the *Tænia*, are never found in any other situation but the alimentary canal, whereas the *Strongylus gigas* resides in the urinary passages. So likewise, the *Trichina spiralis* is only met with between the muscular fibres, and the *Filaria* in the cellular tissue. Their organization is also very variable. There are some Entozoa that consist of nothing else but a parenchymatous mass without any appearance of organs, whose rude and imperfect organization only entitles them to be placed in the lowest rank in the scale of animated beings; whilst we find others, complicated in structure, possessing an evident muscular system, a complete alimentary canal and well-developed organs of generation, with distinct sexes, rudiments of a circulation, and even a nervous system.

The Entozoa have been classed by naturalists according either to their habitation, their form, or their structure. Rudolphi's classification, which is perhaps

the best known and the most esteemed, is founded principally upon their organization. It is, however, objectionable in several particulars, and requires modification in the present more advanced state of zoological science. I shall follow, therefore, a more comprehensive arrangement, which has recently been proposed by Mr. Owen, the accomplished Professor of the College of Surgeons, who, in addition to many highly valuable contributions to the science of comparative anatomy, has done more than any other anatomist in this country to ex-

tend our knowledge of the interesting class of animals now under consideration; and I may refer those who desire a fuller account of their organization than the limits of these lectures admit of, to his able article on the Entozoa, contained in the Cyclopædia of Anatomy and Physiology, to which I must acknowledge myself indebted for many of the particulars that I shall bring before you.

Mr. Owen classes the internal parasites of the human body according to their organization, as follows:—

ENTOZOA HOMINIS.

1. PSYCHODIARIA, from <i>ψυχη</i> , life, and <i>ειδος</i> , like.	1. Acephalocystis endogena, found in.....	Brain. Liver. Heart. Spleen. Kidneys, &c. &c.
	2. Echinococcus.....	Brain. Liver. Spleen. Omentum.
2. PROTELMINTHA, or early form of the Entozoa, from <i>πρωτος</i> , first, and <i>ελμινς</i> , worm.	3. Cercaria seminis	Male semen.
	4. Trichina spiralis	Voluntary muscles.
3. STERELMINTHA, or solid worms, from <i>στερεος</i> , <i>solid</i> , and <i>ελμινς</i> , <i>worm</i> .	5. Cysticercus cellulosæ	Muscle. Brain. Eye.
	6. Tænia solium, or common tape-worm	Small intestines.
	7. Bothriocephalus latus	Small intestines.
	8. Polystoma pinguecola	Adipose tumor connected with the ovary.
	9. Distoma hepaticum, or liver flake	Gall bladder and biliary ducts.
4. CÆLELMINTHA, or hollow worms, from <i>κοιλος</i> , hol- low, and <i>ελμινς</i> , <i>worm</i> .	10. Filaria medinensis, dracun- culus, or guinea-worm	Subcutaneous cellular tissue.
	11. Filaria oculi	The liquor Morgagni of the eye.
	12. Filaria bronchialis.....	Bronchial tubes.
	13. Tricocephalus dispar.....	Large intestines.
	14. Spiroptera hominis	Urinary bladder.
	15. Strongylus gigas	Kidney.
	16. Ascaris lumbricoides	Small intestines.
	17. Ascaris vermicularis, or common thread-worm	Rectum.

Were I to include the numerous Entozoa infesting the animal kingdom, this list might be greatly extended. The various species of internal parasitic animals is, indeed, very considerable, and their study constitutes an important branch of zoology.

I shall not occupy your time by pointing out particularly in what respects this classification differs from the arrangements of

Rudolphi and Cuvier. It is sufficient to remark, that Rudolphi distinguishes them after their external form, whereas Cuvier has classified them after their structure, into the *hollow worms* and *parenchymatous worms*. Linnæus divided the Entozoa according to their seat, into those developed in the cavities communicating with the external air, the *intestinal worms*, and into those developed in the interstitial struc-

ture of organs, the visceral worms,—an arrangement preferred by Cruveilhier on account of its practical nature, though less scientific than the preceding.

You will perceive that I have enumerated seventeen distinct species, many of which, it will be shewn, differ widely from each other in structure and organization. In fact, these animals are not grouped under one head in consequence of any common, exclusive, or distinguishing characters, but are associated together chiefly on account of the nature of their local habitation—the interior of other animals. Many are so common, that perhaps there is scarcely an individual present who has not met with them; some are less frequent, and are indigenous in particular districts or countries; whilst others are so rare, that they have only been detected once.

1. *Acephalocysts*,

(from *ακεφαλή*, without a head, and *κύστις*, a bladder), sometimes called *dead hydatids*. These consist of isolated albuminous cysts, of a spherical form, found in various situations of the body, floating free and independent in a fluid contained in another cyst, connected with the organ or part in which they are developed. Their structure is exceedingly simple, consisting merely of a thin delicate membranous cyst, filled with a transparent colourless serum. The membrane varies in thickness, is smooth externally, whilst its internal surface is generally studded with minute white bodies, which give it a granular character. It is of the consistence of half boiled white of egg, of a semi-transparent pearly appearance, and tears readily and equally in every direction. In the larger specimens the albuminous membrane can be separated into two or more layers. Mr. Owen states that the phenomenon of endosmose is readily seen on placing the recent acephalocyst in a coloured liquid, little streams of which are gradually transmitted, and mingle with the fluid of the parasite. The fluid contained in these hydatids is remarkable on account of its perfect transparency and limpid nature. It consists almost entirely of water, with a very minute quantity of albumen, and does not coagulate on the application of heat or by the action of alcohol. I have observed that when the secretion around the acephalocyst is discoloured, turbid, or purulent, the fluid within still preserves its limpid character. As the acephalocysts present no appearance of organization, are impassive under the action of different kinds of stimuli, and manifest no contractile power, except such as evidently results from elas-

ticity, as, in short, they neither feel nor move, it is a question with naturalists whether they are entitled to be ranked even in the lowest class of organized beings. Rudolphi and Cuvier have indeed rejected them from the class of Entozoa. Laennec, who has given an excellent account of the acephalocysts, founded his opinion of their animal nature chiefly on the mode in which he observed their reproduction to take place. Thus, a number of small bodies of a grey or white colour, more or less regularly rounded, are developed between the laminae of the cyst, and subsequently being detached from the internal surface, enlarge and become separate hydatids. These vesicles formed in the parietes of the cyst may be observed of various sizes before they are cast off from the parent animal, being sometimes so minute as only to be perceived by means of the microscope, at other times exceeding a line in diameter. It often happens that a large acephalocyst includes several smaller ones, one within the other, all similar in structure. We may even find four or five thus included, like one box contained in another. It was owing to this arrangement that Hunter called them *pill-box hydatids*. It is explained from the circumstance of the germ or minute acephalocyst being detached from the internal surface of the cyst where they increase, and in the same manner propagate their kind, so that the successive generations produce the appearance which I have described. In the acephalocysts found in the ox and other ruminant animals, the vesicle is detached from the external surface of the parent, whence the two species have been distinguished; that of the human subject by the term *Acephalocystis endogena*, and the other by the term *A. exogena*. As, then, the acephalocyst

Acephalocystis endogena.

possesses the property of reproducing its species, and furthermore, grows by intrinsic power of imbibition, we must, with Mr. Owen, consider it, though at the bottom of the scale of organization, "still not the less as an independent organized species, sharing its place of development

and sphere of existence in common with the rest of the entozoa."

Cruveilhier, who has written an elaborate article on *Acephalocysts*, in the "Dictionnaire de Médecine et de Chirurgie Pratiques," distinguishes them, independently of their situation and connexion, into the solitary (*acephalocystis eivenita vel sterilis*) and multiple (*acephalocystis socialis vel prolifera*;) a distinction of some practical importance. The first kind is the most frequent in animals. It is rarely developed singly, several being generally produced in the same organ or in different parts of the body. The multiple, on the other hand, which occurs most commonly in man, rarely co-exists in several organs, or in several parts of the same organ.

Acephalocysts, unless loose in a serous cavity, are always inclosed in an adventitious cyst, which separates them from the surrounding parts. The outer surface of this containing cyst is adherent; the internal or free surface is generally rough and irregular, and is sometimes lined by a semi-transparent albuminous membrane. When there are several separate parasites within, the cyst contains a serous fluid; but when the *acephalocyst* is solitary, it often fills the cyst, lining, as it were, its internal surface, but always remaining distinct and unattached. These adventitious cysts are composed of the condensed cellular tissue of the organs in which they are found, and they must be viewed as belonging rather to the part in which the *acephalocysts* sojourn, than to the animals themselves, for they are the result of the irritation excited by the presence of the *hydatids*, and in this respect closely resemble the formation of gall-nuts. These cysts are liable to undergo changes analogous to those experienced by serous cysts in general. They may be thickened and fibrous, and rendered even cartilaginous or bony. I have seen them putting on exactly the appearance of the interior of a large aneurismal sac. They are liable, too, to become inflamed, when, instead of a serous fluid, they may contain pus, which sometimes so acts upon the *acephalocysts* as to destroy or rupture them, leaving only some scattered fragments floating in the turbid secretion. Andral states, that he once found the *débris* of membranes of *acephalocysts* floating thus in the midst of a vast abscess in the neighbourhood of the kidney.

Acephalocysts are developed in the liver more frequently than in any other organ. They have been found, however, in the brain, heart, lungs, mamma, spleen, kidneys, ovaries, lachrymal gland, thyroid gland, tonsils, between muscles, and in the interior of bones; in fact, in almost every organ and part of the body, except the

intestinal canal. As they increase in size, they occasion a corresponding atrophy of the surrounding parts. The most dense and unyielding structures are unable to resist their progress. Thus there is a case on record, in which they had produced a hole through the body of the scapula. They sometimes work their way to the surface of the skin, or reach some mucous surface, whence they are discharged. There are cases known in which they have been formed in the liver, and subsequently expectorated from the lungs. Authors have related cases where individuals have, at various times, coughed up many hundreds of them; and we have a preparation in the museum, taken from a woman, who, for some time before death, gave exit to *hydatids* produced in the liver, both at a wound on the right side of the abdomen and by expectoration from the lungs. They have been known, when originating in the kidneys, to be voided in fragments with the urine; and in other instances they have been ejected from the stomach, or have passed by stool. A less fortunate result has been the sudden rupture of the cyst, either spontaneously or by violence, and the escape of the *hydatids* into a large serous cavity, where they have produced active inflammatory action, terminating in death. The ancients were aware of this, and held the opinion that the rupture of *hydatids* was the sole cause of dropsy; a view which it is somewhat surprising to find received the sanction of so accurate an observer as Morgagni.

Although *acephalocysts* have a tendency gradually to increase, the tumor which they occasion sometimes disappears without any opening being afforded for their escape. This would appear to be owing to the destruction of the animal. Dr. Bright has shown that the offspring of the parent *hydatid* are often so numerous, and increase so rapidly, that they not only press upon and destroy each other, but sometimes rupture the parent cyst. The *acephalocyst* may also be ruptured accidentally, or it may be destroyed by inflammation and suppuration of the containing cyst. It is probable, too, that in the liver they are occasionally destroyed by the access of bile, notwithstanding that they are inclosed in a cyst. When this takes place, the membranous substance curls itself up, shrinks, and is contracted into a small compass. The fluid is gradually removed by absorption, and the containing cyst, by degrees, closes upon its contents. I have in several instances found in the liver, the *débris* of what must, at some former period, have been *hydatids* of considerable size. They consisted of a small cyst, of the consistence of leather, and rough internally, containing a membrane closely

packed in numerous folds, mixed up with albuminous and friable matter, deeply tinged with bile. On carefully unravelling the membrane, it was found to be the remains of one or more large hydatids. In other instances, doubtless of longer duration, the mass has presented a cretaceous and more consistent character.

It is scarcely necessary to allude here to the singular opinion maintained by Dr. Baron, of Gloucester, that tubercles are essentially hydatids. The theory of this distinguished physician, which was founded principally upon the observation of the frequent co-existence of tubercles and acephalocysts in the lungs of ruminant animals, a circumstance rarely remarked in man, has not received the assent of modern pathologists.

The parts in which acephalocysts are developed, appear to undergo no changes beyond those which the bulk of the animal occasions—that is to say, the structures in the immediate vicinity of the containing cyst are perfectly sound and natural. There are no general symptoms that indicate their presence in the system; the derangement which they produce being attributable to the displacement and atrophy of the parts around. They often, indeed, attain a large size before the existence of a tumor is detected. Possessing, however, a natural tendency to increase and multiply, their presence in the cavities of the body becomes a serious evil, since they interrupt the functions of important organs, and in this way ultimately cause death. Such was the case in the boy from whom the preparation which I now show you was taken. Paralysis and apoplexy were occasioned by the production of a large acephalocyst in the lateral ventricle of the brain, which contained sixteen ounces of limpid serum. It is, however, in the abdomen that we more frequently meet with them; and for information relating to the disturbance which these bodies occasion, when developed in this situation, I must refer you to an excellent paper on the subject, recently published by Dr. Bright, in the Guy's Hospital Reports, and to the more

ample account of them by Cruveilhier, already alluded to.

As to the treatment which acephalocysts require when their existence is detected, I have but little to say. When of small size, a puncture with a small trocar, where it can be made with safety, affords the best chance of effecting a cure. If the hydatids are large, this is attended with some risk, from the constitutional irritation consequent upon inflammation and suppuration of the cyst. In superficial situations, as in the extremities, we might endeavour to rupture the animals by violence, as by a smart blow. It has been proposed to attempt their destruction by the agency of electricity; by acupuncture; or by the constant application of ice to the swelling, under the supposition that the parasite would be destroyed by lowering its animal temperature. I should be inclined to adopt the simple operation of breaking up the hydatid with a cataract needle, which, if used with care, can scarcely be attended with any risk.

2. *Echinococcus*

(from *εχινος*, echinus, and *κοκκος*, signifying a body of a rounded form). The echinococcus is found in cysts in the brain, liver, spleen, and omentum.

It consists of a cyst analogous in structure to that of the acephalocyst, containing a number of animalcules, provided with four suckers and a crown of hooklets, which float in the fluid within. It was in consequence of the presence of these animalcules that these animals were called, by Rudolphi, *living hydatids*. The echinococcus is very rarely found in man.

Vermiculi of the Echinococcus, highly magnified.

Neither Rudolphi nor Bremser have met with it. It was first observed in the human body by Meckel. Zeder discovered several in the brain of a young woman, occupying the third and fourth ventricles. Müller has recently described a case, in which a species of the echinococcus was voided with the urine, by a young man labouring under renal disease. One of the best authenticated examples of the occurrence of this entozoon in the human body, is a case published by Rendtorf, in a thesis on Hydatids. The sac containing the vermiculi was developed in the brain. It was of large size, and weighed two pounds three drachms, and filled the right ventricle, which was so dilated as to be reduced to half a line in thickness. —As a cause of disease, we must view this hydatid much in the same light as the acephalocyst.

OBSERVATIONS

RELATIVE TO

CHANGES IN THE CRYSTALLINE LENS,

AND

THE CAUSE AND CURE OF CATARACT.

BY SIR DAVID BREWSTER, K.H. F.R.S.

To the Editor of the Medical Gazette.

SIR,

I BEG to thank you for calling my attention to the queries of your correspondent from Glasgow, which I am the more anxious to notice, as I fear I have neglected to acknowledge a private communication from the same quarter.

In the Treatise on Optics, to which he has referred, it would have been out of place to have entered more minutely into the subject of the changes in the crystalline lens, and their connexion with cataract; and I was the less desirous of doing this, as I had contemplated the publication of a work "On the Diseases of the Eye, considered as an Optical Instrument." As I fear, however, that I shall never find leisure to execute such a task, I shall endeavour to give as distinct an answer as I can, to the *eight* queries of your correspondent.

1. The method of ascertaining that the change on which presbyopia depends

commences generally at the margin of the lens, is to place a taper, or small luminous image, at the distance of thirty or forty feet from the eye. The image of the taper, in place of being perfect, will be elongated in one direction, very frequently downwards, so that the eye is often unable to see the black wick of a candle, in consequence of part of the flame being brought down upon it. If the change were general, or symmetrical, a convex lens would remedy the imperfection of vision which it occasions; whereas it is well known, that until the change has gone round the margin of the lens, the eye does not derive any aid from spectacles. I have especially studied this fact in my own case, and seen it in many other cases.

2. When this change has become symmetrical, and advanced regularly in a sound eye, the application of a lens remedies the imperfection of vision arising from the increase in the focal length of the crystalline. But if the change has not advanced favourably, either from an improper use of the eye, from general bad health, or from other causes, the fibres, and even the laminae, *separate*; that is, they cease to be in *optical contact*, in consequence of the lens not being supplied with a sufficiently aqueous secretion. Now when light passes through a part of the lens where this separation has taken place, it is reflected and decomposed by the fibres, so as to produce not only the prismatic colours, but irregular luminous figures, round the candle. If we now take a plate of brass, with a small hole in it, we may so place it before the eye as to exclude all the light, except that which passes through the diseased part. When this position is found, the eye is *blind*. It can see no objects distinctly, because all the sound part of the lens is shut up. If, on the contrary, we take a small-headed pin, and place the head of it so as to prevent any light from falling on the diseased part of the lens, while the sound part receives rays from any visible object, the vision will be *perfect*. If only a small part of the lens is sound, we may enable a blind eye to see distinctly, by excluding all the light except that which falls on the sound portion of the lens. I have repeatedly performed this experiment, to the surprise of the patient. The colours above referred to are always seen in the crystalline lenses of *animals*, when the laminae or fibres are separated.

3. The *evidence* that a derangement of fibres arises from mismanagement of the eye when presbyopia commences, is not very ample, and has more the character of inference than of demonstration. The separation of the fibres, indicated by coloured images, and irregular luminous branches round and near the principal image, took place in my own eye, and continued for nearly eight months; during which I studied the changes which took place, and made drawings of the luminous figures. As I was in the habit of exposing my eyes to the severest trials, often for twelve and fifteen hours a day, I could not doubt that this *first stage of a cataract* was owing to the greatest mismanagement. It is, besides, universally admitted, that at those periods when the constitution undergoes a change, the greatest attention to the general health is necessary; and surely, in such a delicate fabric as the crystalline lens, composed of *millions* of fibres, it is highly necessary, when it begins to change its mechanical condition, that it should not be exposed to the same hard work which it might at other times be capable of performing.

4. The experiments by which the seat and extent of the disease may be ascertained, have been stated in section 2.

5. I fear it would be presumption in any one, not a medical practitioner, to answer your correspondent's fifth query, respecting the proper remedies for stopping the progress of these changes. I cannot err much, however, in stating what I did in my own case, and leaving your readers to judge whether or not it had any share in the result of restoring my eye to a degree of strength which has enabled it, during the last fifteen years, to perform the hardest work to which that organ can be applied.

Considering the disease as arising from a defect in the secretions by which the lens is supplied with aqueous fluid, I deemed it necessary to give up all experiments; to abandon reading at night; to preserve the eye from strong and numerous lights; to pay the greatest attention to diet; to take regular exercise; but above all, to keep clear the *primæ viæ*, which I did by taking daily the *pulvis salinum compositum* for nearly eight months. It is a curious circumstance that I first saw the

coloured images, when I was making experiments with my eye, while waiting for the moves of a slow chess-player; and *eight* months afterwards, in the same room, and similarly employed with the same companion, I all at once observed the images disappear, the fibres and laminae having then been brought into optical contact. Ever since that time my eyes have been exposed to severe work, and the one which had begun to give way, is now the one which I invariably use in all difficult experiments.

6. I believe it is by no means common to see the coloured images that have been above described, but it is extremely common to have the lens so disorganised by inequality of density in different parts, arising, no doubt, from differences in the refractive power of the secretions, that a distant luminous object is not only seen of an irregular form, but is often subdivided into two, or even more, amorphous images. This I have found to be the source of a great many defects of vision which had been ascribed to very different causes.

7. If spectacles are so constructed as to exclude the rays which fall upon the diseased part of the crystalline, the patient will have the advantage of good vision; but if the sound part is very small, it will be difficult to keep the small aperture opposite to it.

8. As long as the sound part of the lens is of such a magnitude that the patient can see through a small aperture, the art of applying and using which he will acquire by experience, the continued use of the aperture, or the spectacles in which it may be placed, will of course be beneficial.

I have thus answered your correspondent's queries in the way I would have done fifteen years ago; but I have recently been led, by experiments on the crystalline lenses of animals, to more extended views, of which I shall endeavour to give a brief and general idea, referring the reader for more minute information to a paper in the forthcoming volume of the Philosophical Transactions, and to the Reports of the Proceedings of the two last meetings of the British Association.

In these researches I was led to the discovery that the capsule of the crystalline lens is a membrane which performs the functions of *endosmose* and *exosmose*, keeping up a due proportion between

the aqueous element in the aqueous chamber and the lens. Even in the dead state this membrane imbibes distilled water so greedily, that the lens which imbibes it becomes quite soft, expands, and bursts. Viewing the capsule in this light, there can be no doubt that *soft cataract* arises from an excess of aqueous humour imparted to the lens through the capsule, and that *hard or dry cataract* arises from a defect of *water* in the aqueous humour, or an *excess of albumen*.

Let us now suppose that the skilful oculist has ascertained that there is a disorganisation of the lens which does not yet appear as cataract. He will, of course, first try the remedies already mentioned, as they are equally suitable for both varieties; and he may probably succeed in restoring a healthy action in the parts. But if he finds the disease gaining ground, he must resort to more direct methods before the lens becomes irrecoverably injured.

In this state of matters he should puncture the cornea, so as to get a small portion of the aqueous humour, in order to ascertain, from its refractive power, whether it contains too much or too little albumen. In either case it might be advisable by a partial evacuation of the aqueous humour to reduce the quantity of the diseased secretion, in the hope that a healthier one might be supplied; but if the disease should continue to advance, distilled water, or a solution of albumen, should be injected into the aqueous chamber, to restore the aqueous humour to its proper condition. If the aqueous humour first taken out should prove to have the ordinary refractive power of that humour, and to appear otherwise in a healthy state, in that case it would not be advisable to introduce either water or albumen. It is quite possible that the capsule of the lens might lose its power of supplying aqueous fluid to the lens, or might supply it too copiously; but such a defect is likely to shew itself either in partial or general opacity. At all events, this opinion will only be entertained in the case where the aqueous humour is found to be in a healthy state.

Although these views are applicable principally when the disease is taken early, yet even if a lens had *white opacity*, which might not be accompanied with any other disorganisation than the mere want of a fluid to restore the

optical contact of the fibres, I would not despair of effecting the desired change by the methods above given.

It was stated, as an objection to the preceding views, by a distinguished anatomist, when I submitted them to the Medical Section of the British Association at Bristol, that it would be dangerous to inject water into the aqueous chamber. Having been occupied at another Section, I had not an opportunity of answering this objection; but I conceive that I deprive it of all its force, when I state that the celebrated oculist, Professor Maunoir, of Geneva, is in the practice of supplying, by injection, the aqueous humour which is often lost during the operation of extracting the lens.

I am, sir,

Ever most truly yours,

D. BREWSTER.

Allerley by Melrose,
Dec. 9th, 1837.

HISTORY OF DISCOVERIES IN THE NERVOUS SYSTEM.

To the Editor of the Medical Gazette.

SIR,

I SHALL be greatly obliged if you will allow me to explain in your journal a passage in the History of Physiology, which forms part of my History of the Inductive Sciences: and I make this request with the less scruple, since the passage in question has been objected to publicly as well as privately. In vol. iii. p. 425, of the work just mentioned, I have noticed, among the discoveries in nervous anatomy, "the remarkable one made in our time by Sir Charles Bell and Mr. Mayo, that the two offices of conducting the motive impressions from the central seat of the will to the muscles, and of propagating impressions from the surface of the body and the external organs of sense to the sentient mind, reside in two distinct portions of the nervous substance; a discovery which has been declared to be, doubtless, the most important accession to physiological knowledge since the time of Harvey."

This statement has been objected to in the Edinburgh Review, as highly unjust to Sir Charles Bell. In a letter addressed to the Editor of that journal,

and extensively circulated, I stated that I was quite ready to declare my assent to the view given by Dr. Henry (who assigns the honour of the discovery exclusively to Sir C. Bell), "if, in revising the original memoirs, and consulting the best authorities, this view should appear to be well founded." I have now thus re-examined the subject, and am prepared to state the result of my reading and reflection.

I must observe, in the first place, that I have here nothing to do with other parts of Sir Charles Bell's labours besides that which bears upon the discovery of the distinction between nerves of sensation and of volition. As I have already stated, my History of Physiology was professedly intended to be directed only so far as to exhibit, by examples of peculiar portions of the subject, the place and order of that science in the present scheme of human knowledge. Nothing can be more absurd than to blame me for leaving Sir C. Bell's other researches unnoticed. It neither suited my plan nor my power to estimate all the researches of great physiologists. If I have given a just view of the nature and bearing of some of the principal positive and definite physiological discoveries, I have succeeded in the only task which I attempted.

Confining myself, then, to the discovery of the distinction of sensitive and motive nerves, I must remark that according to the mode in which I have viewed all such events, the discovery consisted of two parts: the conception in *idea*, and the confirmation of this by *facts*. I shall speak of these in succession.

In this, as in other cases, it was only by degrees that the discoveries brought the true idea into a clear and definite form. The distinction of sensation and volition had indeed so long been familiar to the minds of physiologists that no originality of thought was needed to hit upon it. But Sir Charles Bell appears at first to have pursued his researches with reference not to *this* distinction, but to others. In his "Idea of a new Anatomy of the Brain," (1811) he endeavoured to establish the opinion that different endowments are in the same cord of the spinal nerves, and held by the same sheath; and the nature of *this* difference was, that both sensation and volition belonged to the

anterior origin of the nerve and another function to the posterior origin. Yet along with this, he appears to have entertained, as a conjecture, the doctrine now in question. For in a letter written by him, and published in Dr. Cook's work on Palsy (vol. ii. pt. i, p. 57, 1821) he says, "the nerves of sensation and motion are bound together in the same membranes for convenience of distribution, but there is reason to conclude they are distinct throughout their whole course." But notwithstanding this conjecture, in his memoirs of 1821 and 1822, the reference of his researches is not to this difference, of sensation and motion, but to another view, resembling his original one. His main point in these memoirs is, that certain nerves are nerves of sensation and volition, and that certain others are "respiratory nerves." Thus, *Phil. Trans.* 1821, p. 417, "the fifth nerve, the nerve of mastication and sensation;" in 1822, p. 310, "this (the respiratory) system of nerves is superadded to that of mere feeling and agency."

Mr. Mayo, in his *Anatomical and Medical Commentaries* for August 1822, (p. 122) proposed objections to Sir C. Bell's attempt to establish the difference of regular and respiratory nerves; and employed the familiar distinction of sensation and volition as the true interpretation of the results of his own experiments. Thus he asserted that the *portio dura* of the seventh pair is a nerve of voluntary motion, and certain branches of the fifth pair nerves of sensation only. In the meantime (in August 1822) M. Magendie, at Paris, made experiments by cutting the posterior roots of the *spinal* nerves of puppies. "I was ignorant," he says, (*Journal de Physiologie*, tom. ii. p. 376) "what would be the result of this trial. I at first thought that the limb corresponding to the nerves was entirely paralysed: it was insensible to the strongest pinching and squeezing, and appeared to me also immoveable; but soon, to my great surprise, I saw it move in a very apparent manner, although its sensibility was still extinct." He repeated his experiments, and began to consider it as probable that the posterior roots of the nerves of the spine were more peculiarly appropriated to sensibility. He then found, by cutting the anterior roots of the spinal nerves, that the limb became immoveable, while it unequivocally retained its

sensibility. M. Magendie's narration appears to show that he had not previously entertained the idea of this distinction, as a guide to his experiments. In the meantime Mr. Mayo was advancing to the same point. For having satisfied himself that the fifth nerve consists, like the spinal nerves, of two portions, a ganglionic and a non-ganglionic part, of which the former is a nerve of sensation, and the latter a nerve of motion, he "was led to conjecture that the double roots of the spinal nerves have also functions corresponding with those of the fifth. . . . When I was engaged," he adds, "in experiments to determine the fact, M. Magendie's were published, which established the justness of my conjecture." (Commentaries, July 1823, p. 10.) The same idea was decidedly adopted by Sir Charles Bell at or about the same time, retaining however his views of the respiratory function of the nerves. For in his next memoir, read to the Royal Society, June 13, 1823, he says (p. 300) "the fifth nerve is the nerve of sensation to the head and face; the *portio dura* (of the seventh) is the motive nerve of the face and eyelids; and the respiratory nerve, and that on which the expression of the face depends." And in the same memoir (p. 303) he asserts that "all the nerves which bestow sensibility have ganglia at their roots, and those which have no ganglia are not nerves of sensation, but are for the purpose of ordering the muscular frame."

Thus the proposition, that there is one set of nerves with ganglions for sensation, and another set without ganglions for motion, was clearly brought into view. Our next business would be to inquire to whom the *experimental establishment* of this proposition is mainly due. This question it is very difficult for a person to decide who has not an intimate and extensive knowledge of physiological researches. A large portion of the credit must be assigned to Sir Charles Bell. For although his experiments on the spinal nerves, made in 1809, had not led him to assert the proposition, they were readily seen to be evidence of it when it was once asserted. His experiments on the nerves of the face, when they had been corrected by Mr. Mayo, further confirmed it; and the earnestness and perseverance which he displayed in seeking to establish differences in the

functions of the different nerves, had a leading influence on the progress of the subject, both through his own labours, and through the impulse he gave to those of other inquirers. Moreover, the very striking and attractive view which he at first presented of the nature of the primary distinction of function in nerves, (including its bearing upon the expression of countenance,) however this view might afterwards be limited or modified, was probably one of the main causes of the advance made in this subject. At the same time I also think it cannot be doubted that Mr. Mayo shewed this view, in its original form, not to be borne out by the experiments. Mr. Mayo also added materially to, and in some instances at least corrected, Sir C. Bell's experiments, and the interpretation of them: as, for example, when in animals, in which the fifth pair of nerves had been cut, he ascribed the disuse of the lips in eating to the loss of sensibility, while Sir C. Bell, less justly, had at first ascribed it to the loss of muscular power. And M. Magendie's experiments on the spinal nerves, while they appear to be independent of the researches of the two English anatomists, were accepted at the time as sufficient to establish, at least with a high degree of probability, the doctrine which he collected from them.

It is not necessary to my purpose to trace the further *confirmation* of this doctrine by succeeding observers. I will only remark, that though the experiments of Panizza and Tiedemann appear to have been highly important for this purpose, the most decisive labours seem to have been those of Professor Müller, of Bonn, who was justly dissatisfied with the vagueness of M. Magendie's statement, in which the proposition was only asserted as approximately true; and who made a remarkable series of experiments on frogs. (Hildebrandt, Handbuch der Anatomie, III. 359. Müller, Handbuch der Physiologie, 1824. I. 627. Treviranus, Organischer Leben II. 38.) I may add that though Treviranus expresses some doubt of the exactness of the proposition, it appears to be at present generally accepted by the soundest physiologists.

Looking upon the case as above stated, with the best judgment I can use, I find myself led to the conclusion that no injustice was committed by join-

ing Mr. Mayo's name to that of Sir Charles Bell, as I did; but that, as I have already stated, this is not to be understood to imply that they had equal shares in the discovery. If I should have occasion to reproduce this part of my history, I should wish to describe the discovery as having been "made by Sir Charles Bell, Mr. Mayo, and M. Magendie; the two latter physiologists having corrected and completed the researches of the former;" to which might be added the above notice of its confirmation. And it is to be observed that this statement is independent of all the credit which may be due to Sir Charles Bell for his share in the discoveries respecting the functions of the nerves—vital, nutritive, sympathetic, instinctive, automatic, respiratory, or by whatever names they may be described, which have been a main object of his labours.

Having thus, to the best of my ability, redeemed my pledge to reconsider the subject, I have only to beg your professional readers to bear in mind the attack made upon me, and the necessity under which I was placed of showing that I had not discharged unfaithfully my duties as an historian, in order that they may acquit me of presumption in thus occupying your pages.

I have the honour to be, sir,

Your very obedient humble servant,

W. WHEWELL.

Trinity College, Cambridge, Dec. 11, 1837.

REPORT

OF A

CASE OF IMPERFORATE ANUS;

IN WHICH THE RECTUM WAS FOUND TERMINATING IN A CUL-DE-SAC, WHICH HAD AN IMMEDIATE COMMUNICATION WITH THE ADJACENT URETHRA.

To the Editor of the Medical Gazette.

SIR,

By inserting the following case and dissection in your valuable journal, I shall feel obliged,

I am, sir,

Your most obedient servant,

J. GORHAM, M.R.C.S.L.

225, High Street, Borough,
Dec. 8, 1837.

Mrs. Nunn was safely delivered of a male child, and, ten hours afterwards, I

was informed by the nurse that no passage existed whereby he might void his excrement; and on examination I found to my surprise, that the anus was imperforate, and there was a bluish discoloration of integument on the spot where the anus ought to have existed.

Twelve hours after birth I made a puncture with a common lancet through the skin, at the point of discoloration, but without entering the rectum: I then incised transversely for about half an inch, and introduced the point of a lancet backwards and upwards, in the direction of the os coccygis. A little wind now escaped, but no meconium. A clyster was attempted to be administered, but it returned by the side of the pipe. I now placed a pledget of lint in the opening, and left the infant.

I may remark that the infant did not cry during the whole of the operation, neither was it convulsed. Ten hours after the operation he has passed urine, but no meconium; no swelling in the region of the anus; no hæmorrhage; the countenance is sallow.

The infant died in a few hours after this visit; but not in convulsions.

Post-mortem appearances. — The small intestines appeared healthy throughout. The duodenum was empty. The jejunum contained some small isolated portions of meconium, while the ileum, besides containing portions of meconium, was also distended with flatus. The transverse and part of the descending colon were full of meconium. The whole of this large intestine was excessively distended with flatus, so that the sigmoid flexus was much straightened.

The rectum was distended with gas and meconium, and terminated in a pouch. At the very bottom of this pouch a small foramen was found, with radii of puckered intestine passing from it in every direction. It was of sufficient size to admit a probe of about half a line in diameter, which passed immediately into the urethra. The bladder contained some urine, but no meconium. On passing a probe into the urethra, it entered at one time the bladder, and at another the pouch of the rectum; this was fully explained by making a longitudinal incision through the upper surface of the urethra, and thus exposing the canal.

A small abnormal opening now presented itself immediately anterior to the prostate gland. This opening was

about the size of three-quarters of a line, and after a passage of about two lines opened into the rectum immediately behind it.

The ureters terminated about a line and a half distant from each other, so that no trigone could exist.

FIG. 1.

- (a.) The rectum slit open longitudinally on its anterior part.
 (b.) The bladder opened in the same manner.
 (c.) A section was continued along the upper part of the urethra, and on its under part an opening is seen anterior to the prostate. On passing a bristle through this opening, it immediately enters the rectum.

FIG. 2.

The bladder has been turned forwards, so that its posterior part is now evident. By this are exposed the termination of the rectum in a *cul de sac*, and the radiated appearance around the opening.

FATAL CONVULSION DURING THE INJECTION OF NÆVUS.

To the Editor of the Medical Gazette.

SIR,

EITHER as a warning from the operation of injecting the vascular nævus, according to the plan detailed in the *MEDICAL GAZETTE*, October 1, 1836, or as an instance of the distressing casualties which beset the hopes of our profession, the following impressive case seems due to the medical world, and you will oblige us by the insertion of it.

The nævus was situated over the angle of the right maxilla, in a healthy and remarkably precocious child, nearly two years old, and had increased from

a slight speck at birth to the size of half a small orange. It was principally subcutaneous, but had a coloured portion in its centre, which seemed covered by cuticle only. On the 19th of October the tumor was pierced with a lancet used for the nasal duct, and injected by the transfusion syringe; the mixture used being nitric æther, with one-fifteenth of nitric acid. No decided effect was produced, so that either too little of the injection had entered or the mixture was too slightly stimulating, and in about a week the operation was repeated; the proportion of nitric acid being increased to one-tenth. No more effect, however, followed this than the former operation.

On the 15th of November the injection was again had recourse to; using, instead of the nitric acid and æther, the

liquor ammoniæ, weakened so that the nose could remain applied to the bottle. The perforation was this time made from the opposite side, and more attention being paid to the compression of the tumor, the piston was felt to descend more, and the tumor appeared more injected. At this instant the poor child suddenly ceased its crying, and at the end of a slight convulsion, continuing not a minute, lay upon the table a corpse.

As to the cause of this melancholy result, the first hurried impression at the conclusion of this harassing scene was, that the attack was merely *coincident* with the operation; that, in fact, it was one of those sudden and fatal succussions of the nervous system which now and then carry off children, apparently without reason, and of which an instance occurred here a few months ago, in a child who was playfully smiling on its mother's knee, and there died almost without a struggle. This also is Mr. Lloyd's idea, to whom the case has been reported, and who in his answer (of which he permits the fullest use) gives the following instance:—

"I was examining a child's throat, as his mother considered there was some difficulty in swallowing, and he had not been quite well for a few days before. Just as I had got the spoon on his tongue (he had resisted very much, and was in a state of great excitement), he threw himself backwards, uttered a scream, and was a corpse." He also adds:—"I may confidently state, that I have performed the operation considerably more than a hundred times, without the occurrence of any thing like a serious symptom;" and "I repeat, that I feel confident that the operation you performed could not have been the cause of the melancholy death of your poor little patient."

Yet though it is impossible to deny that such was the secret of this appalling case, and the harassed feelings cling to the supposition, it seems at least as impossible to deny, that some of the stimulating fluid was forced into the divided veins, thence carried along the external jugular and subclavian to the heart, and thus produced the death; or that a strong irritant, applied to the branches of the seventh and third nerves, is as likely to excite a fatal succussion of the whole nervous system, as those doubtful yet accredited agents,

dentition and gastric sordes. Either of these occurrences would be decisive against the operation, and their possibility demands the publication of the case.

No post-mortem examination was allowed.

However unlikely it is that air should be forced any where but into the cellular tissue of the nævus, it may be well to state, that it was impossible in this case, as the syringe was first filled with particular care, and afterwards held nozzle upwards, to insure the perfect filling of its pipe, and the escape of any air, if possibly any were left in.

We are, sir,
Your obedient servants,

T. PAGET,
Junior Surgeon to the Leicester General
Infirmary, and Consulting Surgeon to
the County Lunatic Asylum.

FRANK FULLAGAR.

Dec. 5, 1837.

REMARKABLE CASE OF TRIPLETS.

To the Editor of the Medical Gazette.

SIR,

PERMIT me, through the medium of your periodical, the MEDICAL GAZETTE, to make known to the profession the following interesting case:—

On Sunday morning, the 10th inst., I was called upon to attend Mrs. Hamet, residing at No. 7, Upper Park Place, Regent's Park, in labour with her sixth child. On my arrival, at half-past ten, I found she had been in labour some hours; the membranes had been ruptured, and on making an examination per vaginam, I discovered a breech presentation; the feet were brought down, and the child delivered in the usual manner. On laying the hand on the abdomen, it was evident the uterus contained another child. On making a second examination, per vaginam, the membranous bag of the second child was detected, and of such volume, and containing so much fluid, as to render it impossible to determine the presenting part. In half an hour after the expulsion of the first child, the pains, which had ceased for a short time, recurred, and before the hour had elapsed the membranes were ruptured, and at least two quarts of fluid escaped; the head of the second child descended, and was,

with the body, quickly expelled. The hand being again laid on the abdomen, detected another child, which, after a few minutes, like the second, evolved under the head presentation, bringing with it its own placenta entire; subsequently the placenta of the two first-born children were expelled perfectly distinct from each other.

The peculiarities of the case are, that the children, two boys and one girl, were born alive, well formed, and apparently of full growth; that each had its own placenta and membranes unconnected with those of the other, and expelled separately; that the second and third membranous cysts were simultaneously ruptured after the expulsion of the first child. The woman is in her 34th year, has suffered no inconvenience, and is at present doing extremely well.

I have the honour to be, sir,
Your obedient servant and constant
reader,

W. LOVEGROVE.

13, Baker Street.

CASE OF AMAUROSIS AND PARALYSIS OF THE EYELID.

To the Editor of the Medical Gazette.

SIR,

IN the diagnosis of obscure disease, it is most important to consider, in addition to the existing symptoms, not only the peculiar idiosyncrasy of the patient, and the characteristic (or, as Sydenham would term it, the *epidemic constitution*) of the season, but also the medical topography of the situation in which the patient resides.

There is no cause which produces affections so varied, so anomalous, and so obscure, as marsh miasmata, or malaria. Not only do we observe all the modifications of *pyrexia*, taken in its most extended sense, but also many maladies purely of the nervous system. A most intelligent physician, of Holland, informed me, not long since, that it was not uncommon in that country to see patients suffering from all the symptoms of apoplexy, originating from the same source as intermittent fevers, and cured by the same remedies. Rheumatism and neuralgia are also to be often traced to the same origin; but it is not often that we see paralysis produced by marsh miasmata. The following case, however, would seem to

have been produced by it, and was cured by the treatment which such an opinion suggested. It occurred under the care of my friend, Mons. J. de la Harpe, physician to the Cantonal Hospital of the Canton de Vaud, at Lausanne, who has allowed me to make use of it.

The Canton de Vaud, in Switzerland, which extends along the shore of the Lake of Geneva, is bounded on the south by that fine expanse of water, extending over upwards of 400 square miles, and on the north by the Jura Mountains. Although, from its vicinity to so extensive a Lake, it might be supposed that intermittent fevers are very prevalent, yet this is not the case; but, on the contrary, they rarely happen excepting at the upper part, at the mouth of the Valley of the Rhone, and in this situation many circumstances concur to produce them. Where the Rhone enters the Lake of Geneva, there is a considerable extent of alluvial and marshy land, having all the characteristics of soil and vegetation common to such situations, and affording a most interesting spot for the investigations of the botanist. The valley of the Rhone, shut in from the cold winds by lofty mountains, and presenting a long extent of exposure to the southern sun, is, during the summer, almost suffocatingly hot; while the Rhone, being supplied from the snows and glaciers of the Alps, is particularly full at that season, and a stream of cold exhalation arises from its surface, almost certainly productive of fever to those who, without additional covering, approach its banks. The above sketch of the medical topography of the country, is, perhaps, desirable for the elucidation of the following case:—

Jaques Deleysin, aged 28 years, agriculturist, of a strong and robust frame, was attacked, without any known cause, in May, 1837, with pains on the left side of the head, which were soon followed by a weakness of the left eye. This was succeeded by paralysis of the superior eyelid and complete amaurosis, while the pains of the head increased in intensity. These symptoms continued, with very little variation, till the middle of July. The medical men who were consulted recommended successively leeches, blisters, and anodyne liniments to the painful part, and many remedies internally, without any material allevia-

tion. The leeches relieved the pains for the moment, but they returned with greater violence afterwards. Finally, a few days before his admission into the Cantonal Hospital, they had applied two moxas; one to the nape of the neck, the other on the left frontal bone.

On the 13th July the following were the symptoms that presented themselves:—Nearly complete paralysis of the upper eyelid of the left side; the patient could raise it but very little. On elevating the eyelid with the finger, the pupil was observed to be very much dilated, and insensible to light; the vision on that side was lost; there was no other mark of disease in the eye. There were very severe and lancinating pains in the upper jaw, the temple, the forehead, and in the whole parietal region of the head on the same side. The moxas were beginning to suppurate around the eschar; the pulse was small, rather weak, but not accelerated. The pulsation of the carotids indicated no cerebral congestion; all the other functions were natural. At the first aspect it was thought that there was some affection of the brain, of which the paralysis of the retina and of the eyelid might be the result; but the absence of every other cerebral symptom seemed to exclude that idea. On questioning the patient more closely, he stated that the pains were not always of the same degree of intensity; that they were more severe in the morning, and became more calm during the night. He added, that he had occasionally some moments of positive ease, but that ordinarily the pain only remitted, but did not cease entirely. He has slept but little for a long time past. The pains were so severe that he could not help crying out, or even weeping. On reflecting that the man came from the situation where intermittents prevail, (almost the only place in the Canton), the impression that remained was, that this was a marked form of intermittent; and as nothing appeared to contraindicate the employment of quinine, he was ordered $1\frac{1}{2}$ grs. of the sulphate every three hours. The moxas were dressed with simple ointment, to promote their healing.

From the second day of the employment of the quinine, the patient experienced decided relief. On the fourth day the eyelid had recovered some degree of movement, and the eye had recovered some degree of vision. The

pains ceased on the sixth day, and the amaurosis diminished rapidly.

The 23d July, ten days after his admission into the hospital, the case was completely cured. From the 17th he had employed a spirituous ophthalmic lotion.—I am, sir,

Your obedient servant,

J. C. Cox, M.D.

Naples, Oct. 1837.

CHOREA FROM PREGNANCY.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case of chorea appear worthy of notice, I would beg as a favour its insertion in the pages of your journal. It appears to me to possess singular features, as seeming to arise from uterine irritation consequent on pregnancy, its remittent type, and its being confined to one half of the body laterally—a circumstance which I have never before observed, and which might entitle it to the name of hemiplegic chorea, in distinction to that form affecting only the upper extremities, or any single limb or set of muscles.

On November 6th, I was called to see Mary Bond, æt. 23, a patient of this institution (General Dispensary), residing at 37, Duke-street, Smithfield, who had recently married, and till then had always enjoyed good health, with the exception of a slight degree of menorrhagia, or rather more frequent return of menstruation than usual. Her friends, who called me in, informed me that since the period of her marriage, which took place about the beginning of September, she had never menstruated, and that during the last week she had been affected with fits, returning regularly about 7 P.M. daily. Accordingly, about that hour I called, and found her lying on the bed, with distortion of the left side of the countenance, kicking violently with the left leg, and striking continually with the arm of the same side, which motion she was wholly unable to cease or restrain, and had bruised the limb severely against the bed-post. These fits never wholly left her; she always had tremor and slight twitching in the limbs of that side during the day, which became ungovernable towards the evening.

She was a tall thin young woman, of fair complexion and light hair, very pale, and with a small, frequent, and compressible pulse, and an appearance of general want of tone in the system. She said she had no pain whatever, excepting an uncomfortable feeling caused by constant spasm of the orbicularis palpebrarum, and corrugator supercilii. On inquiry she told me she had occasional pains in the loins and back of the neck, which she referred to taking cold, but which were not confined at all to either side of the body. She added, that she suffered from morning nausea, slight feverishness, and headache; and on examining the breasts, I found the areola of the nipple wider than usual in the unimpregnated female, and of a darkened hue. From the constant muscular exertion she was in profuse perspiration; and the violence of the spasms, and the state of lassitude in which they had left her, had wholly deprived her of rest for the two previous nights. As this was the case, and the bowels were slightly confined, I ordered—

Pil Sapon. comp. gr. v.; Hyd. Chloridi, gr. iv. ft. pil. ij. hora somni sum.
Pulv. Rhæi, c. Hyd. Chlor. gr. xv. eras mane sumend.

On calling the next day, I found that the opium had disagreed with her, having caused for a time pain in the head; and that since taking the medicines she had suffered, at different periods of the night and day, three distinct paroxysms of chorea. As the bowels had been freely moved, and there was now no pain in the head, I prescribed—

Ferri Sesquioxidi, 3j. ter die sumend.

and on repeating my visit on the 10th, she told me she had already experienced great relief, having slept soundly, found her appetite improved, and the fits less violent and of shorter duration, though she was rather frightened at the black colour of her stools.

Rep. Ferri Sesquioxidi.

The dose to be gradually increased; and as the bowels were not quite sufficiently open, I ordered—

Olei Ricini, ʒss. pro re nata sumend.

and daily exercise for a short time, when the weather was such as to allow it.

After this I did not see her till the 19th, during which period she continued improving, having by my directions increased the dose of iron to nearly ʒiij.

Calling then, I found a material improvement; the motion in the leg had nearly ceased, and the arm was so much under control, that she was able to hold her needlework whilst sewing, although there was towards evening an increase of movement, especially in the arm, which, for her own relief, she placed in a sling. The pain in the neck and loins had wholly left her; she slept soundly; the symptoms of pregnancy appeared more confirmed; and her menses, which previous to marriage always came on every fortnight, had not reappeared. Her pulse was fuller and stronger, her appetite good, and her cheeks, instead of being pale, had assumed the colour of health.

Rep. Ferr. Sesquiox. et Ol. Ricini.

On next seeing her, on the 25th, she declared herself perfectly well, and free from all tremor of the limbs, of which she had regained perfect command; at her own request I merely ordered a repetition of the medicines, in case of relapse, and desired her to give up the Dispensary letter.

Not venturing to offer any theory as to the cause of the complaint, its singular confinement to one-half of the body, or its periodicity of return, but contenting myself with merely stating the facts,

I remain, sir,

Your obedient servant,

GURNEY TURNER.

Dec. 7, 1837.

OBSERVATIONS ON QUARANTINE,

AND

DESCRIPTION OF THE LAZARETTO AT
MARSEILLES.

To the Editor of the Medical Gazette.

SIR,

THE detention in quarantine establishments, of travellers arriving in European ports from countries literally subject to attacks of the plague, is, to say the least, of a very unpleasant and sometimes not improbably a disastrous occurrence, to the subjects of such detention. If, however, the evil rested here, with the interests of a few individuals, the matter would not be one of any very great importance to the public in general; but since the principles of the quarantine system are carried out to such an extent as to effect very materially the commercial relations of

nations and the interests of large communities, any inquiry into the motives and arguments on which this system is founded, may well be considered a matter of public importance; the more especially as of late years the same principles, and the same line of action, have been brought to bear upon the occasional visits of Asiatic cholera, as in cases of plague and yellow fever.

The general principles on which the quarantine establishments of Europe have been founded, all of course rest on the *supposed* properties of contagion or infection; in other words, the *supposed* power of propagating or communicating a similar malady, which, in certain diseases, resides in the persons of men or animals affected by such disease, in the substances which are or have been in contact with them, and in the atmosphere immediately surrounding them.

The duration of quarantine depends on the length of time considered necessary for the purification and removal of the germs of contagion from the persons or substances supposed to be infected. By some unknown process of reasoning, the sanitary legislators of Europe have arrived at the opinion, that various substances possess various capacities of retention with regard to these germs of contagion; that some are highly susceptible and peculiarly retentive of the infectious principle; and that others, which do not, to common understandings, seem much to differ from them, have been said by the same authority to be incapable of either receiving or communicating the seeds of the dreaded disorder.

The substances considered to be most susceptible and most retentive of the plague infection, are, all cotton, wool, and hair, raw or manufactured, feathers, furs, paper, books, &c., silver, gold, copper, wax, sugar, coffee, tobacco, &c.

On the contrary, wood, iron, wheat, dried fruits, water, and other liquids, and many other articles, are considered incapable of receiving the infection, and from these opinions arise a number of remarkable incongruities in the *working* of the quarantine system, as I shall presently be able to show.

As the question of contagion or non-contagion is one which has so repeatedly exercised the inquiry of medical writers as to offer but an unpromising ground for present discussion, I propose confining myself to offering a few remarks on what I have personally

observed on this subject in those countries where the plague is not infrequent, and on those details of quarantine to which I have been personally subjected.

It is not unworthy of remark, that until within the last few years, quarantine has existed only in Christian countries. Of late, indeed, both the Sultan of Stamboul, and the Pasha of Egypt, have introduced the system, rather as an appendage to their other European importations than upon any sounder principles; indeed, the whole practice of the native population of those countries where the plague annually occurs, is opposed to the theory of isolation, as may be gathered from the writings of all eastern travellers. This has been attributed to the all-pervading influence of the Mahomedan doctrine of fatalism on the minds of the people; but it should be remembered, not only that the extent of this influence has been greatly exaggerated, and that a considerable portion of the population of the Levant are not Mahomedans, but Christians, of the Greek and Latin churches, but also that the customs of nations are generally found to be based upon something of experience, and from some notions of their fitness and utility.

To suppose that the Turks and Arabs, as a body, are careless of their health, and unsolicitous of means to avert or remove serious disease, but ill accords with what I have witnessed of their character; on the contrary, among no people is there a greater respect for, or a fuller confidence placed in the professors of the healing art, and none are more desirous of benefiting by the skill and resources of European practitioners.

Poverty, ignorance, and superstition, no doubt produce their legitimate effects; but we have only to recal the scenes witnessed by members of the Boards of Health in this country during the prevalence of the cholera, to assure ourselves that the doctrines of Mahommed are not necessary to the production of a sluggish indifference to danger, and a disregard for the means of averting it, among the pauper population of any town or country. Of the European residents in those countries in which the plague prevails, neither the medical practitioners or others are at all agreed as to its contagious or non-contagious qualities, as to the substances capable of communicating it, or as to the proper precautions to be observed. At Alexandria,

in Egypt, some Europeans perform a strict voluntary quarantine during the whole continuance of the disorder; others pursue their usual occupations and preserve their accustomed intercourse with the world, and both plans it would seem occasionally succeed and occasionally fail. At the same place many of the French and Italian medical officers of the Pasha's service, took every possible precaution against the communication of the plague from their patients to themselves; dressed in a kind of envelope of oil-skin, having their saddles covered with the same material, a supply of aromatic vinegar constantly to the mouth and nostrils, and never touching an affected person with the bare hand; yet these precautions failed in several instances to procure an immunity from the disease, while an Englishman, Dr. Laidlaw, practising in the same city, a man of a firm and decided turn of mind, despising every kind of precautionary measure, visited and manually assisted a considerable number of plague-struck individuals, without the slightest apprehension of danger, and without any evil result. One case attended by Dr. Laidlaw is worth recording: A captain of an English merchant vessel, in the harbour of Alexandria, was seized with symptoms of plague (then raging in Alexandria,) and placed under the care of Dr. Laidlaw. A large bubo formed in one groin, suppurated and sloughed extensively. One morning Dr. L. was sent for in haste, and on arriving, found that considerable hæmorrhage had taken place from the wound in the groin. From the circumstances of the case there was no doubt but that the blood had issued from the femoral artery, and Dr. L. immediately resolved on tying the external iliac artery, an operation which he performed with equal skill and success. The hæmorrhage ceased, the ulcer healed, and the man perfectly recovered. Now if ever the plague was to be propagated by contact from one individual to another, one would suppose that it would have been communicated in this instance. Dr. Laidlaw, however, related the circumstance to me many months after its occurrence. I need hardly say, that Dr. L., who has had charge of a plague hospital at Alexandria, and therefore enjoyed very favourable opportunities for observation, and for the formation of a correct opinion, is a *non-contagionist*.

On arriving at Kiumh, on the right or eastern bank of the Nile, in my route from India, in April, 1833, I was informed that the plague was raging at Siout, Manfalout, and other towns and villages down the course of the Nile; and this I found to be the case. The Arab fellahs, or cultivators of the soil, miserable, half-starved, and not half-clothed wretches, barely able to earn sufficient to support existence, were sinking in numbers under the disease; but though my fellow traveller and myself daily visited the villages where the disorder prevailed, and though our servants frequented their bazaars, still we never heard the doctrine of contagion broached, or for an instant suffered the idea of danger from the communication of the disorder to enter our imaginations.

Any person who has voyaged on the Nile must have observed the countless flocks of pigeons which swarm in the Egyptian villages; they are familiar in the streets; they roost on the low huts; and must necessarily have much communication with infected substances. Living animals and feathers are two articles most highly susceptible, retentive, and communicative of the germs of contagion, according to the received doctrines of all quarantine establishments. But how put the laws of isolation of person in force against the pigeons? and if this is impossible, it is evident that individual isolation of infected persons is, in Egypt at least, quite out of the question. I shall have occasion to point out, that precisely the same arguments apply to the lazarettos of Europe.

Mohammed Ali, the Pasha of Egypt, has during the last twenty years driven a very flourishing trade in cotton. This cotton is grown on the banks of the Nile in all Egypt, from Alexandria to the cataracts of Assouan, and is brought down the Nile to the depot at Alexandria, whence it is shipped to various European ports, both British and continental. This cotton being picked and packed into bales by the fellahs, perhaps at the very time (nay, to my own knowledge, at the time) when the plague is raging in their villages, and not improbably by the hands of men actually at the moment suffering from plague, is naturally enough considered by the sanitary authorities of European quarantines as the substance most susceptible of the contagious germs, and

best calculated to retain it to the longest period. All ships laden with cotton, and all passengers in such ships, are therefore subjected to a quarantine of considerable duration in all, but of variable periods in the continental ports.

In the summer of 1836 I embarked at Alexandria, in a French brig laden with cotton, and bound for the port of Marseilles. Her cabins were stowed with bales of cotton, and her decks so entirely covered with them, that we walked constantly on the cotton. We dined in the open air upon these bales, and in short lived upon, and almost in cotton, for about three weeks. Not a person on board, to my knowledge, complained of a headache during that period; but on arriving at Marseilles our troubles began.

Having hoisted the yellow flag as a signal of a foul bill of health, the ship was brought to an anchor in the quarantine harbour, which was then crowded with other vessels also undergoing quarantine. As each vessel touched its neighbour, of course the whole were connected; but as some were from Smyrna, some from Constantinople, others from Bona and Algiers, each vessel had a different period of quarantine to undergo. Had a sailor of a vessel from Smyrna, which had perhaps but three days more to remain in quarantine, touched a sailor or a rope belonging to another vessel, his period of quarantine would have been extended to the same number of days as that of the man he had touched. But the rats and mice of each vessel most probably exchanged visits in spite of the quarantine regulations; added to which, the fomites of the contagion must have been pretty effectually dispersed (if the doctrine be worth any thing) over the adjoining vessels, on opening the ship's hold, and removing her cargo thence to the lazaretto. As a passenger I was immediately removed to the lazaretto, there to remain in quarantine during twenty-one days.

The lazaretto at Marseilles is a very extensive establishment, being an inclosure of some acres of ground, open on one side to the sea, surrounded by a high double wall, and guarded by military sentinels. It contains within its walls apartments for individuals in quarantine, the house and garden of the captain of the lazaretto, the offices of a restaurateur, and spacious warehouses

and large yards for the deposit and exposure of merchandize. Each individual in quarantine has an apartment assigned to him, and a guardian attached to him, whose duty it is to watch over all his actions, and prevent or report any contact between him and any other person or thing undergoing quarantine. This guardian will also act as a servant. A considerable space of ground is allotted to the prisoners (for such they really are) for exercise, each walking out attended by his guardian. All communication with the town is carried on at the barrier, or toward entrance of the lazaretto; and here those in quarantine may see and converse with their friends from the outside, under certain regulations. To every individual in quarantine, strangers, guardians, or labourers, are assigned a certain number of strokes on a bell, by means of which all orders and communications are conveyed. When summoned to the barrier, the person in quarantine enters one of a series of small rooms, one side of which is covered with a network of wire, and separated by an interval of about six feet from a similar row of chambers, in the opposite one of which his friend from the town is placed. Here conversation may take place in comparative privacy, while at the same time contact is most effectually prevented.

Any attempt at escape would be most severely punished; if the individual had reached the outside of the lazaretto, and touched any person without the walls, he would be liable to capital punishment, and would be shot by the sentries if detected in the act of escaping.

On entering the lazaretto I first underwent a fumigation, or *parfum*, as it is termed, produced by pouring sulphuric acid over common salt. This was repeated at the middle, and at the termination of my period of confinement. My baggage was examined, and all woollen or stuff articles removed to undergo certain purifications. My letters were taken from me, and some canisters of gunpowder confiscated to the use of the captain. I was placed in a small room with a brick floor, bare walls, and an iron bedstead, and a keeper assigned to me. This room formed one of a row of similar ones, inhabited by individuals of various nations, each having a different period of quarantine allotted to him. The last

room in the row was smaller than either of the others, and its window secured with an iron grating. This was destined to be the abode of any unfortunate wretch among us who should shew any symptoms of commencing plague. In such a case the unhappy sufferer would have been shut up in this miserable hole, an object of terror rather than of compassion, and would have stood a fair chance of perishing, as much from neglect and despondency as from any actual disease. The whole yard was surrounded by a wall, and its gate closed every evening at eight o'clock.

A tenant of the yard I occupied was somewhat out of health, and a physician was sent for, who came accompanied by the captain of the place. He stood about two feet from his patient, looked at his tongue, asked a few questions, and prescribed. Had he touched such person, he would have been compelled to perform the same length of quarantine as his patient. Yet this physician and the captain himself having walked amid bales of infectious cotton, and approached closely to infectious persons, (for if not infectious, why confine them in a Lazaretto) were permitted, by the regulations of the establishment, to re-enter the town of Marseilles, and mix with its inhabitants. In the case of a poor boy who had injured his arm, and therefore required manual treatment, a young medical *élève* was placed in attendance, (and also in quarantine) upon him. The keepers or guardians are also, nominally, under the same restraints and regulations. Conversation is allowed, and indeed every thing but actual contact or communication with a conducting medium. Thus a person may throw a book or a stick to another, but if he hand it to him the quarantine of each must be equalized. Yet those persons who may not hand a stick, may sit together on the same bench without danger. The guardians play at quoits together, it being decided that iron is not susceptible of the contagion, while a piece of silver money must be placed in a basin of vinegar before it can be passed from one to another. These worthies freely circulate among themselves, cigars, tobacco, &c., although they are prohibited articles. Moreover, money judiciously applied will here, as in all other parts of the world, render the guardians incapable of seeing any un-

fortunate mishap which may occur to an individual in quarantine. In short, the contradictions and puerilities which come under observation in this establishment are innumerable, and cannot but lead to the suspicion that the whole affair is altogether useless, if not worse. Rats abound in the Lazaretto; sparrows fly in and out without regard to the sentries in the barrier, and above all, the captain of the establishments keeps rabbits, some of which are running about wild in his garden. Indeed, during a residence of twenty days in this large, and, to the French nation, most expensive establishment, I saw more than enough to convince me that the isolation of persons must be impracticable by any other means than rigorous solitary confinement, and enough to induce me to think that even could it be carried on to its utmost extent, it would be an unprofitable and useless measure as regards the preservation of the public from the propagation of the plague.

It appears, indeed, to be now a very general opinion, and one which will, no doubt, every day gain strength, that the plague can be secondarily communicated only under very peculiar circumstances, if at all; and these circumstances are, chiefly, confinement of the sick in the deteriorated atmosphere of an unventilated apartment. If the force and energy of this propagating power be in proportion to the state of the immediate atmosphere, as to ventilation and purity, the isolation of the person affected must be a matter of very secondary importance, compared with the necessity for altering and renewing the atmosphere around him.

The former is a precaution of doubtful, the latter one of certain value; and this is precisely what makes the difference between a plague-hospital and a lazaretto. The former, if well arranged and properly conducted, is, as at Alexandria, a most valuable public institution, inasmuch as its object is to relieve actual suffering, and remove existing disease. The lazaretto, on the contrary, in its double office of isolation of *suspected* persons, and isolation of *suspected* goods, is a cumbrous and comparatively useless piece of machinery, instituted for the removal of that which does not exist.

In speaking of the isolation of goods, I remarked that they are all exposed to

the air, and made to undergo certain purifying processes in the yards and warehouses of the Lazaretto.

Amongst others the bales of cotton brought from Egypt are each opened, exposed, and manipulated by a particular class of labourers, who remain in quarantine during the period required for the goods on which they are employed. These are, for the most part, healthy, active, young men, who, labouring in their vocation in the very heart and centre of the supposed infectious material, are yet preserved from the disorder in a very remarkable manner, supposing any danger of contagion to exist. It would be desirable to ascertain with accuracy how many cases of plague have occurred among these people during the last twenty years.

The period during which the quarantine of goods is to be prolonged, does not appear to be fixed according to any rules either of experience or of inference. It varies in different countries, and is much more severe in the Austrian ports than at Marseilles, and seems to be dictated merely by caprice, or to suit the particular views of the legislators. When, indeed, we recollect that it was once gravely stated that the plague in Paris was derived from some old rags which had lain several years undisturbed in an old well, and that it is now as seriously urged that 20, 30, and even 60 days are occasionally necessary for the removal of the contagious fomites from cotton or feathers, we cannot but be desirous of ascertaining on what grounds these decisions have been founded; there can be no reason for disbelieving the story related by Alex. Benedictus, in his book "de Peste," of the feather-bed which retained infectious properties during seven years, when we are called upon to suppose the same circumstance possible during a period of seven weeks. If it be once allowed that the much-dreaded fomites can attach themselves to and reside in any substance, whether animate or inanimate, I do not see how any limit is to be fixed to the term of their residence; if once they take up their habitation, I imagine they will not be, in the general acceptance of the term—tenants at will. If this be true, nothing short of an *eternal* quarantine can *positively* secure against the communication of the infection. Under these circumstances, the time cannot, I hope, be

far distant when a clearer view of the subjects of contagion and quarantine, than habitual fears and long-standing prejudices at present permit, will be adopted by the governments now most zealous in maintaining rigorous measures, erroneously supposed capable of preventing the danger, even if it did exist, or of averting a calamity which derives its origin from causes not to be controlled by the operation of the quarantine laws.

I am, sir,
Your obedient servant,
D. W. NASH.

1, North-place, Cheltenham, Nov. 24.

HYDROPHOBIA—RECOVERY.

To the Editor of the Medical Gazette.

SIR,

I AM anxious to lay the following case before the profession, and especially as there was amongst the medical attendants great variety of opinion with regard to its nature. One would have it to be mania, another inflammation of the brain: *ramollissement* of, and tumor in the brain, were likewise mentioned. With regard to the opinion I formed of its nature, I deem it right to say, that I relate only what I myself saw, as during the three first days I scarcely ever left the patient.—I remain, sir,

Your humble servant,
WILLIAM DU NEAUME,
M.R.C.S.L.

Jersey, Dec. 7, 1837.

On Saturday, Feb. 11th, at 10 P.M. I was called to see Mr. L. F. "who," I was told, "was dying." I found him in a sitting posture, supported by pillows. His face was flushed and his eyes shut, but, on being opened, the pupils were sensible to the stimulus of light. His respiration was *convulsive*, and the pulse quick. He continually repeated the word "*achève*." He had been in this state some minutes. The history I had of the case was this:—He had returned from sea a fortnight since, and during the latter part of the voyage had suffered much from anxiety of mind. His friends had found him quite altered; he was lonely, and shunned society; he was sleepless, and

wished to be always walking. He had before experienced a few slight convulsions, and he could exactly tell how and where he had been seized, and what he had done during the paroxysm. He now occasionally spit out his saliva, and turned violently on his abdomen, making efforts as if to throw it off by vomiting. I immediately applied twenty-four leeches to his temples, and occasionally ammonia to his nostrils, and ordered him to have a turpentine enema. After being in this state twenty or thirty minutes, he repeatedly sighed, and (as it appeared) gradually recovered himself. I was, however, surprised to find that he had all along been in his perfect senses. He had heard and recollected, and when his eyes were opened he had seen every thing about him. He was also sensible that he had continued repeating the word "achève," which was part of a prayer he was saying when the paroxysm came on. I left him at twelve. He expressed himself much relieved; indeed he seemed quite well.

12th.—At five in the morning I was called, as he was again in the same state; the chief symptom being, as in the former paroxysm, that the respiration was convulsive. I again occasionally applied ammonia to his nostrils, and, when he could swallow, gave him a few drops of liquor ammoniac in water. I ordered cold applications to the head, and an effervescing draught to be taken. At 8, I found that he had remained well since 5 o'clock. His face was still flushed, and pulse quick. As he was much troubled with flatus, I ordered an assafoetida enema.—I must now describe his state between the paroxysms. He always lay on his back, with his eyes widely and constantly open and turned upwards; the pupils were dilated, but naturally contractile. When a question was put to him, he always answered correctly. He appeared engaged in deep thought. When told to shut his eyes, he would do so, but he could not keep them shut. When a paroxysm of convulsions came on, it was generally announced by his spitting out his saliva with violence; his countenance becoming exceedingly animated, and his mental faculties much increased.

I applied a blister to the calf of each leg. The cold applications to the head were continued, and during the day he had several purgative enemata.

He had no paroxysm during this day, but at 9 p.m. he became much excited. This I attributed to the irritation of the blisters, as the slightest touch of the blistered part greatly increased the excitement. I could not take off the blisters without the assistance of several friends. His appearance was now much altered; his countenance was exceedingly animated, and his eyes brilliant; his manner was also remarkable. I now offered to him some water to drink, but the instant it was presented to him he was convulsed, and violently gnashed with his teeth. Soon after, Mr. C., who passed the night with me beside him, brought the basin near him, in order to wet the cloth about his head; he was again convulsed, and tried as if to plunge violently into the water. I applied twenty-four more leeches to his temples, and ordered cold applications to be continued to the head. I stayed with him the whole night. He had numerous paroxysms, during which his mind appeared to be perfectly lucid, as he requested us by name to hold him, and he wished us to stay always one at each side and another at his feet. Of the approach of a paroxysm he was always sensible, and on one occasion that only one of the attendants was with him, he requested the others to be called, "as one alone," he said, "could not hold him."

13th.—The countenance of the patient was still more animated; the face flushed; the eyes more brilliant and red; the pulse rather quick; the tongue natural. He complains of a burning pain in the chest. He is quite rational, but very irritable. It was agreed, in consultation, that he should have the following mixture:—

℞ Tinct. Opii, ℥℥. ; Vin. Antim. ʒiij.;
Spiritus Ammon. ʒj.; Mist. Camph.
ʒviis. M. Capiat cochleare magnum
2dâ quâq. horâ.

I continued watching the case closely, as there appeared to me something uncommon in the symptoms. There was no delirium whatever, but his mental faculties were wonderfully increased. He could hear the lowest whisper; the smallest cinder falling would make him start up; the noise made by the water falling when the cloth was dipped into it, was insupportable; a carriage passing threw him into a convulsion; his

vision was also wonderfully increased. Sometimes the dread of water was exceedingly well marked, at others not so. He could at times manage to get down a little, but that little seemed to distress him greatly. He was asked if he would like an orange. Having expressed a wish to have one, it was given to him, with the top cut off; it was curious to observe him bring it to his lips, but the instant the moisture touched them he was convulsed. This was well marked. He himself asked "how it was that when he brought the orange to his lips he was so pulled back?" On inquiring, I found that two years ago he was bitten by his own Newfoundland dog, in the upper part of the left arm: the dog was then greatly irritated, but it was stated that it was alive and well. He had since often complained of pain in the part, and there was now, at the bitten part, some redness; which, however, might have resulted from his being held by that part during the convulsions; and that arm was throughout observed to be more convulsed than the other. At this time the bitten part could not be touched without inducing convulsive twitches, and the patient himself asked why this occurred when that arm was touched, and not the other. His appearance was now frightful; his tongue was greatly protruded, and his jaws were incessantly moving; he was continually spitting out his saliva, which it was evident he could not at all swallow. Sometimes when asked if he would have a drink, he would say, "I wish I could drink, I know it would do me good, but I cannot." During this day he had several paroxysms; in the afternoon a straight-waistcoat was put on, not because he evinced any disposition to do harm, but because it enabled fewer hands to hold him during the paroxysms: those who were often or constantly with him, observed throughout that he was anxious not to do any harm.

At 9 p.m. it was decided in consultation that he should be largely bled, and that he should have the following draught:—

R. M. Camphoræ ʒiiss.; Tinct. Digitalis, ℞x.; Acid. Hydrocyanici, ℥ij.; Sol. Acetat. Morphię, ℥v. M. Fiat haustus. Capiat haustum statim, et repetatur 2da quaque hora ad sex vices si opus sit.

A vein was opened in the arm, and it

was not closed till the blood ceased of itself to flow. He took the first draught at 10; at 12 he was pulseless; at half after 12 the pulse was again perceptible; he then took the second draught.

Feb. 14th.—He had no convulsion during the night; the bandage about his arm having become loose, he had lost some more blood. He had taken five of the draughts. He was now pulseless and insensible, with extremities cold. At 12 he had a violent paroxysm, which lasted fully two hours; after this he had only a few, and very slight. It was not until this period that his mental faculties were impaired. Before, he spoke much about religion, and quite rationally, but not so now.

He was salivated; had a blister to the scalp, and occasionally leeches to the head; under which treatment he gradually recovered.

One of the medical attendants gravely asserted, "that it was because his throat was dry that he could not drink." The following fact, however, shows that his aversion to fluids did not result simply from the difficulty experienced in swallowing them. He would occasionally ask to smell Eau de Cologne; at times it was grateful, but at others insupportable. I could not at first account for this; but I observed that when it was brought near him, he carefully turned his eyes away from it, and as long as he did not see it, it was grateful; but if it was so placed that he could not avoid seeing it, or if it was shaken before his eyes, then he could not bear it. This I repeatedly tried, and also Mr. L. B., and always with similar results. With regard to the pulse and tongue, they give little information: the pulse was quicker than natural, and the tongue clean throughout; the bowels were all along obstinately constipated—so much so, that twelve drops of croton oil did not affect them. I must not omit that he always wished the persons most dear to him to keep at a distance from him, being evidently apprehensive of doing them harm.

Now I would ask, if this be not a case of rabies, what is it? I am aware that it may be objected to its being rabies, that the dog was only irritated, and not rabid; that so great a lapse of time intervened between the bite and the occurrence of the above symptoms; that the dread of water, though generally well and strongly marked, was occasionally absent; and lastly, that

the patient has recovered, for rabies is deemed incurable. If, indeed, it be allowed that a dog greatly irritated can communicate rabies, the last objection falls to the ground; for can we conceive it possible that a dog should communicate rabies if at the time it be not rabid? If, then, in one single instance, a dog which remained afterwards well has communicated the disease, I think we are bound to consider it curable, at least in the dog. Dr. Colles, in his lectures, mentions a case which occurred to him. A lady, on seeing her lap-dog attacked by another dog, ordered her footman to separate them; in doing so, the man was bit in the thumb. Both the dogs were chained up, and continued well, yet the man died of rabies. Now I do not believe the powers of imagination so great as to cause the peculiar symptoms of true rabies, though they might cause hydrophobia.

I may observe, that those who only saw the patient occasionally, or for a short time, might easily believe him out of his senses; but all those who were with him constantly are agreed that he was not mad, but in his perfect senses; his manner being very remarkable, but quite different from what occurs in delirium or mania. I shall offer no apology for describing this case so minutely, for I consider it interesting, whether it be regarded as one of rabies (which I believe it to have been) or not.

[We should like to have further particulars about this very interesting case; particularly as to the mode in which the "salivation" was produced.—E.G.]

CASE OF

RETENTION OF URINE,

FROM TUMORS WITHIN THE BLADDER;
WITH A SACCULATED BLADDER; AND A
LARGE ACCUMULATION OF CALCULI.

To the Editor of the Medical Gazette.

SIR,

In the second volume of your journal, I published the case of a patient, who, during a severe illness, was found to have an unnatural enlargement connected with the bladder, in which the urine had been so long retained as seriously to endanger his life; but where the quantity of water passed, and the absence of the swelling above the pubes usual in cases of distended bladder, de-

layed, to a very late period, the employment of the catheter.

The remarkable circumstance in the case, as stated in the memoir referred to, was, a tumor in the abdomen "of an oblong form, situated in the right hypochondrium near the outer edge of the rectus muscle, extending nearly from the eleventh rib to the right side of the symphysis pubis, and being particularly prominent about the situation of the inner abdominal ring. It somewhat distended the integuments, so as to be perceptible to the eye, and might be considered to be about three inches in width." It is further stated, that the swelling corresponded with the description of no kind of hernia; was not elastic, betrayed no fluctuation, seemed to possess considerable solidity, and was not tender to the touch. The introduction of the catheter emptied the tumor of its urinary contents, and the patient rapidly recovered. The conclusion I came to was, that the case was one of preternaturally enlarged bladder; the mucous membrane having been pressed by the accumulation of urine, through the muscular coat; thus forming an enlarged sac through right hypochondrium.

Before this illness, Mr. Jones, the subject of the communication, had occasionally experienced some difficulty in passing his water; a bougie was introduced to ascertain if stricture existed, and the condition of the prostate gland was examined by the rectum, but no adequate cause for any obstruction to the free discharge of urine could be detected. On his recovery from this attack, which was in November 1827, he was not able to make water; it was evident that either some mechanical obstruction to the exit of the contents of the bladder existed, or that there was a complete atony of its muscular coat; there was no obstacle to the introduction of a catheter, nor was any calculus discoverable. He was taught to employ the catheter himself, and found it necessary to introduce it from four to six times in the twenty-four hours. At first he used a silver instrument, but afterwards gave preference to the elastic gum catheter. His health, which before his illness was not robust, was more impaired after that period: he was not often confined to bed, but complained of debility, and latterly had found walking fatiguing.

For the last twelve months his health had more declined: he was compelled to employ the catheter more frequently.

At times the drawing off the water was very painful to him; on which occasions it was scanty, and contained much purulent mucus. Sometimes small scales of calculeous matter stuck in the apertures at the point of the catheter, and rendered its withdrawal painful; and whenever a metallic instrument was used for some months before his death, it was felt to grate against a calculus.

He was under the necessity of taking opium for a considerable time, though not in large quantity; latterly he took a tea spoonful of the tincture at bed-time, and a small quantity once or twice in the day. He continued to walk to a short distance almost daily until the beginning of the present year.

On the 7th of February, 1837, he was seized with the usual symptoms of influenza, which was then universal in this city, in a severe form. Bronchial inflammation came on: he became much exhausted by the complaint; and the disorder of the bladder was more troublesome, the urine requiring to be drawn off every hour. The catarrhal symptoms, however, subsided, but he did not rally from the attack, and died in eleven days from the commencement of influenza, in the 66th year of his age.

As no objection was made to a post-mortem examination, the opportunity was not neglected of ascertaining, as far as was practicable, the original cause of impediment to the exit of the urine from the bladder; the nature of the distended sac, which was so remarkable a feature during the illness of 1827, and the condition of a bladder which, for nine years, had never evacuated its contents by its own muscular efforts.

On opening the abdomen, the fundus of the bladder was seen above the pubes, apparently distended with urine, but really containing very little: its coats were thickened, and its surface irregular, several rounded prominences being observed upon it. These projections, upon being felt, were found to contain calculi. During the unavoidable moving of the bladder, in the progress of the dissection, the calculi fell out of their cysts, and were heard to rattle within the bladder when it was at all inverted.

The object in this examination was to remove the bladder entire with the ureters, that these parts might afterwards undergo a careful inspection. On separating the connexions on the right side, on a level with the fundus of the

bladder, a cavity was unexpectedly penetrated, from which a gush of three or four ounces of clear urine took place; this proved to be the right ureter greatly distended, and brought much nearer to the parietes of the abdomen than was natural. The ureter was then divided at the part where it was wounded, and the portion connected with the bladder was removed with that viscus, as well as the left ureter, throughout its whole length. The right ureter was then traced to the pelvis of the kidney, and taken out with a part of the kidney. The right kidney shewed no peculiarity; the left was not minutely examined.

The appearances of the removed parts were as follows:—

The right ureter was much thickened in its coats, and enlarged in its calibre; the little finger could be introduced into it. At its connexion with the bladder it was particularly thick; and the bladder, at the point where this canal entered it, felt almost cartilaginous.

The left ureter was a little larger than natural.

The bladder and prostate gland were slit open from the caput Gallinaginis to the fundus. The prostate gland was increased to the size of a small orange. Attached to the prostate within the bladder were three distinct tuberculated, semi-cartilaginous excrescences: two of them were on the left side of the urethra; one was very prominent and loosely adhered by a narrow neck, and was about the size of a small hazelnut; the next, more in contact with the urethra, was less circular, and appeared more like an irregular projection of the gland itself. The third, on the right side, was the largest tubercle, and was firmly attached to the prostate. When the divided portions of the prostate were put in apposition, it was clear that these tumors entirely closed the aperture into the urethra from the bladder; the looser, and rounder one, might be aptly compared to the bullet valve of the stomach pump.

Within the bladder an extraordinary number of calculi presented themselves, of all sizes, from that of a moderate Spanish chestnut, to the dimensions of a small sweet-pea seed. Many of these were still embedded in pouches formed between the muscular fibres of the bladder; and similar cavities, from which other stones had escaped, were very numerous.

Of those stones that were removed, there were thirteen weighing, when dry, from four drachms and a half to ten grains, and about fifty smaller ones, weighing together two drachms and a half: their total weight was rather less than four ounces. Some of the smaller stones were so embedded in their pouches, that they could not be removed without squeezing them out, in consequence of their being larger than the mouth of the cavity containing them: a proof that these at least were formed in the part where they were found. In those parts of the bladder where they were embedded, the muscular fibres were so strongly marked as to give the surface very much the appearance of the fleshy bands and pillows found within the ventricles of the heart.

The valvular apertures where the ureters terminate in the bladder, were previous and natural.

A peculiarity in this case was, the uniformity in shape of nearly all the calculi, which were, with scarcely an exception, tetrahedral, even the minutest exhibiting the same appearance. Very few shewed any marks of attrition; and several were so situated as to be protected from rubbing against others, by their firm inclosure in their respective sacs. These calculi therefore exhibited their original form, having suffered no disturbance from contractions of the bladder, or attrition with other calculi. To any other cause than the effect of the muscular fibres in modifying their form, I am unable to attribute their angular shape, but it does not seem very easy to determine why so much similarity of form should have existed. How far this shape is common to calculi thus deposited in sacs, and excluded from friction with other stones, I am unable to say. In the beautiful collection of calculi in Mr. Richard Smith's museum in the Bristol Infirmary, consisting of four hundred specimens, I do not find one resembling them. They approximate most in figure to some biliary concretions, but the smooth sides of such formations seem to depend upon attrition within the gall-bladder. At what period these concretions began to be formed it is impossible to determine; had any existed at the time when the inability to void urine became confirmed, it is not probable that they would have escaped detection during the various explorations of the bladder which were

had recourse to, or the frequent introduction of the metallic catheter at that time employed. For several years he used elastic gum instruments, and had rarely occasion for surgical assistance in the employment of them.

The calculi, according to the analysis of a friend, consist almost entirely of phosphate of lime: a white sand, which coats most of the specimens, and is found to intervene between some of the layers of the solid parts, is uric acid.

Upon reviewing the symptoms in this case, and comparing them with the post-mortem appearances, there seems little room for doubting that the distended sac, which was so remarkable a feature during the patient's illness in 1827, was formed by the right ureter. No part of the bladder itself afforded any evidence of preternatural elongation: and though the ureter was now not more than a fourth part of the size of that tumor, the thickened state of the lower part of the tube, and of the bladder at the point where this canal opens into it, favour the probability of its having been formerly in a state of considerable distension.

The case presents an interesting example of a bladder which for nine years had never evacuated its contents by natural efforts, and of the changes produced within its cavity by so unusual a condition. The calculi lodged in the numerous sacculated cavities of the bladder, confirm the opinion of many writers, that such concretions are often deposited from the mucous secretion of that viscus, and not entirely from the urine: they were found to be as abundant at the fundus (where probably little urine reached them, from the bladder never being very full,) as they were at its lowest part near the neck; and many were lodged in little hollows of the mucous membrane, with only a very small opening communicating with the cavity of the bladder.

It was remarkable that the presence of so large an accumulation of foreign matter in the bladder produced no very material aggravation of the patient's inconvenience. More irritation than had formerly existed certainly supervened during the last year or two; purulent matter was often drawn off, and a more frequent introduction of the catheter was required; but as the coats of the bladder did not contract upon the stones, the ordinary sufferings of this

distressing complaint were not experienced.

The propriety of recommending the patient to undergo an operation for the removal of the calculi, was of course duly considered; but no hesitation was felt in the decision that, in such a case, it was inadmissible.—I am, sir,

Your obedient servant,

J. B. ESTLIN.

Bristol, December 15, 1837.

DIAGNOSIS IN ADHERENT PERICARDIUM.

To the Editor of the Medical Gazette.

SIR,

I TAKE leave to inclose herewith the case alluded to in my last communication, of adhesion between the heart and pericardium: ascertained by symptoms during life, and demonstrated in the examination of the dead body.

I have the honour to remain,

Your obedient and obliged servant,

THOS. WATSON.

Henrietta-street, Cavendish-square,
Dec. 23, 1837.

On the 11th of October, 1836, I was asked by my colleague, Dr. Sweatman, to see a patient with him, in St. John's Wood:—a Mr. S.

I was introduced to a gentleman, 39 years old, with a pale face and sharp thin features, sitting up in bed, breathing shortly and laboriously. His legs were anasarcaous; and his belly was tense and fluctuating. I had been previously informed that for years he had been given up to intemperance in drinking, and to indolent and low habits of life. Twice or thrice he had been affected with delirium tremens.

He complained to me that he was troubled with wind, shooting upwards through all the left side of his chest: on further inquiry I found he meant that he had much pain there.

A diffused sibilous wheezing was audible in the upper portions of the lungs on both sides: both sides were dull on percussion, in front and behind, at their lower part;—and on the right side no sound of respiration could be heard in that part. The jugular veins were swollen and tortuous. His pulse was frequent, and very feeble.

On applying my ear to the præcordial

region, I was immediately sensible of a very loud and harsh *to and fro* sound; a noise of rubbing, apparently close to the ribs, drowning all other sound in that space, keeping time with the alternate motions of the heart, and equally manifest when the patient held his breath. This sound was distinctly perceived by Dr. Sweatman.

I stated to him my conviction that our patient was labouring under recent and acute pericarditis. I concluded that he also had hydrothorax, and that, with respect to the heart, there was dilatation of its right cavities at least.

I ventured to predict that either Mr. S. would speedily die, while the rubbing sound continued, in which case the pericardium would be found inflamed, but unadherent, or only partially adherent, to the heart:—or, if he survived a few days, the remarkable sound of friction would altogether cease, which would indicate, with certainty, that adhesion had taken place.

He had been suffering in the same manner for three or four days; the pain in the left side, and (in all probability) the inflammation of the pericardium, having commenced on the 8th of October.

In the spring of that year, after having from indolence kept within the house for several months, he had crossed from the Isle of Man to Liverpool, and suffered a good deal from sea-sickness during the passage. As soon as he landed, he set out, in company with two other gentlemen, to walk a distance somewhat exceeding a mile. His companions, engaged in conversation, inadvertently outstripped him; and after some time they were called back, and found him supporting himself against a wall, very pale, greatly distressed in his breathing, and unable for some time to proceed. He attributed all his subsequent complaints to the over-exertion he then made; for he had been ailing thenceforward, though not confined to the house, till the attack on the 8th of October.

Mercury and some diuretic medicines were prescribed, and leeches were applied to the painful side.

I visited Mr. S. again on the 15th. He had been greatly relieved by the treatment adopted, being free from pain, and less swelled. The *to and fro* sound, however, continued; but it was less harsh, and confined to a smaller space.

On the 20th I saw him for the third and last time alive. The rubbing noise was entirely gone, and a dull, systolic, deep-seated bellows sound, had taken its place. He was making a vast quantity of urine, the dropsical affection had greatly diminished, and he professed himself to feel much better; but his pulse was scarcely perceptible.

On the 31st it was noticed that he spoke in an odd and unusually loud tone, and his pulse, as Dr. Sweatman informed me, could not be felt; but he said he suffered no pain, and he seemed to breathe with tolerable ease.

In the course of that evening he sat up in bed to swallow a dose of medicine; and having done so, he leaned his head against the nurse, who was supporting him, and presently expired.

The body was opened the next day by Mr. Shaw, in the presence of Dr. Sweatman and myself. I did not hesitate to express my certain persuasion that the heart and pericardium were adherent.

The abdomen was first examined. It contained a large quantity of clear serous fluid. The liver was covered with a thin layer of reticulated lymph, and connected by a few slender and soft strings of lymph to the diaphragm.

There was much fluid in each pleura also. The right lung occupied exclusively the upper part of the cavity, its inferior margin being turned upwards, and fixed by a strong band of adhesion, half an inch in length, to one of the ribs, about midway between the diaphragm and the clavicle; so that the fluid must have been poured out, and have floated the edge of the lung to that height before it adhered.

The left pleura was quite healthy.

The heart was large. The cavity of the pericardium was entirely obliterated, the opposed serous surfaces of the membrane being united by means of a thick layer of soft mottled lymph. They were easily separated by very gentle traction.

All the cavities of the heart were larger than natural; those of the right side were much dilated; the left were filled with dark clotted blood; the walls of the ventricles being considerably thickened. Both the mitral and the aortic valves were morbidly thick and stiff, but there were no "vegetations."

The aorta expanded, just beyond its valves, into a small pouch, in some spots of which circular depressions were visible. Here the coats of the vessel were thinner than elsewhere, and translucent, presenting apparently the first steps towards aneurism. At a greater distance from its mouth, the surface of the aorta was rendered irregular by small opaque, yellow patches, projecting its inner membrane.

To make the case complete, I have given the history and the dissection in full; but its chief interest consists in the confirmation afforded, by the inspection of the dead body, to the special diagnosis derived from the auscultatory symptoms during life.

The existence of the *to and fro* sound was good evidence (as I thought) that the pericardium was made rough by inflammation; the total cessation of that sound was to me a sign that the pericardium had become fixed, more or less extensively, to the surface of the heart, and the further continuance of the rubbing thus rendered physically impossible. In many previous instances, reflection upon this succession of phenomena had satisfied my mind as to the state of the parts within the chest. On this, and on one former occasion (see *MED. GAZ.* vol. xviii. pp. 701, &c.), an early examination of the affected organ—the actual spectacle of the serous surfaces glued together by tender and recent lymph—brought the force of demonstration to that which before had only been a matter of circumstantial evidence.

I may add, that my colleague, Dr. Wilson, has just dismissed from the hospital a lad, in whom, during an attack of acute rheumatism, a well-marked *to and fro* sound arose, continued a few days, then ceased entirely, and was succeeded by a strong systolic bellows or cooing sound. Dr. Wilson showed me also, some days ago, a young woman, in whom, as I well remembered, the same rubbing sound had been equally distinct and temporary, in a severe attack of the same disease which she suffered in the hospital two years before. She has now the appearance of perfect health, and the cardiac sounds are not unnatural. But there can be no reasonable doubt that, in both these persons, the pericardium is adherent to the heart; and such cases are common.

Artis Medicæ tueri: potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”

CICERO.

A CASE OF LIFE-INSURANCE.

A REMARKABLE trial, lasting three days, which turned upon the validity of a policy of life-insurance, lately took place in the Court of Queen's Bench. We take the report from the *Times* of December 15th.

An action was brought by the Eagle against the Atlas Insurance Company, to recover 4000*l.* upon a policy effected by the former company upon the life of Mr. John Cockrane. The life of this gentleman was insured on the 24th of September, 1834, for four years. The Eagle Office gave him 12,000*l.*, on condition of receiving 16,000*l.* if he survived the above time; and having advanced the whole of the money in the first instance, insured his life in the Atlas, the Hope, the Promoter, and the Union Offices. Mr. Cockrane died in April 1835. The Sun alone paid the sum insured, the others refusing on the grounds—1st, that at the time the insurance was effected, Mr. Cockrane was afflicted with a disease tending to shorten life; 2dly, that his habits were those of a confirmed drunkard; and 3dly, that these facts had been concealed, by which circumstance the policy became void.

The first witness called was Mr. H. Porter Smith, the actuary of the Eagle Insurance Company, who deposed that, in 1834, an application was made to lend Mr. J. Cockrane a sum which involved an insurance of 12,000*l.* for four years; that he was examined by Dr. Spurgin and Mr. Sayner, the medical officers of the institution, and reported

an eligible life; that as the Eagle does not insure more than 5000*l.* on one life, he gave Mr. Cockrane a note to the Atlas, and soon received an answer accepting the proposal. Mr. H. P. Smith applied in the same way to the Economic; but on the 22d of September, Mr. Downes, of that office came, and said that there was an objection to the life.

Mr. Sayner and Dr. Spurgin were the next witnesses, and deposed to having examined Mr. J. Cockrane in September 1834, and having considered him an unexceptionable life.

Then came Mr. Bennett, the medical attendant of the deceased, who stated that, in September 1834, Mr. Cockrane was in good health. He gave answers to the office at the request of Major Williams. Among other things Mr. Bennett is made to say, “I have heard people say that he was given to drinking, but I do not know that it was the common talk, and never considered his habits intemperate.”

A cousin of Mr. Cockrane's was next examined, who did not visit him; he stated that he had no appearance of being addicted to drinking.

Then there comes one Rickman, a news-keeper, who confesses, on cross-examination, that he has seen Mr. Cockrane take shrub and peppermint at all hours, perhaps five or six times in the course of the day, according to the distance they went when driving out together; and that he had also two or three houses in the neighbourhood at which he would take a glass of ale, or sherry and water, before going out. He has seen Mr. Cockrane's servants dine with him at his own table, and believes they did so every day.

On re-examination, Rickman says, with a coolness worthy of a higher station, “Cockrane never appeared to me to take any thing to hurt a man. I

never saw him drink more than the rest of the company. I only saw him intoxicated fifty or sixty times in four years. His health did not seem to be impaired by what he drank."

After the testimony of another cousin to the goodness of the constitution of the deceased, we come to the very curious evidence of Frederick Hammond, his groom. He stated that he had "seen him tipsy a hundred times, perhaps, but not beastly drunk." When he was going about he drank sherry and water, brandy and water, ale, rum, shrub, and gin and peppermint; it did not matter what. He would sometimes lie in bed for three or four days at a time, and then he had liquors in his bed-room, and the servants drank theirs also in his sleeping-room—"we all had our song together."

He adds, "Mr. Bennett has seen us in the bed-room with the liquor. * * There was always liquor about when my master was at home. I have heard Mr. Bennett say it was a pity that Mr. Cockrane drank, and that it was his rattling about so that made him ill."

The depositions of a number of persons residing at Paris and Calais, at the latter of which places Mr. Cockrane died, were now read. One of the witnesses deposed that the death was caused by severe inflammation of the lungs; the others stated that he was an insurable life.

The evidence of another witness, stating that the appearance of Mr. Cockrane, in 1834, was that of a strong healthy young man, and that "he looked in the face something like a strong Welch girl, as he had no whiskers," closed the plaintiff's case.

Mr. Serjeant Wilde, who now addressed the jury for the defendant, observed, that even the case as set forth by the plaintiff's witnesses, must decide their verdict in favour of the defendant; but that if any doubt remained in their

minds, it would be totally removed by the evidence which he should bring forward. He abandoned the first and second pleas, which alledged that at the time of effecting the insurance, Mr. J. Cockrane was afflicted with a disease tending to shorten life; but he contended that his habits of life were known to the Eagle office through a communication made to them in the report by Mr. Travers, examining surgeon to the Economie; and that as these facts had been concealed by them from the defendant, the policy was void, and his client entitled to a verdict.

Among the numerous witnesses called by the learned Serjeant, Dennis Wooding deposed that, in 1833 and 1834, Mr. Cockrane "was almost always muddling; his eyes were ready to start from his head, and his hands shook so that he could not sometimes write his name for two or three days." Mr. Missing, a barrister, deposed to Mr. Cockrane's coming to his house to dine in a tipsy state, so that he could not eat, but drank only.

A publican, whose house was frequented by the deceased, states that he had frequently seen him intoxicated, and that Mr. Bennett remarked he was taking all the pains he could to kill himself.

Mr. Russell, who kept the George, at Kingston, deposed that the deceased once came to his house with Rickman, and died there. "He went to bed soon after dinner; and shortly after he went to bed, some musicians played under the window. He rang for his servant, and I saw them dancing about the room together. He was intoxicated. He got up the same evening, and they all left together. This took place the latter end of September 1834." On cross-examination, the witness stated that Mr. Cockrane associated so much with his servants, that, for the first two years, he thought they were all grooms.

Another witness, ostler to Rickman, says that Cockrane used to get the better of the liquor he had taken at night by repeating it in the morning. Witness dined with the deceased in 1834, the remainder of the party consisting of five servants.

Mr. Travers visited him at home, in bed, at half-past 4, in a state of stupid intoxication, and then went to see Mr. Bennett. His medical attendants led him to suppose that his habits were not confirmed, but that he was only occasionally in liquor. Mr. Travers, however, suspecting that all was not right, made a special report, and the directors of the Economic rejected the life.

Mr. Aston Key saw Mr. Cockrane, at the Promoter office, on the 24th September, 1834. His first impression was that he was under the influence of liquor, but his opinion was altered by the certificates of Mr. Bennett and Mr. Neale*.

We have been compelled, by want of room, to abridge the evidence extremely; yet we hope we have retained enough to make the case intelligible. Young Cockrane appears to have had an invincible taste for low company; sometimes drinking spirits with publicans and mews-men, sometimes dancing about his room, or playing at skittles, with his servants, and at all times enacting the part of a groom, with a fidelity unrivalled on any stage; so that for two whole years he deceived a most practised eye, and was the very character for which he dressed! As for the drinking part, most of the witnesses whom we have quoted, and many whom we have not had room to quote, testify to his being continually tipsy, flustered, or drunk. From patrician Champagne down to plebeian gin, nothing came amiss to him; "from morn

to dewy eve," rum-and-milk, ale, brandy-and-water, shrub, and wine, had their turns.

"He certainly does appear," says Lord Denman, "to have been one of the most wretched young men one has ever heard described. Well born, without a single decent habit; well connected, without one respectable companion; the young son of a widowed mother, without any appearance of feeling or affection."

In a medico-legal point of view, the case presents some difficulties.

For the plaintiff it might possibly be argued, in the first place, that Cockrane's life was really an insurable one, and would have been so, even if all had been originally known that came out upon the trial; that the drunkenness which renders a life uninsurable must be an habitual and deep intoxication, and not a mere habit of muddling; that if all habitual deviation from extreme sobriety rendered a policy void, life-insurance must be at an end, or confined to *tea-totallers*; just as if we strictly interpreted the warranty that the insurer is not liable to any disease tending to shorten life, we should exclude all who were subject to headache, dyspepsia, or winter-cough, *i. e.* ninety-nine in a hundred.

In the second place, it might be urged for the plaintiff, that he had no knowledge of the facts now produced; that Mr. Bennett, the medical attendant of the deceased, positively certified that he was not intemperate; that Dr. Spurgin and Mr. Sayner were both satisfied with his appearance; and that the temporary doubt created by Mr. Travers's report was speedily cleared up by the explanation given by Mr. Bennett, namely, that Mr. Cockrane's confused appearance and short answers arose from grief, occasioned by the recent death of his mother.

To this it might be replied for the defendant, in the first place, that Cock-

* Lord Denman, in his charge to the jury, asks, "Who is Neale?"

rance's life was not substantially and truly an insurable one: that Mr Aston Key, after whose "not very favourable" report the life was accepted by the Promoter, says in his evidence, that if he had heard at the time one-tenth of what he has heard during the trial, he should have said the life was not insurable; that to make a policy void, it is not necessary that the drunkenness should be of the kind called "bestly" by one of the witnesses, but that the constant muddling which disorganizes the brain, the liver, and the heart, is quite sufficient; that two cases in which it was proved that habits of intoxication were concealed from the insurers, although the individuals were at the time apparently hale and healthy, have been decided against the plaintiffs*; and that a habit, scarcely if at all compatible with long life, ought not to be compared with dyspepsia and other ailments which, in many cases, do not sensibly affect the duration of existence. And, in the second place, even if we do not regard the facts of the case as they now appear in all their deformity, but as they might reasonably appear to an impartial judge in September 1834, we have the very unfavourable certificate of Mr. Travers, and the not very favourable one of Mr. Aston Key, which, if communicated, would have settled the business, and prevented any further insurances.

Lord Denman charged the jury for the defendant, on the ground of the certificates given by Messrs. Bennett and Neale having been contrary to plain facts which must have been well known to them: the jury found for the plaintiff, probably believing that though the certificates were far from being correct, the plaintiff had not sufficient ground for distrusting them, more especially as Lord Denman allowed that the reports

made by medical examiners to their officers were confidential communications, not to be divulged.

The point, it must be owned, is a dubious one; and we shall not be surprised to hear of an application for a new trial.

CASE OF GLANDERS IN THE HUMAN SUBJECT.

To the Editor of the Medical Gazette.

SIR,

THE inclosed is the history of a case of *Glanders*, copied from my note-book, which occurred in a patient of Mr. Morgan's; being one of his dressers, the case consequently came more directly under my notice. If deemed sufficiently interesting, I shall feel obliged by your inserting it in the next number of your valuable periodical.—I am, sir,

Your obedient servant,

J. G. DA. C. DENHAM.

Library, Guy's Hospital,
Dec. 12th, 1837.

Thomas Worcester, æt. 21, of plethoric habit, was admitted into Philip ward, Guy's Hospital, on the 27th November, 1837, under the care of Mr. Morgan, labouring under acute synovitis. A short time after admission the following history was obtained from him:—He states that he is a carman, in the employment of Mr. Nichol, of Dowgate Hill; has enjoyed good health for the last four years. About a week prior to admission, it appears that he injured his left knee, by its becoming jarred between two barrels; for the first four days after the accident he experienced but little inconvenience; but early on the morning of the fifth day he awoke with excruciating pain in the knee, and on the same day applied at the surgery of the hospital, where he was seen by Mr. Rose, one of the dressers for the week, who gave him some medicine and cupped him on the knee, by which he was greatly relieved; but on the following day and night he suffered a great deal of pain, and on the next morning, being brought in a cart to the hospital, he was received into the above ward.

Nov. 27.—Present condition is as follows: Knee swollen, hot, and painful; countenance anxious; breathing hurried; tongue furred. Pulse 96; skin hot and dry; bowels costive. He was shortly seen by Mr. Morgan, who ordered the following:

* Beck's Elements of Medical Jurisprudence, 5th edit. p. 385.

R Hydr. Chlor. gr. i. cum Extr. Coloc. co. gr. vj. statim sumend. Haust Magn. Sulph. hor. post pil. Hirud. No. xx. parti dolent.

Leg to be kept semiflexed, and supported by pillows.

28th.—Bowels have been freely opened; knee is still very painful; did not sleep during the night; tongue continues furred. Pulse 98; skin hot and dry; he was ordered—

R Pulv. Jacob. gr. iv.; Hydr. Chlor. gr. ij.; Pulv. Opil. gr. i. statim cap. Hirud. xx. ut antea applicentur.

29th.—Much the same as yesterday.

Rep. Hirud. et Med.

30th.—Slept better last night; knee not quite so painful; complains of thirst; urine is high coloured; tongue still continues furred.

R Haust. Efferves. t. d.

R Julep. Menth. Pip. Ziss. cam Liq. Op. Sed. (Battley) nxxx. horâ somni, o. n.

Dec. 1st.—Is better to-day; knee continues swollen; slept very well last night; skin not so hot; pulse 96; tongue cleaner.

Rep. Med. Efferves.

2d.—Knee very painful; had an attack of rigors last night; tongue furred; skin hot; pulse 106; complains of sensation of chilliness over his body. Mr. Morgan ordered the leg to be kept in an extended position by means of a splint.

Rep. Medic. ut antea. Omit. Haust. Anod. h. s.

3d.—On entering the ward this morning, the nurse states that he had had a very restless night, and during sleep was constantly talking about horses. There is a slight discharge to-day from the right eye, and several faint spots seen over the face and body. The general swelling of the knee has greatly subsided; on the inner side a small abscess has formed, which has been opened, and a poultice applied.

4th.—The spots observed yesterday are much more visible to-day; the knee still continues discharging; skin hot; upper lid of right eye rather more swollen than it was yesterday. Mr. Morgan saw him at 1 p.m., and wished him to continue the effervescent medicine, and stated most probably we should in the evening be able to decide what the eruption was; at present there are several small red indurated points, one or two vesicular at their summits, which induced Mr. Morgan to suppose it might be a case of modified small-pox.

5th.—The right eye is very much swol-

len and painful; the discharge from it has increased; there is also a sero-purulent discharge from the nose. Pulse 120; bowels open; head painful; delirium at times present. The eruption has at present a good deal of the appearance of small pox; many are decided pustules, with an inflamed base. Skin is hot and dry; the knee is improving, but there is still a discharge of pus from it.

R Pulv. Jacobi, gr. iv.; Hydr. Chlor. gr. j. statim. Rep. Med. Efferves.

6th.—The right eye is completely closed; lid much swollen; and the forehead on the same side has a crimson appearance. The discharge from this eye is becoming purulent; the left eye is also becoming affected; there are several fresh spots about the arms and legs; skin still continues hot; head painful; he was delirious during the night. Bowels freely open; pulse 120, having a good deal of power; breathing hurried.

Rep. Pil. ut heri, cum Hydr. Chlor. gr. ij.

7th.—Has several fresh spots; those having first appeared are losing their small-pox character, although there are several which still resemble that eruption. There are this morning on the lower extremities several purple spots, about the size of a four-penny piece, the base of which can be felt indurated. Both eyes are now closed; there is great tumefaction over the forehead, accompanied with tension, heat, and pain. There is excessive discharge from both eyes, and also from the nose, and the right cheek is also slightly swollen; the discharge seems to be of a sero-purulent character. Pulse 120, and continues full; skin hot; tongue covered with a brown fur; passes both stools and urine involuntarily; motions are dark-coloured and offensive. Mr. Morgan ordered face, eyelids, and forehead, to be scarified, and the effervescent medicine to be repeated; poultices to be applied afterwards to the above parts.

8th, 10 A.M.—Discharge from eyes and nose has increased considerably; tongue very much swollen, and covered with a black fur. Shortly after yesterday's report, about half a cupful of dark blood came away from his mouth. The indurations already observed beneath the purple spots have increased in size. He was delirious during the night. Pulse is at present 110, feeble; respiration hurried; the integuments about the knee have commenced sloughing. Mr. Morgan saw him at half-past 1 p.m., and ordered the following:—

Port-wine poultice to knee.

R Julep. Ammon. ʒij. t. d.; Pulv. Ja-

cobi, gr. ij.; Hyd. Chlor. gr. ij. h. s.; and port-wine, beat up with eggs, to be given three or four times in the course of the day.

During the afternoon he was seen by Dr. Addison, who thought, from the present appearance and peculiarity of the eruption, that it resembled more than any thing the eruption peculiar to glanders; but not having seen a case of this disease, he stated that he could not confidently decide as to its nature.

5 P.M.—Continues much the same as in the morning; his pulse, if any difference, is rather quicker. The pulse 140; the indurated swellings above noticed have increased since the morning, and are now covered by an inflammatory blush. Mr. Key saw him at 9 o'clock P.M., who also coincided in the opinion that it resembled a case of glanders. Many of the hard swellings had by this time softened down. His breathing is now very laborious. From this time he gradually became worse, and died at a quarter past twelve.

Further particulars.—This being rather an interesting case, I was anxious to obtain a further history of the patient; consequently I called upon his mother, on Friday evening, the 8th instant, and obtained from her the following account:—She stated that her son had enjoyed very good health during the last four or five years; he had the small-pox when he was six years old, and at present he was in the employment of Mr. Nichol, of Dowgate Hill, for whom he was taking care of a sick horse; and also that she never heard him complain of having been *hit on the hand, or any other part of the body*, by the horse. This statement not being sufficiently satisfactory in my mind to account for the disease, I went, therefore, yesterday morning and called upon Mr. Nichol, from whom I obtained the following additional history. He stated that the patient had the charge of one of his horses, which had been ill for some time, but was now *rapidly recovering*. The veterinary surgeon had told him the horse had farcy. From Mr. N. I also learnt that the patient was, in his habits, very intemperate; so much so, indeed, that he was unable frequently to pay for his lodging, and was obliged consequently to sleep under the manger of the sick horse. This very horse happened to be on Mr. Nichol's premises when I called; I therefore saw him, and the only peculiarity I observed about him was a discharge, of a mucopurulent character, from the nose, and two or three swellings on the legs; from one of them there was a slight discharge.

Worcester's body was not examined after death.

	F.	58	Burn on the neck.
	F.	40	Scald on the foot.

In-patients..... 28

Out-patients..... 34

Total during the week .. 62

(a.) This man quitted the hospital contrary to advice the day after admission, but returned again in three days, with erysipelas of the head and face, and was again taken in. It is a general rule at the hospital to admit all patients applying with cuts on the head, since, when treated as out-patients, in consequence of intemperance and exposure, they frequently return affected with erysipelas. The patient is doing well.

(b.) This patient was brought to the hospital from some distance in the country, by a surgeon who had made ineffectual

efforts at reduction. The hernia was reduced, however, in a short time, by one of the house-pupils.

(c.) *Femoral Hernia—Difficult Diagnosis—Operation.*

This patient was a female, aged 50, who was brought to the hospital, Saturday, Dec. 8th, in the evening, supposed to be labouring under strangulated hernia. She was weak, and gave indistinct replies to the questions put to her; she stated, however, that she had been subject to a swelling in the left groin for two years, but that it had become painful since Monday last, from which time no motion had passed from the bowels. There were two small tumors, about the size of hazel-nuts, moveable, round, and closely connected in the situation of the femoral ring; they were slightly painful on pressure, received no impulse on coughing, and at their base there was something like a narrow neck leading towards the ring. The abdomen was tense, tympanitic, and painful on pressure; the pulse small and quick. She had been sick before admission, but could now retain fluid upon her stomach. Considerable doubt being entertained as to the existence of hernia, she was ordered—

Magnes. Sulphat. ʒij. in Aq. Menth.
Piperit. donec alvus responderit; and a purgative clyster.

Dec. 9th.—About 2½ P.M. she had a motion, consisting of a quantity of hardened feces and the enema. In the morning, about 9, as she was unable to pass her water, it was drawn off, and the clyster repeated, but without being followed by evacuations. The purgative draught was omitted, but resumed again at 2 P.M.

9½ P.M.—She was evidently much worse. Vomiting; extremities cold; pulse almost imperceptible; bowels still constipated. It was now thought advisable to make an examination of the inguinal tumor; and the patient was operated on in the ward near the fire.

The two small tumors were found to consist of adipose matter, invested with condensed cellular tissue. Beneath, but closely adherent, was perceived a whitish membranous substance, which being divided, was found to be a hernial sac, with a very small portion of dark coloured intestine adherent to it. The neck of the sac was afterwards divided with a bistoury, to remove all constriction, and the wound was then closed. A quantity of turbid serum escaped from the abdomen after the opening of the sac. During the operation the woman was in such a state of collapse, that it became necessary to give her brandy; and she only survived it five hours.

The body was examined eleven hours after death. The peritonæum generally was found much injected. A small protruding portion of the ileum, like the end of a finger-glove, and of a dark colour, was adherent to the peritonæum at the femoral ring. This was the part met with in the operation; but about an inch and a half beyond there was an evident constriction of the whole calibre of the intestine, with thinning of the coats. Whilst handling the gut, a quantity of liquid feculent matter escaped from an ulcerated opening at the contracted part. There were several ounces of turbid serum, mixed with feculent matter, in the general cavity; but whether any part of the latter escaped during life, could not be satisfactorily determined. Heart, lungs, and liver, sound.

This case is of considerable interest, and of an instructive nature. The diagnosis was extremely difficult. An accurate history could not be obtained, as the woman gave conflicting statements. On one occasion she said that there had been a larger tumor when she was first taken ill, but it had subsequently gone away. This would agree with the morbid appearances, since it was found that the contracted and ulcerated part of the intestine was not strictured at the time of the operation. Indeed, there is every reason to believe that the intestine had been reduced before the patient's admission, although the ill effects of the stricture, ulceration and contraction of the intestine, adhesion to the sac, and peritoneal inflammation, remained to impede the functions of the intestine, and were ultimately the cause of death. Had not the two adipose tumors been accidentally developed on the exterior of the sac, it is very questionable whether any hernial tumor would have been detected. When the patient was first admitted, in consequence of the glandular feel of these tumors, the statement of the woman that she had been ill nearly a fortnight, and the absence of vomiting, the swelling was pronounced not to be hernial, and the case peritoneal inflammation. As the obstinate constipation continued, and was succeeded by vomiting, and as the patient was gradually declining, it was eventually thought desirable to make an examination of the swelling; and although no benefit can be said to have resulted from the operation, the case tends still to confirm the general rule, "that in all cases of tumor, the hernial nature of which is doubtful, it is better, provided the symptoms of strangulation continue, to operate."

PHYSICAL SOCIETY, GUY'S HOSPITAL,

December 16, 1837.

MR. ASTON KEY IN THE CHAIR.

MR. MOLLOY read a thesis,

On the Influence of the Circulation in producing certain Cerebral Affections.

The object of the author, in this essay, was to show the great influence exercised by the vascular system, in producing certain cerebral affections. For a considerable time past, it had been very much the custom with pathologists, when tracing the origin of disease, to refer it ultimately to the nervous system. The universality of this explanation was objected to by the author; 1st. By reference to the physiology of that system, which demonstrated that was adapted to receive and transmit impressions; but, as far as our knowledge yet extended, was never capable of originating them. 2d. In many of those instances where the nervous system was admitted to be deranged, the cause of such derangement might, with a little consideration, be traced to the circulating system.

After discussing the physiology of the cerebral circulation, the author proceeded to comment upon those diseases in which the vascular system was undoubtedly disturbed: such were cerebral congestion and apoplexy.

The latter affection being of most frequent occurrence, occupied the greater part of his attention; and the action of the heart (hypertrophy of) and arteries in their production, was dwelt upon at considerable length. Other causes of cerebral lesions, less generally known, were referred to—viz. those arising from various conditions of the pulmonary system, and of the cavities on the right side of the heart; also tumors pressing upon the jugular and other veins, whereby the free return of blood from the cerebral mass to the heart was impeded.

Dr. GUY rose to mention a fact which he thought might bear upon the subject of the cerebral circulation. It was, that the body being placed in the inverted posture, the pulse became diminished in frequency. This result was in direct variance with that obtained by Dr. Graves, from similar experiments: this difference, Dr. GUY thought, might be explained by the supposition that Dr. Graves had allowed muscular action to be used by the subject of experiment, while assuming the inverted posture; whereas he himself had taken the precaution of performing his experi-

ments with the aid of a revolving board. Dr. GUY left the explanation with the Society.

MR. HILTON remarked, that there was a simple anatomical explanation for this phenomenon. When the body is inverted, a great accumulation of blood in the brain takes place, from the agency of two powers—gravitation, and the action of the heart: the former, because the column of blood in the inferior cava (unsupported by valves) and lower veins, pressing by gravitation into the right auricle of the heart, fills it, and prevents the free admission of that from the superior cava;—the latter, because the heart still continues to send blood into the brain, which, from the operation of the first cause, cannot be readily returned. Hence arise congestion in the brain, diminished respiration, and a sluggish pulse.

MR. GREENWOOD wished to know if it was well proved that the circulation of blood through the vertebral arteries was more necessary to life than that through the carotids.

MR. KEY said, that the experiments of Sir Astley Cooper and of Mr. Bransby Cooper upon dogs, published in the Guy's Hospital Reports, appeared to have completely decided the question. A case, however, occurred in Guy's some years ago, in which he had tied the carotid artery on the distal side of an aneurism: the patient was carried to bed, and died three hours afterwards, tranquilly, as if going to sleep. Upon inspection, the carotid artery of the opposite side was found obstructed to such a degree that a probe could scarcely be passed*.

The discussion now turned upon several points connected with the pathology and symptoms of certain cerebral lesions; in the course of which, many interesting facts, with observations, were brought forward by Dr. Whiting, Mr. Hilton, Mr. Roderick, Mr. Aspland, Mr. Chevers, Mr. Haygarth, Mr. J. Chapman, Mr. Key, and the author of the paper. These our limited space prevents us from giving at full length, whilst it would be doing injustice to their value to attempt a mere outline.

At the close of the discussion, thanks were voted to Mr. Molloy for his communication, and the Society adjourned to Saturday, 30th of December, at 8 P.M.; when Mr. Birkett will relate some cases of Psoas Abscess: Dr. Hughes in the chair.

* The preparation is in the Museum of the hospital, and the case was reported at the time, in the MEDICAL GAZETTE.

FURTHER REPORT
OF

CASES OCCURRING IN THE
CLINIQUE OF M. LOUIS,

At the Hôpital de la Pitié, Paris.

By HENRY CURLING, Esq.

CASE I.—*Pleurisy—Dilatation of the Bronchi—Fœtid Sputa.*

A FEMALE cook, aged 36, of a strong constitution, was admitted, under M. Louis, March 1st, 1837. She stated, that she had been very subject to colds for several years, and that, eighteen months ago, she had an attack of inflammation of the lungs; since then she has often "heard noises in her chest," but always on the right side. She has had the *grippe*, and was in La Charité, which hospital she left eight days since, but was not quite convalescent. Previous to her entry, her neighbours had remarked the fœtid odour of her sputa. The day after she left La Charité, she felt a pain in her right side, which was increased by coughing, and accompanied by fever and anorexia. These symptoms have continued, so that she walked with difficulty to the hospital.

Her countenance is pale, otherwise natural; heat of skin natural; pulse 68; coughs at intervals; sputa few in number, very fœtid, round, flattened, and of a greenish hue, floating in a salivary fluid; pain inconsiderable, situated laterally two inches above the right false ribs. Posteriorly, on the right side, percussion yields an obscure sound in the two inferior thirds extending laterally, as far as a perpendicular line dropped from the axilla. Bronchophony in many points of this space, and very well marked about two inches above the false ribs. Gargouillement and cavernous respiration heard in the same spots anteriorly. Percussion is obscure on the right side, to within two inches of the clavicle; the respiration is not bronchial, but harsh; doubtful ægophony and a little cræpement. On the left side, percussion and respiration are healthy, with the exception of a subcrepitant rhœphas posteriorly and inferiorly.

She has had three children; commenced menstruating at 15 years, and since she has been in Paris (four months) has menstruated every fortnight. The youngest child is sixteen years old.

Ptisan. Sodæ Chlorid. ʒj. in die sum.

March 2d.—The symptoms the same as yesterday. Percussion and auscultation afford the same results. She has never expectorated blood. Sputa not fœtid.

To omit the Chloride of Soda. Eau de Vichy, half a bottle daily.

On the 4th inst. she left her bed, but auscultation, daily repeated, did not vary in its results. On the 6th, the retentissement was almost amphorique. Her strength improved daily, and she soon gained her original embonpoint. At the end of the month she entered the service of the hospital as a nurse, but the gargouillement and pectoriloquy still existed. The sputa were not, however, fœtid, and percussion was not so dull on the right side.

REMARKS.—M. Louis's first impression, before he had fully interrogated the patient, was, that the disease was pneumonia; but reflecting on its slow march, on the great extent of the dull sound, on the little fever which had attended it, and on the gargouillement and cavernous respiration, he attributed these symptoms to gangrene of the lung. The diagnosis was apparently confirmed by the presence of fœtid sputa at the commencement; which symptom is considered pathognomonic of gangrene. But this symptom is not always constant; M. Louis has seen many cases in which the fœtid sputa have disappeared and returned, and yet, after death, gangrene of the lung has been discovered. Other physicians have remarked the same, so that this symptom seems to be of doubtful value. M. Louis has also observed fœtid sputa in pneumonia. But there is another disease very frequently accompanied by fœtid expectoration—viz. dilatation of the bronchi. When the bronchi are dilated, their parietes are thickened, the surrounding lung is compressed and rendered denser, and therefore percussion is generally duller on that side. But this would not account for the extensive dullness in this case; so that M. Louis ultimately attributed the symptoms to pleurisy, complicated with dilatation of the bronchi. The situation of the cavity at once showed that it had not a tubercular origin; besides the patient had no symptoms of this disease.

Dilatation of the bronchi is not always a chronic affection. Three years ago, M. Louis had under his care a female, suffering from a very severe headache, which, during a long period, had resisted all treatment. The pain ceased, however, after the application of a blister to the head. When on the point of leaving the hospital a cough was developed; and, on examining the chest, the existence of tubercles was discovered at the summit of both lungs. After the expiration of three weeks she died. Tubercles were found in every stage, and some of the bronchi were very much dilated. When she was first admitted into the hospital, her chest

was examined with great care, to detect some cause for the headache. It was again carefully examined when the cough commenced, but at neither of these periods was the dilatation detected; so that at that time it apparently did not exist.

CASE II.—*Chlorosis—Pericarditis.*

A woman, aged 30, was admitted into La Pitié, March 21st. She says that she has not been quite well for eighteen months. Her menstruation has become scanty, of a light colour, and followed by a little leucorrhœa; her countenance has grown pale, and she has been frequently troubled with headache, but her appetite has always continued good. About a fortnight ago her face began to swell, particularly her eyelids; her legs were also in the same state, and she was at the same time attacked with palpitations and dyspnoea, and a little slight cough.

21st.—She presented the following state:—Dark hair; a pale-yellow complexion; tongue and lips pale; face and eyelids swollen; no desquamation of the skin; the lower extremities pit slightly on pressure; she complains of headache; has never expectorated blood, nor had palpitations or swelling of the feet, before this time. A bruit-de-soufflet in the precordial region, but the respiration is audible there; continual bourdonnement in the carotids; percussion not so loud over the precordial region as elsewhere; a little eraquement inferiorly and posteriorly on both sides.

R Ferri Carbon. gr. iv. bis in die sumend.

23d.—The palpitations and bruit-de-soufflet continue; pulsations of the heart deep and obscure; a dull sound upon percussion between the sternum and left mamma, for about $1\frac{1}{2}$ inches; respiration inaudible in this space; there is also a slight projection of the chest, extending to within two inches of the clavicle. Pulse 92, regular, and without intermittance. Percussion is painful on the left side; sleeps with her head elevated, but only during the last month; heat of skin natural.

Ptisan to contain Potass. Acet. ʒss.
Diet. Lavement. Venæsectio ad ʒx.

24th.—Feels relieved; pulse 84 yesterday evening, 100 this morning, but accelerated by the visit. Tongue and cheeks more coloured; respiratory murmur audible in the precordial region, and a louder sound upon percussion. Pulsations of the heart more superficial, but not distinct.

Pil. Digitalis, gr. j. Venæsectio si opus sit.

On the 25th, the palpitations ceased; the obscurity of sound was less on the left side; the pulse was 104.

On the 28th the pulse was 86, and she had a little appetite.

She was ordered Carb. Ferri, and to continue the Digitalis.

April 1st.—There was no œdema, and scarcely any difference of sound between the right and left sides, and the respiratory murmur was every where audible. She soon left the hospital convalescent.

There were two distinct epochs in this case. At the commencement, the patient's disease was chlorosis, indicated by alteration in the menstruation, loss of colour, and headache. The palpitations, which were developed at a later period, might be attributed to that disease; but the dull sound upon percussion, the alteration in the form of the chest, the slight fever, and the absence of impulsion, seemed to indicate the existence of pericarditis, and to exclude the supposition of the palpitations being attributable either to hypertrophy of the heart or chlorosis. Still the effusion might depend on the latter disease, though, according to M. Louis's experience, effusions into the pericardium are comparatively very rare, even when they exist in the pleura. The symptoms of pericarditis are frequently very obscure. The heat, in this case, was but slightly raised, and the pulse was regular. M. Louis has found the pulse regular in about half the cases which have fallen under his observation; it, however, often varies, being regular one day and irregular the next.

Dry cough often accompanies pericarditis, and seems to be caused by the pressure of the pericardium upon the diaphragm. In the present case there was a little pulmonary catarrh.

CASE III.—*Gastritis.*

A female servant, aged 57, was admitted into the hospital, March 27th, having been ill eight days; but four or five days previous to this period, she had not felt quite well. On the 19th instant, about five in the morning, she was attacked with vomiting, and a pain in the epigastrium, followed by headache, and an acute pain in the loins, which have continued to the present time. The vomiting has been repeated, and she has not eaten any thing from the commencement of her illness, and has had no stool for seven days. She is naturally of a strong constitution; her senses are all healthy; her tongue natural in its circumference, but a little greyish and villous in the centre; considerable headache; pain in the epigastrium, extending to the umbilicus, and latterly to the false ribs; the pain much increased by pressure. The epigastrium is depressed, but affords sound upon percussing; complains much of the pain in her loins, but it does not inter-

ferre with her movements; respiration healthy; complete anorexia. Pulse 72 yesterday evening, with a little fever; 80 this morning.

Ptisan. Diet. Emollient Cataplasma to be applied to the epigastrium. Hirudines xx. ad lumbos applicand. Injection of infusion of senna.

March 28th.—No nausea, but vomited yesterday a little green fluid; less pain in the loins; tongue natural; no stool.

Rept. inject. cum Sodæ Sulph. 3j.

On the 30th instant the pain in the epigastrium had entirely left her, and she had a little appetite; in a week she was convalescent.

REMARKS.—The loss of appetite at the commencement, succeeded by complete anorexia, continued pain in the epigastrium, and repeated bilious vomiting, indicated a lesion of the gastric mucous membrane.

Gastritis is a very rare affection, that is to say, when it does not complicate other diseases; it is even more rare than pericarditis. M. Louis has seldom more than two cases during his clinique, which lasts three months. They always terminate successfully, and require only the administration of cooling drinks; opiates to calm the vomiting; and bleeding if there is considerable fever.

CASE IV. — *Hæmatemesis — Pneumonia — Death*—*Varicose state of the Veins of the Stomach.*

A man, aged 72, became a patient under M. Louis, in the month of February, and gave the following history of his complaint:—About fifteen years ago, after a violent exertion, he was attacked with severe hæmatemesis, which returned at intervals during a year; he also passed blood in his stools. His appetite and strength failed him; but being in good circumstances, and able to take great care of himself, he gradually regained his strength, and enjoyed perfect health till very lately. Having failed, he came to Paris, became a marchand-de-vins, and drank considerably. He was again attacked with vomiting, and purging of blood, and giddiness, for which he entered the hospital. He was then very weak; his face was pale, and had the hue of a person affected with cancer; the pulse was not quick; there was no pain; the respiration was natural. Rest and a strict regime were enjoined, and acidulated drinks prescribed. Under this treatment the stools became natural, and his appetite returned. He was gradually regaining his strength when he was attacked with shivering, sore throat, and dyspnoea, and a few days after with acute pain in the chest; his pulse became very much accelerated, and auscultation de-

tected the existence of pneumonia on the right side, and on the following day on the left.

He was bled, but died at the expiration of 36 hours.

Autopsy.—The brain was quite healthy; the ventricles contained a little serum. The inferior lobe of the right lung was infiltrated with pus, and the middle lobe was hepatized. The inferior lobe of the left lung was in a similar state. There were remains of an ancient pleurisy, and a recent exudation of lymph on the left pleura. The stomach was of its normal size, containing a yellow fluid; the mucous membrane was quite healthy, but veins, considerably enlarged, and full of coagulated blood, were seen under it. On the right of the cardiac orifice there was a small tumor, which, upon being cut into, proved to be coagulated blood. The submucous cellular tissue was slightly thickened. The intestines were natural, and their veins of the usual size. The spleen was hypertrophied, and its texture softened.

REMARKS.—The seat of the hæmorrhage, in this case, was evidently the stomach; and M. Louis attributed it to cancerous ulceration of the stomach; for continued hæmorrhage, except those from the nose, are almost caused by an organic lesion. It is impossible to say whether the hæmorrhage depended upon the varicose state of the veins. M. Louis has seen three cases of a similar state of the veins in the stomach; but though they were more numerous, they were less dilated. In none of these cases was there any hæmatemesis during life. The hæmorrhage, in the present case, was, in the first instance, preceded by violent exertion. The veins were also thickened, following the general law, that "when a tissue is preternaturally distended for any length of time, it becomes hypertrophied."

CASE V.—*Enteritis—Recovery.*

A female, aged 30, of a weak constitution, was admitted into La Pitié, under M. Louis, April 12th. She had been attacked on the 2d instant, about noon, with a rigor, which lasted two hours, followed by increased heat. She had likewise vomited, but had neither headache nor giddiness. These symptoms were soon succeeded by pain in the abdomen and diarrhœa, which, with the fever, have continued to the present time. The pain has been confined to no particular spot. On the second day of her illness she had considerable nausea and vomiting, attended with slight pain in the epigastrium, to which she had never been subject. On the third or fourth day, cough was added to these symptoms. For the six or seven days preceding her illness she had a little

tinnitus aurium, but it has since ceased, except when she coughs. She has one child; and menstruated about three days ago.

April 12th.—Pulse 94, full; yesterday evening 100; skin hot; eyes hollow; the inferior lip covered with a white crust; countenance expressive of weakness, but there is no appearance of stupor; memory exact; the circumference of the tongue red, white, and villous in the centre; nausea increased by drinking; complete anorexia; four stools yesterday; no pain in the abdomen. A little below, and to the left of the umbilicus, there is a swelling about two inches in width. It is hard, fixed, and gives no sound, and is not at all painful; respiration quite natural.

Diet. Ptisan, Olij. Extract. Opii, gr. i.

15th.—Feels better, and is in good spirits; has eaten some bouillon without being followed by nausea; pulse 100, regular; heat natural; no pain in the epigastrium; the tumor is more moveable, and is very close to the neck of the uterus, which is not, however, displaced; tongue white and villous; has had one stool.

All these symptoms gradually subsided, with the exception of the diarrhoea, which persisted to the 22d inst. A few days after, she left the hospital convalescent.

CASE VI.—*Enteritis—Recovery.*

A man, aged 53, of a moderately strong constitution, was admitted under M. Louis March 22d, having been ill seven days. His illness commenced with pain in the abdomen and diarrhoea, which have continued to the present time. He has had as many as thirty stools in one day, but no tenesmus. The matter voided was often compared by the patient to white of eggs, and was frequently mixed with blood. He has had considerable fever, attended with perspiration and headache. He ceased working from the commencement, but has not kept his bed. He has never had a similar complaint.

March 23d.—Countenance natural; tongue moist; thirst moderate; has vomited twice; six stools yesterday; abdomen well formed, sensible to pressure; the pain does not follow a transverse direction. Pulse 52; no fever; subcrepitation posteriorly and inferiorly on both sides, but especially on the right.

Tr. Opii, 5j. in injectione administ.

The diarrhoea ceased the second day after the administration of the injection, and in three or four days he was quite well.

[To be continued.]

CAUSE OF THE VARIATIONS OF THE PULSE IN DIFFERENT POSITIONS.

To the Editor of the Medical Gazette.

SIR,

HAVING experienced the difficulty of coinciding with certain views offered to the Physical Society of Guy's Hospital, which are recorded in the MEDICAL GAZETTE for the 28th of October, and finding the subject again recurred to in the valuable pages of the same periodical, at a subsequent period, I am induced to solicit your attention again to the subject, in the hope of eliciting further information.

I was among the number of those present, when, as the MEDICAL GAZETTE announces, Dr. Guy "vindicated to himself his claim to originality, and stated that others had only surmised, while he had proved, that muscular contraction was the cause of the difference of pulses in different positions." Now I scarcely think he will find those who are willing to deprive him of the honour of this discovery.

The pulse is under the influence of a variety of agents, both as to retardation and acceleration; in running, wrestling, leaping, and such like vigorous exercises, accelerated pulsation clearly ensues; but in mere change of posture, the appreciation of such muscular influence appears to me wholly absurd.

In a treatise on the Effect of Posture on the Pulse—one, too, not hastily produced, but preceded by numerous "experiments," and followed by tabular statistic deductions—we may reasonably anticipate an enumeration, at least, of all the more obvious appearances ensuing upon change of posture. The attention of the observer, however, appears to have been so restricted upon one point, to the prejudice of the rest, as to induce error and obscure the true origin of the phenomena. A person suddenly jumping out of bed, experiences a sense of giddiness, with fluttering palpitation, succeeded by a bounding, energetic action of the heart, &c. which oblige him to assume a sitting posture for a few seconds; after which the untoward sensations retire, and he rises with comfort; the heart, however, continuing to beat considerably quicker, and with greater force than when the circulating system occupied a horizontal position. Here we have change of posture succeeded by a disturbed action of the pulsating organs; and, according to Dr. Guy, the muscles which the individual made use of in getting up, by compressing the blood-vessels, caused all this commotion. Then, although certain effects of posture on pulsation are so obvious and severe as often to oblige the individual to be seated, and not only so, but in some

cases even to prove instantly fatal, Dr. Guy, in his observations, passes by all this, and contents himself with fingering the radial artery after the principal action is over; for he does not begin his counting till the main results of change of posture have subsided! It may be observed, also, that after rising, the heart acts, not only with greater frequency, but also with greater force; it is felt throbbing vigorously, with more and more energy up to a certain point, then gradually subsiding to comparative calmness; but still continuing to act with a permanent equable energy, beyond the force required in a horizontal position. This additional energy, however, cannot be estimated by fifths and sixths; and, therefore, in certain "valuable" statistics, would have spoilt the value of their integrity; consequently it was more than convenient to pass it by without appreciation.

Seeing, then, that I regard Dr. Guy's notion concerning the agency of the voluntary muscles as utterly erroneous (not to say ridiculous, for courtesy's sake), I shall be expected to supply an efficient explanation; and this I find close at hand in the physical effects of fluid gravitation. In the change from recumbency to an erect position, we necessarily have from gravity a diminished pressure upon the brain. "When the heart has to send blood upwards, it requires to act more strongly than when the body is horizontal, and the pulse increases five or six beats in a minute." Increased frequency, in conjunction with additional force, is surely, then, an effort to restore and to maintain the equilibrium. This view of the subject is so perfectly obvious on all sides, that I need not endeavour to trespass on your valuable pages any further concerning it.

With regard to Mr. Gorham's paper, whatever he may think with regard to the "relevancy" of its object with that of Dr. Guy's, they are essentially distinct; the one considering pulsation in different postures, the other pulsation in different ages. Mr. Gorham himself even insists upon it, that in many of his observations, relative posture neither was nor could be considered; which alone was Dr. Guy's main object: yet Mr. Gorham's distinctive powers perceive no irrelevancy between these two objects. Allow me to assure Mr. Gorham, that although an infant cannot be made to stand for the purpose of experiment, yet, if it be held erect, increased pulsation will ensue; but infants are so constituted as to bear an unusual position with greater impunity than the adult, and consequently the effect is comparatively less.

A GUY'S STUDENT.

METHOD OF PUFFING QUACK MEDICINES.

To the Editor of the Medical Gazette.

SIR,

I THINK you would be doing a public service were you to expose the system pursued by proprietors of quack medicines, in giving out to the world by their hand-bills, opinions purporting to emanate from the leading journals of the metropolis in reference to their nostrums, but which are, in point of fact, gross deceptions on the public.

It was only the other day that, travelling in the country, I met with a person who, in testimony of the high reputation which quack medicine was held, pulled out of his pocket a hand-bill whereon the opinions of at least twenty of the leading London journals were given, of course highly laudatory of the nostrum in question.

Their system is as follows:—An advertisement is sent to—say twenty different newspapers, all containing the PUFF intended to be re-conveyed on the hand-bills of the advertiser, and accordingly in a few days afterwards such puff is translated into the hand-bills, and the journals in question put as the authors thereof.

I need not say one word more upon a subject so likely to mislead unwary persons, and hope that your insertion of this will be the means of correcting the evil.

I am, sir, yours, &c.

A CONSTANT READER.

London, Dec. 6, 1837.

GANGRENE OF THE LUNGS.

To the Editor of the Medical Gazette.

SIR,

IN Mr. Laycock's cases of Pulmonary Affection, published in your journal last week, I find allusion made to a case of recovery from gangrene of the lungs, which occurred under my care in October 1832, and which was inserted in the MEDICAL GAZETTE shortly after (vol. xii. p. 134.) As it might be doubted whether the convalescence became complete, I trouble you with these few lines to state, that the man is still alive, and in excellent health, which fact I ascertained by having happened accidentally to meet him in Regent-street about a month back.

I am, sir,

Your obedient servant,
J. W. CRANE, M.D.

Dec. 14, 1837.

EPIDEMIC SMALL-POX AT PARIS.

AN epidemic small-pox has prevailed for about two months, particularly in the hospitals; most of the physicians of the Hôtel-Dieu have had a considerable number of patients. The vaccinated have not been spared more than the unvaccinated, only in the former the small-pox has generally been distinct, and in the few cases where it was confluent the pustules were fine, with a good central depression, and the patient recovered.

The number of persons affected of either sex was nearly equal; the mean age of the patients was between 20 and 30.

The majority of the unvaccinated patients had the confluent small-pox, which broke out irregularly, the pustules being of different sizes, and appearing at the same time; they were often flattened, and rarely had a central depression: some pustules did not appear till the others were completely suppurating; and then continued very small, and suppurated almost immediately.

When the pustules were well developed, the disease terminated favourably, though of the confluent type.

Serious symptoms, or death, occurred in those cases where there had been no swelling of the eyelids, nor hands, and where the fever continued after the eruption; the pustules then remained flat, and of a silvery white.

We are unable to give an accurate account of the patients admitted, and even of the number of deaths, as the returns have not yet been made, the epidemic not having entirely ceased. A case of the confluent form, under the care of M. Honoré terminated by the complete and sudden disappearance of the eruption. M. Magendie pointed out to us that all the patients under his care, who had been vaccinated, had been so more than ten years ago.

There was nothing unusual in the treatment, excepting that M. Legroux (who had the care of M. Petit's patients) found the chlorides useful when administered internally during the period of suppuration; he gave the patient food at the same time, and these means conjoined seemed to him useful in preventing reabsorption. He employed tonics at the end of the treatment.

M. Legroux is now trying vaccination on all parts of the body, and even the face, at the period when the pustules begin to appear.—a method which, it seems, has succeeded in other hands. We have no result as yet to announce.

This small-pox has been attended by a varioloid epidemic, which has not offered any thing remarkable.—*Gaz. des Hôp.*

UNIVERSITY OF LONDON.

DIFFERENCES IN THE SENATE.

THE resolution of the Senate of the University of London to institute an examination on certain points connected with religion before granting any degree (as stated by us the week before last), has excited such dissatisfaction on the part of the minority, that they have laid a case before the Attorney-General, to know whether such decision be not incompatible with the Charter. We hear, also, that the Home Office has been beset by gentlemen of the Jewish persuasion during the last fortnight, and that a great effort is making by certain individuals, to accomplish by pressure from without, what it was unsuccessfully attempted to effect by any influence within.

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine.

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE V.

Application of the general doctrine of Evidence to the special subject of Forensic Medicine—Practical Rules thence deducible for the Collection of Facts and Induction of Inferences—No article of Circumstantial Evidence to be neglected because it is weak—No article to be neglected because it is not in itself conclusive—The Aggregate Mass not insufficient because of the insufficiency of the Elementary Parts—The aggregate mass not insufficient because an article of one particular description be wanting—Necessity of care that no intermediate link be wanting—Circumstantial Evidence not insufficient on account of the absence of Direct Evidence—Direct Evidence not insufficient on account of the absence of Circumstantial Evidence—No mass of Circumstantial Evidence conclusive in all cases; still less against Counter-Evidence—Strength of a Confirmative Fact to be tested by its opposing Infirmative Supposition—Circumstantial Evidence not useless on account of the abundance of Direct Evidence—Preservation and Identification of real Evidence—Why the Conduct and Language of all Persons about the Patient should be attentively observed—Record immediately to be made of all that is observed—Why the Investigation should be minute—Mode of Deposition—Conjoint Investigation—Language appropriate to the Medical Witness—Duty of the Medical Witness to state fully every thing known to him—Conduct towards an opposing

Medical Witness—Exception in the case of Secrets communicated in Professional Confidence.

1. No article of circumstantial evidence to be neglected because it is weak.—Whenever you are called to take a part in a judicial investigation, neglect to observe and record no article of circumstantial evidence, because it may appear at the moment to be weak. You do not know how important a link in the chain of evidence a very trifling circumstance may hereafter become, nor how closely connected with an essential fact an apparently irrelative circumstance may turn out to be.

2. No article to be neglected because it is not in itself conclusive.—Much less neglect to observe and record any article of circumstantial evidence, on the ground that it is not in itself conclusive. You know that, from the nature of circumstantial evidence, no single fact can be conclusive; that the force of persuasion produced by circumstantial evidence arises from the accumulation of a number of facts, each independent, but all related; each, taken by itself, inconclusive, but the whole forming a body of evidence which produces irresistible conviction.

3. The aggregate mass not insufficient because of the insufficiency of the elementary parts.—Hold not the aggregate mass insufficient for the separate insufficiency of the elementary articles. There is not a single fact in the chain of evidence attaching guilt to Donnellan which, taken by itself, is sufficient to prove scarcely any thing; and yet, viewing all the facts in combination and in relation, the aggregate mass produces an irresistible persuasion of his guilt.

4. The aggregate mass not insufficient because an article of a particular description be wanting.—Hold not the aggregate mass insufficient, from the mere want of an article of this or that one description. If

the evidentiary facts are sufficiently numerous, and if they stand related to each other with sufficient closeness, their probative force is not to be disregarded because a fact of this or that particular description is wanting.

5. *Necessity of care that no intermediate link be wanting.*—Nevertheless, in every chain of evidentiary facts, let it be your special care that no intermediate link be wanting. The detection of the poison of laurel-water by its smell, in the so-called purging draught taken by Sir Theodosius Boughton, was an intermediate link, connecting the fabrication of the poison by secret distillation on the part of Donnellan, with the anxiety manifested by him to destroy the odour of the poison in the phial from which the pretended physic had been taken. In like manner the effects produced by the contents of this phial, the precise effects known to be produced by laurel water, formed a connecting link between the fabrication of the poison, and the advice to the young baronet to keep his physic bottles in the outer apartment. Take away either of these links—still more, take away both of them—how greatly is the probative force of the evidence diminished.

6. *Circumstantial evidence not insufficient on account of the absence of direct evidence.*—Hold not circumstantial evidence insufficient, as such, from the want of direct evidence. It is seldom, as you have seen, that direct evidence can be obtained; and the perpetration of a crime could hardly ever be brought home to an evil-doer, if credence were refused to evidence wholly circumstantial.

7. *Direct evidence not insufficient on account of the absence of circumstantial evidence.*—Hold not direct evidence insufficient merely for the want of circumstantial evidence. With regard to whatever fact you are really a percipient witness, your testimony as to that fact will of course be decisive; but you can never, after what has been stated, fall into the error of confounding a fact witnessed with an inference deduced from the fact.

8. *No mass of circumstantial evidence conclusive in all cases.*—Set down no article, nor any aggregate mass of circumstantial evidence, as conclusive—not even so much as provisionally conclusive—in all cases.

9. *Still less against counter evidence.*—Much less set down any article or mass as conclusive against, or to the exclusion of all counter evidence.

10. *Strength of a confirmative fact to be tested by its opposing infirmative supposition.*—Whenever you meet with any strong confirmative fact, neglect not to search for every infirmative fact which can by possibility exist. The use of infirmative sup-

positions is to afford a test of conclusiveness, and in some sort even of probative force. A given principal fact appears to you to be supported by a given evidentiary fact. In such a case never fail to look around you to see if there can be found no fact, the tendency of which is to lessen its probative force. If any such fact be supposable, and if, on investigation, its existence be established, the existence of the principal fact may be positively disproved by it; because the existence of the former may be incompatible with that of the latter; or if the existence of the principal fact be not positively disproved by it, it may be rendered less probable. Whenever any such infirmative supposition is established, the probative force of the evidentiary fact can never be so great as to be conclusive. But if after your utmost endeavour you find yourself unable to discover any such infirmative supposition, then in that particular instance, and in as far as regards your own persuasion, the probative force may be conclusive.

A man was found shot by a ball; the wadding of the pistol stuck in the wound; on examination it was found to be part of a ballad, called Sweet Poll of Plymouth; this corresponded precisely with another part found in the pocket of the prisoner.

A man was found lifeless; in the head of the deceased there stuck a chip or splinter which exactly fitted the cavity in a bludgeon from which a piece had been lately broken; this bludgeon the prisoner carried in his hand when he was apprehended.

These are evidentiary facts strongly tending to produce the persuasion of the principal fact, that the prisoner in each of these cases was the perpetrator of the murder. In the absence of all other evidentiary facts—standing alone—they prove nothing; because the probative force of each is reduced to nothing by the infirmative supposition that the ballad and the bludgeon had been thrown away by the real murderers; that these objects had attracted the attention of innocent men passing by that way, and that the one had naturally put the ballad in his pocket, and the other had carried the bludgeon in his hand.

11. *Circumstantial evidence not useless on account of the abundance of direct evidence.*—Reject not circumstantial evidence as useless, on account of the abundance of direct evidence. Direct evidence may be deceptive; direct testimony may be mendacious; but the peculiar advantage of circumstantial evidence is, that the greater the number of facts of which the mass consists, the greater is the chance that every false allegation will be disproved by some notoriously true fact with which the

falsehood is incompatible. And the greater the number of false facts, the greater is the probability that some one or more of them will clash with some positively known fact.

In like manner, the greater the number of deposing witnesses, the more seldom it can happen that any such successful concert can take place between them, as is necessary to give effect to a plan of mendacious testimony.

12. *Preservation and identification of real evidence.*—Take care to preserve every object which is capable of affording real evidence, in such a state that it may exhibit precisely the same evidence hereafter. Take instant and effectual precaution to prevent it from passing of itself, or from being purposely or accidentally brought by others, into a condition in which it can no longer afford evidence; or in which the evidence it indicates may prove fallacious. In a case recorded by Dr. Alison, a Scotch farmer is represented as having acted in a manner which affords a model for the conduct of a medical practitioner.

In 1812, a man of the name of Muir was tried and condemned at Glasgow for poisoning his wife. In the course of the day on which she became ill she was visited by a farmer of the neighbourhood, who had studied physic a little in his youth. The farmer learnt from his friend that she had breakfasted on porridge a short time before she felt herself ill; and that she suspected the porridge to have been poisoned. The farmer instantly procured the wooden bowl in which the cottagers of Scotland keep the portion of meal, used each time for making the porridge. Observing in it some meal, with shining particles interspersed, he wrapped a sample in paper, and took the proper means for preserving its identity. At the same time he secured a sample taken from the family store in a barrel. The two parcels were produced by him on the trial; and from experiments made in court, the late Dr. Cleghorn was enabled to declare, that the meal from the bowl contained arsenic, and that the meal from the barrel did not. These facts, besides proving that the woman had next to a certainty taken arsenic in the porridge, conducted, in conjunction with other circumstances, to establish the further facts, that the poison had been mixed with the meal in the house; that it was mixed with the meal on the morning when the deceased was attacked with illness; and that all this happened before any stranger entered the house.

In like manner, whenever you are called to a patient attacked with sudden disease, the symptoms of which are suspicious, the moment you have given directions for the treatment your thoughts should turn towards the collecting and

securing of evidence. Ascertain in what articles it is possible for poison to have been administered; endeavour to secure at once the remains of that portion in particular of which your patient has partaken; or if this cannot be done, then look to the ingredients of which the dish is stated to have been made; do not neglect the salt, nor any article with which the dish may have been seasoned; and take the necessary precautions to verify the identity of every thing of which you get possession.

13. *Why the conduct and language of all persons about the patient should be attentively observed.*—Keep a watchful eye upon the conduct of every person with whom you come in contact. Mark well the answers they return to any questions that may be put to them by yourself or others. Be not inattentive to the language which may spontaneously fall from them. There is not a word spoken by the patient, or the persons about him, not a thing done or suggested, of which you should not be observant. Conscious guilt is apt to betray itself. It is seldom that it can maintain the indifference requisite to its own security. By saying or doing too much or too little, it is apt to show that it is in possession of too much or too little knowledge, and this suspicion is often excited by the very efforts directly or indirectly made to produce the impression, that it knows absolutely nothing. All the words and actions of all persons in the first moments of alarm, the community has a deep interest in having noted. In this, as in so many other instances, your position and your office combine to make you the guardians of the interests of the community.

The observation of all that passes at the moments of which I am speaking, may be of the utmost importance to the vindication of the innocent, no less than to the punishment of the guilty. Long before suspicion has told her tale to justice, long before the servants of justice have been put upon the search for evidence, long before any steps have been taken to fix guilt upon any individual, you may be in possession of decisive evidence. Lady Boughton had obtained damning proofs of the guilt of her companion, before the conception of his guilt had so much as entered into her mind. A surgeon one day examined a woman who swore that she had been violated; he obtained from her an acknowledgment that she did not scream at the time; the woman died in the interval between her deposition and the trial; she had sworn positively that the accused had consummated his crime. In this declaration she persisted to the hour of her death. On the trial her evidence

could not be sifted; could not be exposed to the ordeal of cross examination; nevertheless, in this case, by the rule of English law, it must be taken absolutely as given, because it is conceived that the solemnity of the occasion, death being supposed to be immediately in view, the ordinary security may be safely dispensed with. What, then, in a case like this, could save the life of a person falsely accused? Precisely the fact of which this medical witness, by his promptitude and sagacity, had obtained possession.

14. *Record immediately to be made of all that is observed.*—Of all that you observe, make an accurate record at the time. The minute circumstances that surround the main facts are apt to be forgotten, and the facts themselves to receive a colouring from subsequent events. Dates especially, the intervals of time between events and the proportionate quantities of substances, are exceedingly apt to be forgotten; but some fact of this kind may possibly become of the utmost importance in the subsequent inquiry. By noting down every thing of this sort on the spot, or as soon as your examination is finished, all possibility of error is avoided.

15. *Why the investigation should be minute.*—Do not satisfy yourself with a general and superficial inspection; let your examination of every circumstance in every case that comes before you, be most minute. The correctness and completeness of the evidence you obtain, and consequently the soundness of the decision to which you come, will commonly be in proportion to the minuteness of your investigation; and minute investigation may possibly open to you new sources of knowledge as valuable as novel,—a splendid example of which I lately brought before your view in the discovery of the different appearances exhibited by burns in the living and the dead body, the characteristic marks of which were observed and described by the late Dr. Duncan, by which it can now be determined with absolute certainty whether the burning took place during life or after death.

16. *Made of deposition.*—I have laboured to the utmost of my power to impress upon your minds an adequate sense of your responsibility, arising out of the circumstance that, on all subjects connected with your profession, the facts you state, and the inferences you deduce, are alike received as evidence, and to show you how sacred the duty consequently becomes, that you should take all possible pains first to give to your facts the qualities of correctness and completeness, and secondly, to draw from them only strictly logical conclusions.

But having done this—having taken all

needful precaution to verify the correctness of your observation, and to ensure the soundness of your induction—you are bound to state the result with decision, and to abide by it with firmness. You have made yourself master of the subject in hand. You go into court to state what you know; results which you have ascertained. What is there in this which a man of sense and integrity should shrink from or fear? Temerity is out of the question; there will be nothing of it, there can be no indication of it, in any one who is in possession of competent knowledge, and who is conscious of the purpose to which it is to be applied; but timidity is equally misplaced, and you must not allow the cause of justice to sustain injury, nor your own reputation to suffer, from a want of firmness equally unreasonable and undignified. Suppose you had examined with due care the wound inflicted on the head with the snuffers, to which I directed your attention in the first lecture, could you have spoken with any degree of doubt or hesitation as to whether this wound were or were not inflicted by a body capable of penetrating the brain to a certain depth? Such a wound must have presented such and such characters; and such characters presenting themselves, the inference to be deduced is inevitable. Not to deduce it implies either an ignorance of the nature of wounds, or an ignorance of the nature of evidence.

17. *Conjoint investigation.*—But there may be some points on which you may be called to give an opinion, on which, with the degree of knowledge you possess, you may hesitate to give a positive opinion. The facts may appear to you, upon the whole, to warrant such and such an inference; but still you may not be quite sure of it. This may very reasonably be the case with some appearances in the stomach, intestines, and other organs, that may seem to exhibit the characters of disease—disease of a specific nature—disease produced by a specific cause. Are these appearances really the result of inflammation, and are they produced by an irritant poison? Now your eye may not be sufficiently experienced in the structural changes produced by disease to give you entire confidence in your own judgment. In like manner, if you are not a well-practised chemist, you may doubt as to the perfect accuracy of some result which you obtain from your chemical investigation.

In all cases of this kind, what ought you to do? Join some one else with you in the inquiry. Discuss the matter with other medical men. Obtain the advantage of their eyes if you can, but at all events get the benefit of their judgment. Before you form your opinion, or give

your testimony, counsel with the best-informed and the soundest-minded among your brethren to whom you can gain access, both as to the correctness and completeness of the facts, and as to the logical soundness of the inferences.

"It is of the greatest importance, says Beck, that two or more professional persons should be united together. They will assist each other not merely mechanically, but by suggesting various points of inquiry. While he who is most skilled in anatomy is pursuing his dissection, the other may note the appearances as they successively present themselves. And the same course may be adopted while performing chemical experiments. The advantage will be thus obtained of having a complete statement of facts, prepared at the moment of observation, which may be afterwards reviewed both in coming to a decision on the case, and in giving evidence before a jury."

18. *Language appropriate to the medical witness.*—In the answers you return to the questions put to you by counsel, let your language be clear, concise, terse, and free from technicality. Never make use of a technical term, unless you introduce it for the express purpose of defining it, and in order to give to your statement greater clearness as well as greater correctness. Do not, for example, speak of *vascularity* when you might say redness, of *syncope* when you might say fainting, or of *cephalalgia*, when there is such a plain word as headache. There is scarcely a single fact or event on which you can be called to speak in a court of justice, however peculiarly it may relate to your own profession, which you may not communicate in the language of common parlance. Follow in this respect the excellent advice which Sir William Blizard was accustomed to give his pupils. "Be," said he, "the plainest men in the world in a court of justice. Never harbour a thought that if you do not appear positive you must appear little and mean; many old practitioners have erred in this respect. Give your evidence in as concise, plain, and yet clear a manner as possible; be intelligent, candid, exact, and just, yet do not aim at appearing unnecessarily scientific. State all the sources from which you have gained your information. If you can make your evidence a self-evident truth; thus, though the court may at the time have too good or too mean an opinion of your judgment, yet they must deem you an honest man. Never, then, be dogmatic, or set yourselves up for jury and judge. Take no side whatever; be strictly impartial; you will frequently hear the counsellors complain when a surgeon gives his opinion with any the

least degree of doubt, that he does not speak clearly; but if he is loud and positive, if he is technical and dogmatic, then he is allowed to be clear and right."

Let not the bad example so justly reproached by this experienced teacher mislead you. The counsellor is an advocate; it is his object to obtain a decision on the side on which he is engaged, whether that be the side of truth or falsehood, of innocence or guilt. But it is your object to establish the truth, and nothing but the truth; and you deviate grievously from your duty when you speak confidently and absolutely in a case in which there is ground for reservation and doubt, and hesitatingly in a case in which the facts are positive and demonstrable.

19. *Conduct towards an opposing medical witness.*—If ever you should happen to be placed in collision with a fellow medical man, forget not the respect which is due from one person of education and science to another. Let your manner be courteous, and the opinion you express be given with diffidence. If you really differ in opinion, state plainly and simply in what the difference consists, and the ground on which you have arrived at your own conclusion: if the difference be merely a matter of opinion, show that it is a point on which persons of knowledge and judgment may be allowed to differ without reproach. Even if, according to the best judgment you can form, you think an error has been committed, it will reflect disgrace upon yourself, and justly beget doubt whether your intellectual and moral qualifications fit you for forming a sound and trustworthy judgment, if on such an occasion you deliver your opinion with an air of triumph, with self-confidence and self-satisfaction. There is no reason why you should conceal your opinion; there may be grave reason why you should avow it; but your feeling should be sorrow that you are under the necessity of doing so, and your manner that which real sorrow will produce.

On a trial some time ago, Mr. Tickner, a surgeon, was asked—"Supposing a person to have retchings and purgings for several hours, and that you found these attended with frequent and fluttering pulse; in that state of the illness what should you have prescribed?" His answer was—"I should have prescribed diametrically opposite to the prescription of Dr. Edwards. I should consider that prescribed by Dr. Edwards as adding weight to a porter's back."

The course and vulgar mind indicated in this reply, received merited reproof from the court. Lord Tenterden said to the witness, "Don't speak metaphorically: you were speaking just now of a gentleman

of experience and respectability. I don't wish you to conceal your opinion, but only to speak it in different language."

Contrast the feeling in which this language and deportment originated, with that which dictated the language and deportment of a man of genius and science. The story is related by Mr. Abernethy, in reference to a case in which he himself took a part.

"A medical man," he says, "was prosecuted for killing a child by giving it opium; at least that was said. I happened to be in the country at the time, and was strongly solicited by him to attend and give my opinion. I considered that the character of the profession was at stake, and although rather against my inclination, I went. After waiting in a crowded court the greatest part of the day, I was called upon and placed in the witness-box. The lawyers had taken it into their heads that the child had died from mal-treatment on the part of the surgeon; the child had been scalded severely, and he had given opium, and they thought they should be able to make the jury think as they did. The first question put to me was, 'Mr. Abernethy, will you inform us what is considered the proper treatment for scalds?' This was a question broad enough, to be sure; I was puzzled a little how to answer it: I did not know but they would require a lecture on burns and scalds. I considered a minute, and then said, 'That which was adopted in the present case.' Oh! that was what they did not expect; it was giving a turn to the case which they did not like. 'You have heard the evidence, have you not?' 'Yes, but it is contradictory.' 'But judging from the evidence?' 'I have no right to judge; you may judge, if you please, or the jury may judge, but I shall not.' 'But I ask you, for the information of the jury, your opinion respecting the opium; whether you do not consider it too large a quantity for a child?' 'The statements respecting the opium have been contradictory; but admitting that the child had, as was said, eight drops immediately after the accident, and ten drops two hours after, I should say that the child had not taken one drop too much.' 'But are you aware that the child had no pain?' 'Yes, perfectly. When the skin, or any other part of the body, is severely injured, the nervous system of the part is so affected that the peculiar actions of the nerves on the brain, or spinal marrow, by which alone pain can be felt, do not take place. A man may have a serious injury inflicted by a mechanical cause—may have a leg smashed, and nearly torn off by machinery—and yet feel little or no pain; and

we are in the habit of giving, in such cases, wine and opium, not to act as a narcotic, but to arouse the energies of the vital powers, and call them again into exercise: the nervous system has sustained a great shock, from which it requires to be roused.' The judge said, 'that he understood it; he saw the principle on which the treatment was founded, and had no doubt but it was correct.' 'But, my lord,' said the counsel, 'the child slept to death.' 'So he may have appeared to sleep, but he would have done so if no opium had been given; it was the torpid state into which the nervous system had fallen, which caused that appearance, and from which the child could not be roused.' Here the business rested; the treatment was admitted to be correct, and the character of the gentleman exculpated."

20. *Duty of the medical witness to state fully every thing known to him.*—Bear in mind that the counsel and the judge are frequently placed under peculiar difficulties, difficulties arising from their want of information on the subject in question—difficulties which you are called upon for the express purpose of obviating. They may not know, and often they do not know, how to frame their questions so as to bring out the whole of the evidence of which you are in possession. There cannot be the slightest doubt as to your duty whenever you observe this. All that you know bearing upon the point in question, and the knowledge of which is necessary to form the ground of a just decision, you would be guilty of a flagrant violation of duty if you did not state, whether the questions that are put to you lead to the statement or not. In the language which I have so often repeated, you are bound, as far as in you lies, to give to your evidence, not only the property of correctness, but that of completeness also; by the terms of your oath, you are bound to speak, not only the truth, but the whole truth.

21. *Exception in the case of secrets communicated in professional confidence.*—Occasionally, indeed, you may be placed in a difficult and painful situation. By virtue of your office as professional men, secrets may have been confided to you by your patients, or you may have obtained possession of them in consequence of the implied confidence which they have reposed in you as medical men, which it is of the last importance to your patients to keep secret. It is in the power of a court of justice to require you to disclose facts even of this nature. However peremptorily commanded, I can conceive of cases in which a disclosure thus extorted must be extremely painful; and so much is it for

the interests of the community that every communication between the physician and his patient should be sacred, that I would myself never reveal any fact, to the knowledge of which I had come by means of this sort, unless required to do so in the most express manner by the court; and even then there may, I think, be cases in which strict integrity on the part of the medical man would justify, and even require, disobedience to the mandate.

CLINICAL LECTURE

ON A

CASE OF PUNCTURED WOUND OF THE ABDOMEN,

Delivered at the London Hospital, Dec. 19, 1837,

BY T. B. CURLING, ESQ.

A CASE of punctured wound of the abdomen, with protrusion and injury of the intestine, having been recently admitted into the hospital, I am desirous, whilst the particulars of it are fresh in your recollection, to call your attention to some of the principal points in the pathology and treatment of wounds of this kind which this case is calculated to illustrate. Injuries of this nature in these days of peace, and in the present civilized state of society, are of rare occurrence, although, by a singular coincidence, this is the third case of wounded abdomen which has been admitted into the hospitals of the metropolis within the last six weeks; the first having occurred at St. George's, and the second at the University Hospital.

The patient, Thomas Hawe, a stout young man, aged 25, was brought to the hospital on a shutter, about half past 11 at night, Dec. 12th, having been stabbed in the abdomen with a large blunt clasp-knife, about half an hour previously, in a quarrel at a neighbouring public-house, where he had been regaling. I was immediately sent for, and arrived within a few minutes after his admission. I found the man with a pallid countenance, lying on the floor bleeding, and his intestines protruding at a wound in the abdomen, ineffectual attempts having been made to return them. I immediately had the man placed on a bed in the ward, and proceeded to secure three large sized vessels in the mesentery, which had been divided and were bleeding copiously. The arteries were tied with fine silk ligatures, which were cut closely off. I then observed that about eighteen inches of the small intestines, with the mesentery attached, were protruding at a wound about an inch and

three-quarters in extent, on the right side of the abdomen, a little below the level of the umbilicus, in the direction of the linea semilunaris, but nearer the median line. The intestines were rather darker in colour than natural, and not collapsed. There were two wounds on opposite sides, and corresponding, shewing that the gut had been transfixed. The larger was transverse, and about eight lines in length; the other was about a line less in size, and at both the mucous membrane was protruding. I grasped the coats of the bowel around each of the openings between the blades of a broad pair of elastic forceps, and caused fine silk ligatures to be applied, and the ends cut shortly off. The protruded intestine was then gently pushed back into the cavity of the abdomen, but not without some little difficulty, and during the operation the man complained greatly of pain, was very restless, and required the aid of assistants to keep him quiet. The wound in the skin was dressed with a compress, and gentle pressure was directed to be kept up, in order to prevent reprotrusion. A long incision, skin-deep only, at the back part of the right thigh, was likewise dressed. When I first saw him the patient had vomited, and was in such a state of collapse, that, after securing the bleeding vessels, I immediately directed some warm brandy and water, and forty drops of laudanum, to be given him, but it was very soon rejected from the stomach.

I saw the man again in five hours. He was still very low, and in great pain, and his pulse was quick and small. He had not vomited during the last hour, and I ordered him to take forty more drops of laudanum, and fomentations to be applied to the abdomen.

About half-past 9 in the morning the pulse had risen considerably, the tongue was dry, and the man complained of thirst, and was still in much pain. The nurse had given him a little tea, which had been retained on the stomach, but it was directed to be discontinued, and the mouth only allowed to be moistened. Two grains of calomel, with half a grain of opium, every fourth hour, with leeches to the abdomen, and fomentations, were prescribed. About 12 at noon sixteen ounces of blood were taken from the arm by one of the house pupils.

2 P.M. — I saw the patient with Mr. Andrews and Mr. Adams. His pulse was weaker than in the morning, but equally quick; there was great tenderness of the abdomen, and constant pain, with frequent vomiting, and short and hurried respiration. In consequence of the irritable state of the stomach, it was considered inadvisable to continue the administration of

remedies by the mouth. A clyster, therefore, of an ounce of gruel, containing a drachm of laudanum, was ordered to be given immediately, and a drachm of the ung. hydrarg. fort. to be well rubbed in on the inner part of the thighs every hour. From this time the man sank gradually, and died at a little before ten at night, having survived the wound only twenty-three hours.

The body was examined sixteen hours after death. It was muscular and well-formed, and the surface exsanguineous. In the vicinity of the external wound the subcutaneous cellular tissue was infiltrated with blood and serum. The lower belly of the rectus muscle had been divided in the direction of its fibres, and on reflecting it from the posterior part of the sheath, the wound in the fascia and peritoneum was seen to be about half an inch on the outer side of the epigastric artery, in size corresponding to the external wound. The peritoneal coat of the small intestines appeared much injected, especially on the right side towards the iliac fossa, in which situation there was a small quantity of faecal matter. A small part of the canal was slightly coated with lymph. The larger of the two wounds was still open, and presented the hernia of the mucous membrane characteristic of incised wounds of the intestine, the ligature having slipped off. It was discovered that the ileum, about an inch from its termination, had also been transixed; for two longitudinal incised wounds, corresponding to each other, and five lines in extent, were likewise found at this part of the bowel. Immediately beneath was observed a wound in the peritoneum and fascia, which extended half through the *psoas magnus* muscle. It was situated about half an inch to the outside of the external iliac artery. There was ecchymosis in the cellular tissue around the muscle and beneath the cæcum, and a small quantity of faecal matter, mixed with purulent serum, in the pelvis. About eight inches from the first-mentioned wound in the intestine there was a small spot of sanguineous extravasation in the mesentery, at the point where it joins the intestine, the peritoneum being slightly lacerated. The heart, lungs, and liver, were healthy.

From the particulars which have just been related, you will readily perceive that these cases are of a formidable and embarrassing nature, and require prompt treatment on the part of the surgeon. The source of immediate and most imminent danger was the free hæmorrhage from the branches of the superior mesenteric artery; vessels large in size, near the centre of the circulation, and so situated

as not easily to admit of the bleeding being spontaneously arrested by their retracting within a cellular sheath. These vessels were, however, readily secured, and all danger of this kind soon removed. I had next to determine what was to be done with the ends of the ligatures. Should they be cut closely off, or should they be left attached, when the gut was returned, with the extremities hanging out at the wound? Had they been applied to vessels in the omentum, I should have had no hesitation in cutting off one end of each, and confining the other at the external wound; so that if the patient survived, there might be no difficulty in bringing it away after separation had taken place, the omentum being placed in front of the intestines. But there are several objections to this proceeding, when the ligatures are applied on vessels in the mesentery. Thus, when the parts are returned, as we cannot well confine the mesentery near the wound, situated as it is behind the intestines, if the ligatures are suffered to remain, they must necessarily trail amongst the bowels, and thereby tend to excite and keep up peritoneal inflammation. If, too, the ligatures were attached, or at all confined at the external wound, and did not yield, they would be liable to girt or even produce stricture of the canal; whereas, if loose, they might be drawn, by the motions of the viscera, completely into the peritoneal cavity, and be involved amongst the convolutions; an occurrence which I have known to happen once, in the case of ligature applied to a vessel in the omentum, in the operation for inguinal hernia. The disadvantage of cutting both ends closely off before reducing the protrusion, arises from the circumstance that, after the ligatures have separated, there being no ready mode of escape, they must remain as extraneous bodies, and continue to keep up irritation in the cavity. This would certainly appear to be an inconvenience attending this plan; nevertheless I adopted it as the least objectionable of the two. Besides, the ligatures constituting but a small mass, would, if the patient recovered, be so surrounded with lymph as to be confined to the situation in which they were placed, and, like foreign bodies, as bullets, or some of the entozoa which have frequently been found in the centre or in the vicinity of the most important organs, they might remain encysted for years without causing any inconvenience.

Having disposed, then, of the question as to the means to be pursued in reference to the divided mesenteric vessels, the next point to decide was the treatment to be adopted in regard to the wounded intestine; for if returned into the peritoneal

cavity in the condition in which it was found, the escape of faecal matter from one, if not from both, of the openings, was certainly inevitable. This opens an inquiry of much interest and importance, which has at various times occupied the attention of medical men, though the practice founded upon it cannot yet be said to be firmly established, or finally settled. Formerly, when swords were worn and duelling was much in fashion, punctured wounds of the abdomen were of common occurrence; accordingly we find, on consulting the works of the older writers on surgery, especially the excellent memoirs of the French Academy of Surgery, that many of the surgeons of those days exhausted their ingenuity in devising plans to effect the union of the injured bowel by different kinds of sutures and mechanical contrivances, which they considered to be essential to the healing of the wound and to the patient's recovery. The best and most experienced modern surgeons are of opinion that sutures were employed formerly much too freely, and that too little was left to nature. Scarpa even has gone so far as to assert, that in penetrating wounds of the abdomen, accompanied with an injury to the intestine, whether the canal be divided longitudinally or transversely, a suture is always not only useless, but even dangerous and fatal. I would say, that experience does not altogether sustain Scarpa in this sweeping conclusion, although the observations of that eminent surgeon, as well as those of many other modern pathologists, clearly show that a safer and more simple plan of treatment may frequently be adopted with advantage and success. The course to be pursued in these cases must evidently depend, in a great measure, upon the nature and extent of the wound. It is here necessary that you should bear in mind that an opening in the intestine, from an incised wound, differs from an aperture consequent upon ulceration, in one respect, which is well worthy of notice. It is this: that when the opening is produced by a wound, there is always more or less protrusion or hernia of the mucous membrane; so that when the wound is small, the edges appear everted, and the mucous membrane is seen of its natural rosy hue, protruding in folds and blocking up the wound. Now this kind of hernial protrusion was remarked in the case just related, and may even be observed in the portion of the wounded bowel removed from the deceased, that I now show you. When the opening is consequent upon ulceration, as was seen in the examination of the case of hernia operated on last week, the mucous membrane being destroyed by the ulcerative

process to a greater extent than the peritoneal, the edges are thin, and altogether different, and offer no bar to faecal effusion. If, then, there is only a slight puncture, the hernial protrusion is sufficient to prevent the escape of the faeculent contents of the canal, and the application of a suture, therefore, is both an unnecessary and injurious interference. The surgeon has only to return the intestine into the abdomen, and then leave it to chance; in which case it will, in all probability, soon contract an adhesion to a neighbouring fold, or become coated with lymph, and thus be placed in a condition favourable for ultimate recovery. In confirmation of the accuracy of this observation, I may recal to the recollection of some present the last case of wounded abdomen admitted into this hospital. It was the case of a man who accidentally fell backwards against a pitch-fork. One prong wounded only the muscles at the back of the pelvis; the other entered the right lumbar region, penetrated the peritoneum close to the ascending colon, which, however, escaped injury, and then transfixed a fold of the ileum. The man died two days afterwards of peritoneal inflammation, when the nature of the mischief was ascertained. There was an abundant effusion of lymph, by which the openings were concealed, and the wounded intestine connected to the neighbouring folds on each side, but no feculent matter could be found in the cavity. In this case, the escape of the faeces was prevented, in the first instance, by the hernial protrusion of the mucous membrane, and subsequently by the effusion of lymph. A slight puncture, therefore, in the coats of the intestine, is the least dangerous kind of wound, and one requiring the simplest treatment.

The wound may, however, as in the case of Thomas Hawe, be more extensive, so that the protruded mucous membrane would be insufficient to close it effectually and prevent faecal effusion. In a case of this kind, some surgeons recommend that a ligature should be passed through the mesentery and around the intestine, and that the bowel should, by this means, be confined at the external wound, where it would very soon become adherent, and through which the contents of the canal would be discharged, the patient recovering with an artificial anus, which might subsequently close spontaneously or admit of being cured by operation. Scarpa regarded the use of the ligature even in this case as unnecessary, and was of opinion that the wounded intestine would readily unite at the external wound without it. But notwithstanding the rapidity with which adhesions form, there must necessarily be a considerable risk, both from the

motions occurring in respiration and from the peristaltic action of the canal itself, of the injured intestine quitting the outer wound. At any rate, in the case now under our notice, where no measures were taken to confine the intestine, the wounded part was found some way from the opening in the peritonæum, and concealed amongst the convolutions. In a case of hernia, where an opening in the gut is consequent upon ulceration or mortification produced by the stricture, the circumstances are altogether different, for here peritoneal inflammation precedes the lesion in the coats of the bowel, so that there is scarcely any risk of its moving away. In an injury, therefore, of the intestine of this kind, I should be disposed, if I applied no suture for the purpose of closing the opening in the intestine, to pass a ligature through the edges of the aperture, and attach it to the sides of the external wound, and in this way secure the gut from quitting the part. In the case, however, of this patient, there were greater difficulties to contend with. The intestine had been transfixed; there were two wounds, one on each side of the canal, so that this proceeding could only be applied to one of the openings. I therefore adopted a plan once employed by Sir A. Cooper, in operating in a case of strangulated hernia. An aperture giving issue to the intestinal contents was discovered in a portion of the sound bowel just when the part was about to be reduced. Sir Astley, including the aperture in his forceps, caused a fine silk ligature to be carried beneath the point of the instrument, firmly tied upon the gut and the ends cut off close to the intestine. The part was then replaced, and the patient did well. Ligatures were then applied to both of the wounds in the intestine. The one applied to the larger of the two, either not having been tied with sufficient tightness by my assistant, or having been displaced by the long manipulation necessary, in order to return the protruded parts, or the wound being too large to admit of being safely secured in this way, slipped from its hold; and had the patient survived, would not have accomplished the object that I had in view. The other aperture, you will perceive, is completely closed, without much diminution in the calibre of the gut. You might suppose, that when a ligature is applied to a wound of this kind in the way mentioned, that the result is the union of the parts thus kept in apposition, as happens in the case of a ligature upon an artery. This, however, is not the case, for the surfaces immediately in contact being mucous, are by no means disposed to unite, and the ligature only serves to close the wound and prevent fecal effusion until the injured

bowel has contracted a firm adhesion to the neighbouring parts. When a ligature is applied to any part of the alimentary canal, it first cuts through the inner, the mucous and muscular coats, leaving the exterior, the peritoneal, in tact. The part having been encased in lymph, the process of separation soon commences, ulceration is set up, and the ligature finds its way into the bowel, from whence it is ultimately discharged by the anus. In many cases the wound is too large to admit of the application of a ligature in this way; it becomes necessary, therefore, to apply either the interrupted or the continued suture. In expectation that the wound would unite more readily if two serous surfaces could be kept in contact, Jobert, a French surgeon, proposed to invert the edges of the wound before the application of the sutures, in order to obtain union between the peritoneal coats. I do not regard this as a point of much importance, when the gut is only partially divided, since whatever kind of suture is employed, direct union of the parts brought together is by no means essential to the subsequent integrity of the bowel; and provided that the first object, the escape of fecal matter, is obtained, there is afterwards so free an effusion of plastic lymph, that the continuity of the canal is ultimately effected in the way I have described, without any future risk.

When there is a complete division of the canal and protrusion, it is necessary either to leave the divided ends of the intestine at the external wound, thus giving the patient the chance of recovery with an artificial anus, or to bring the two extremities together, and confine them with sutures. I should certainly prefer the former practice, which succeeded in a case treated in this way by Baron Larrey, and is, I think, attended with the least risk. Mr. Travers states, in his *Inquiry into the Process of Nature in repairing Injuries of the Intestines*, a work which will well repay you for an attentive perusal, that "wounds amounting to a direct division of the canal are irreparable, and, therefore, invariably fatal." There are cases, however, on record, in which recovery has taken place after an injury even of this severe description. Mr. Travers endeavours to show, that in transverse wounds of the canal the longitudinal fibres constantly tend to retract the edges, and consequently he recommends the employment of the uninterrupted or Glover's suture. But it does not appear that the absolute contact of every part of the divided bowel is absolutely essential to cure, for Sir A. Cooper, and Dr. John Thomson of Edinburgh, in experimenting upon dogs, succeeded in obtaining union of a

divided intestine by using the interrupted suture. The suture which I believe to be best adapted for the purpose is passed as follows:—Introduce from without, inwards, at about four or five lines from the solution of continuity, a small curved needle, armed with a fine silk ligature, through all the coats of the intestine, except the mucous, and bring it out externally at about a line from the wound. Pass it then in the same manner through the other end of the gut, commencing at a line from the divided part, and bringing it out at the distance of four lines. Having passed the number required, which in a complete division of the canal need not exceed four, the ends of the bowel are to be brought together and the ligatures tied separately, taking care at the same time to invert the edges of the wound so as to bring the serous surfaces in contact. Having made a double knot, the ends are to be cut off close. The direct union of the peritoneal surfaces in complete division of the intestine is to be desired, since, in order to perfect the union, the whole circumference of the canal must become adherent or coated with lymph, which, if not tolerably firm, might, after the separation of the ligatures, yield to the action of the longitudinal fibres of the intestine. Jules Cloquet adopted this plan, with success, in a case of divided intestine, and applied only two sutures. Other modes of effecting the same object have been proposed. Thus it has been suggested to introduce the upper portion of the wounded bowel into the lower, over a cylinder of isinglass, or the trachea of some animal, and then secure them with ligatures. But as the propriety of most of these plans is very questionable, I think it needless to dwell upon the subject.

But whatever practice may be followed, our chief reliance for success is on the early setting in of active peritoneal inflammation and the rapid and abundant effusion of lymph. I would say that a copious hæmorrhage, such as occurred in the case of this patient, was a circumstance highly unfavourable in an injury of this description, since it tends to retard the excitement of inflammatory action, upon the early development of which the probability of recovery mainly depends. This poor fellow, when first admitted, was so sunk from loss of blood, that I scarcely expected that he would live throughout the night, and I considered it necessary to give brandy to restore him. He recovered slowly, was restless, and could scarcely be restrained from moving about, so that every opportunity was afforded for the escape of fecal matter with which the alimentary canal had evidently been distended. The post-mortem examination

exhibited merely a thin coating of lymph, effused over a small part of the canal, none having been found around the ligature and wounded parts, although the patient had survived more than twenty-three hours, a period which must be considered fully sufficient for effusion to take place, when it is recollected that in an instance adduced by Sir E. Home, lymph was effused and organized on an inflamed intestine in less than twenty-four hours.

Of course it was not discovered until after the patient's death that the case was really more serious than it appeared when he was admitted. It was impossible to ascertain during life that a second fold of the ileum had been transixed, and that the knife had penetrated even the *psaos magnus* muscle. It would appear that the blow must have been struck with great force, and that the knife had taken rather an oblique direction. The external iliac artery narrowly escaped being wounded.

Having now considered the more important points connected with this case, I have but little further to add. There was some difficulty experienced in returning the protruded parts back into the abdomen. It has been suggested that when there is no wound, and much difficulty exists, it would be proper to puncture the coats of the intestine with a needle, in order to allow the escape of the air contained within. It is better, however, to dilate the wound in the peritoneum, in performing which care must be taken to avoid the epigastric artery. The wound in the integuments was closed with adhesive plaster, and an assistant was directed to keep up gentle pressure with the hand, in order to prevent reprotrusion. Formerly surgeons were so much afraid of the intestine appearing again at the wound, that they stitched up the aperture in the peritoneum and applied the quill suture externally. But these are proceedings which are abandoned in the present day.

The after-treatment in injuries of this nature chiefly consists in subduing the peritoneal inflammation, which, though desirable in the first instance, if not checked, soon becomes the principal source of danger. It must be combated by local and general bleeding, mercury, fomentations, low diet, and perfect rest. Purgatives are objectionable, as they tend to disturb the intestines, which should be kept as quiet as possible; but clysters may often be given with advantage, unless the large intestines should happen to be wounded. Opiates are admissible, especially if there is much suffering.

In conclusion, let me remark, that formidable and dangerous as is the character of punctured wounds of the abdomen, attended with protrusion and injury of the

intestinal canal, these cases are not necessarily and invariably fatal; and the efforts of nature are sometimes so extraordinary, that it is always the duty of the surgeon to call in aid all the resources of his art, and to adopt whatever his skill and judgment can suggest. The records of our profession, and the experience of military surgeons, furnish many instances of almost miraculous recoveries after wounds of this description. Let, then, the recollection of these cases serve to encourage us in the execution of our dispiriting task.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

BY WILLIAM GRIFFIN, M.D.

Limerick.

Introductory.

AFTER the passing away of a pestilence which spread terror and death throughout these countries for so long a period, and on whose treatment, unsuccessful as it has been, information was so liberally supplied by medical men, it may seem a very hopeless attempt to engage public interest to the subject again. One naturally gets tired of the endless conjectures and experiments of the profession, always multiplied just in the proportion they are erroneous or fruitless; and with a great many, the mere probability that we shall not be visited by the dreadful epidemic any more, at least in our own times, is fully sufficient to lay all spirit of inquiry. Those, however, who really desire the improvement of medical science must not write for an age or a country; for as the value of a fact or a truth can never be increased by any interest it obtains, so it can never be diminished by being for a time neglected. For my own part, convinced that the observations I shall offer in the subsequent pages are of some practical importance, I can have no anxiety about their immediate influence. They may, perhaps, have little interest at present for any, except for those few zealous gleaners in the fields of science, who are yet lingering to pick up some ears after a wasted harvest; but even through them they may reach those parts of Europe where the cholera still prevails, and where any suggestions thrown out must admit of immediate application.

I am not singular in having seen a great deal of this unfortunate malady, but my opportunities of observation have, I believe, exceeded those of any gentleman who has written upon the subject in this country. The city in which I reside has been more severely visited than almost any other in Ireland. I have myself treated many hundred cases, and been attached successively to the three hospitals in which the disease shewed itself in its greatest malignity. I have seen the disease both in town and country, and watched the modifications which might have resulted from situation. I have seen it totally abandoned to nature; and in the anxious effort to save life I have sometimes seen so much done, that nature was left no opportunity of exerting herself. Finally, I have received much useful information from my professional friends, which assisted me in arriving at just conclusions on many points of extreme doubt and difficulty.

I do not profess, in these papers, to bring any new discovery under consideration, or to throw any clearer light on the pathological condition which constitutes cholera; that seems to be still as mysterious as is the seat or essential condition of fever, and, I believe, is as likely to continue so. My chief object has been to give statements of facts and results, in such a manner as must make the connexion of the latter with the former obvious, and so lead to unquestionable inferences; and I have endeavoured to determine the application and comparative merits of a particular treatment, not unsuccessfully adopted in other countries, but carried to a greater extent, and given a fairer trial, in Limerick than any where else. If, on reviewing the merits of various other modes of cure, tested as this has been by the results of numerous cases accurately classified, it should appear to advantage, as I believe it will, it may only require a little experience to qualify the disagreeable consequences by which it is sometimes followed. But, on the other hand, should it be ascertained that other remedies are of equal or greater success, and less objectionable, I shall yet feel that I have effected much good, in having been instrumental in placing absolute inductions, with respect to their value, on record, and preventing new adventurers from seducing the profession by accounts of as-

sumed specifics, whose only claim to reputation is that fictitious one which they have acquired in the imagination of the discoverer.

I have, however, also aimed at the attainment of what may prove hereafter of far more importance than any thing I could offer on the subject of treatment—a mode of fairly comparing one line of practice with another, without reference to mere medical opinion. This, a simple matter in most other diseases, and certainly not impossible in cholera, has been rendered inconceivably difficult, partly from the varying nature of the disease itself, and our ignorance of the resources of nature; partly from a disingenuous and wicked disposition in a portion of the profession to magnify the success of particular remedies, for the sake of a temporary celebrity or gain; but perhaps most of all from the unphilosophical precipitation with which most medical men pass to general conclusions on contemplating a few isolated cases.

The consequence of this last and most fatal error is just what might have been anticipated; that we are now, after certainly a very sufficient intimacy with the disease, almost as much in doubt about every thing connected with it, as when it commenced at Sunderland. If one asks what is its nature? some will answer that it is a simple local inflammation; others, that it is a species of epidemic fever; a third party, a corruption of the circulating fluids. If one inquires where is its seat, or what texture it affects? we are told, the brain—the spinal cord—the solar ganglia—the alimentary canal—or the whole mass of the blood; and it would fain be proved, even by pathological evidence, that it is each, or any of these. If one demands whether it be contagious or not? half the profession rise up on either side of the question. I do not, of course, mean to deny that some important negative advantages have been derived from our experience—that physicians in general have become more familiar with the character of the complaint, or that they are not individually better satisfied with the efficacy of certain remedial measures. But we have sufficient evidence in the periodical publications, that, as a body, they are little agreed about any—nay, that they are actually opposed to one another as to the value of these

which are most influential, and which must of necessity effect either extraordinary good, or incalculable mischief. The calomel and the saline treatment, the brandy and cold water, stimulants and antiphlogistics, vomits and sedatives, purgatives and astringents, have all to this hour steadfast and respectable advocates and opponents; and what can be more mortifying than the conflicting sentiments expressed regarding blood-letting? One authority is for drawing no blood at all, early or late, cholera being a disease of debility which will not admit of such treatment. Another advises to take it at an early period of the complaint, but never in the stage of collapse. A third (Dr. Thackrah) observes, that we should bleed in the collapse, but not abstract too much, since a small bleeding is fully sufficient to relieve the venous congestion. On the other hand Mr. Bell asserts (and he is supported by most of the Indian practitioners), that small bleedings do harm, but free venesection, where practicable, has scarcely ever failed. Dr. Brown regards a considerable degree of collapse, indicated by feebleness or arrest of the circulation, as an imperative reason for abstaining from drawing blood. If the temperature, he says, be in any considerable degree below the healthy standard, with the hands cooling rapidly on exposure to air, the pulse at the wrist either very feeble, or totally suspended, the breath and tongue cool, the surface shrunk and pallid, or in certain parts livid, the vomiting and spasms diminishing in their intensity, or totally ceased; at whatever period of the disease this state of things may exist, bleeding is inadmissible. Mr. Spence, who saw much of the disease, also says, to think of bleeding a person in such circumstances, is against every principle of common sense. Mr. Bell, on the contrary, recommends “that no time should be lost in endeavouring to bleed the patient, whenever there is a sunk countenance, with blue lips and nails;” and as to the extent to which depletion is to be carried, he tells us “it has no reference to the prostration of strength or constitutional stamina.” “When the blood flows *stillatim*, black and tarry, stimulants,” he says, “sometimes appear to do good, and to increase the strength of the pulse, upon which renewed attempts should be immediate-

ly made to remove blood, *nor should these be desisted from while life remains.*"

Such is medical opinion, and such are the foundations on which inexperienced practitioners are expected to build their practice! If in their stead we are furnished with a simple report of only twenty cases of collapse, in which bleeding had been resorted to, and as many others, *ceteris paribus*, in which it had not been employed, with the results in both instances, what opinion could either add to or take away from the value of such a document? Accurate and candid reports are all we can want to remove the clouds which at present obscure our inquiries; not such as are daily issued by Boards of Health, or even by hospital physicians, from which little could be gathered beyond the amount of the dead, but statements of the admissions, classified as the patients may happen to be, in the premonitory, or primary, or collapsed stage of cholera, with the general plan of treatment, and the results in each. Almost all the controversy with regard to the treatment of cholera has arisen from the remedies having been employed at different periods of the disease, and afterwards extolled as available in any stage of it. If, in reported cases, we have no distinction or classification; if they are, however unlike, jumbled together by a common cypher, all inquiry is baffled. There can be no comparison between the treatment in one hospital and another, nor is it possible for one man to reason on another man's practice.

The two points to which the public chiefly direct their attention in estimating the success of any particular treatment, are, the numerical amounts of deaths and recoveries, or their proportions to one another. How superficial and erroneous inferences formed in this way have proved, is manifest from the fact now well ascertained, that the mortality has varied considerably under the same treatment, and has at other times rated at exactly the same under very different treatment. None, indeed, but medical men, can fully comprehend the extreme difficulty which attends this subject, a difficulty which can only be surmounted by a thorough knowledge of the modes or habits of the complaint—the circumstances which may influence its phenomena—or the

effects of remedies in controlling or altering them.

The rate of mortality or of recovery always has an infinitely closer relation to states of the atmosphere than it has to any treatment whatsoever; the poisonous miasmata with which it is loaded, either varying in quantity or intensity, or losing or acquiring activity from certain changes which escape our observation. In the early stage of the disease this is chiefly remarkable in the rapidity with which patients fall into collapse at one time, the tardiness at another, and the facility or difficulty of arresting it by remedies. In the latter stage of the disease or collapse it is not only observable in its intensity, or the contrary, but in the varying proportion in which the admissions into hospital in that state occur, and as a consequence in which patients recover or die.

On considering the rate of mortality in cholera throughout Europe, one is necessarily struck with the fact, that under every possible variety of management and medicine, the average has, in each country, been very much the same. It has been hence hastily inferred by general reasoners, that the influence of medicine in this disease really amounts to little or nothing. The circumstance, however, is easy of explanation to those whose information extends a little into details. In violent incursions of cholera, those who are attacked fall into collapse, and die every where before remedies can be efficiently applied, so that the difference of mortality between one country and another must be inappreciable, or relate only to the virulence of the epidemic. On the other hand, when it sets in under a milder form, when there is time for the application of remedies, and even when they are in a great proportion of cases efficacious, there may still be no essential difference in the average recoveries; as in a complaint about the treatment of which there exists such a variety of opinions, even among the best informed of the medical profession, we may infer fairly that the average amount of judicious and injudicious treatment is in every country pretty much the same. Deductions, as to the influence of remedies, from large averages of the mortality, are in fact, too loose and liable to error, to be worth a moment's consideration in medical sci-

ence. The comparisons which are to influence our opinions of medical remedies must be much more close and accurate, not only as to the conditions of the patients when they first fell under treatment, but as to the conditions of the atmosphere, and locality in which the disease originated. If the inquiry be entered into in this spirit of fairness and accuracy, it will not be difficult to show that in the vast number of cholera cases in which there is the least time for the influence of medicine, that influence in skilful hands is more evident, and, to use so proud an expression, more triumphant, than in any other disease whatsoever.

There is one of those circumstances to which I have referred, that must make the comparative influence of different remedies in the treatment of cholera a matter of great moment: I mean the variable nature of the disease itself. Those of second-rate power, which sometimes obtain great celebrity whenever it begins to assume its milder form, are clearly not only useless but mischievous, in cases of a severer type, taking place, as they do, of medicines on whose timely exhibition the lives of the patients depend. The occasional success or efficacy of remedies of inferior power is, indeed, far from advantageous to the sick, in most dangerous diseases, and is unquestionably an evil, as it relates to such as are eminently destructive, since it tempts the inexperienced practitioner to trust to them in cases where their administration leads to utter failure. I have often questioned whether, as regards cholera, it would not be better for the community that medicines of that class had never been discovered or applied. The practice of those who are too indolent or indifferent to make the respective merits of remedies a subject of important study, would then be confined to such as are influential under the worst states, compatible with recovery.

In concluding what may, perhaps, be considered a somewhat tedious introduction to my recollections of cholera, and to those impressions respecting its treatment to which they led, it will be seen that I have not sought to attach value to any views I entertain which are founded on mere opinions; such I have already deprecated; and that nothing is confidently advanced which is not a fair induction from an extensive collection

of facts. My object has, indeed, been not so much to win public attention by new suggestions, new remedies, or new modes of management, as to point out the proper application and merits of some already before the world, and prove the necessity of more accurate hospital reporting, if we would have our labours become in any way useful to the future scientific inquirer, or advantageous to mankind.

Before entering into discussions on these subjects, however, I shall venture to give a short sketch of the incursion and progress of the disease, from its commencement to its close, in Limerick.

[To be continued.]

NEW STETHOSCOPE.

To the Editor of the Medical Gazette.

SIR,

I HAVE read with much interest the opinions of Drs. Budd and Williams on the acoustic principle of the stethoscope, with the latter of whom I fully agree that the sounds are conveyed from the parietes of the chest to the ear, *principally* by the air contained within the tube, and that they are rendered more intense by their reflection from the internal surface of the instrument, and by their consequent convergence.

This being the case, I cannot but think that, by a little more attention to the mathematical principles of acoustics in the construction of the stethoscope, its powers and utility may be much increased. As it is now made, the inner surface is generally left rough and unequal, which must in a considerable degree diminish the intensity of the sounds; and the excavation at the lower end is made without any fixed principle, being bell-shaped or conical according to the fancy of the maker.

Now if the body of the instrument could be hollowed out in the form of a very eccentric ellipsis, and the ends cut off by planes passing through the foci, the rays of sound which enter one end would, after one reflection, all converge at the other. This portion is for examining the sounds caused by the voice, as pectoriloquy, &c. For the purpose of examining the respiratory sounds, another part must be added, excavated in

the form of a parabola, having its latus rectum equal to that of the ellipsis, and its upper portion cut off by a plane passing through its focus. This part of the instrument should be so adapted to the other, that the focus of the parabola may coincide with one of the foci of the ellipsis.

It is unnecessary for me to add, that all rays of sound entering the lower end of this stethoscope parallel to its axis, will, after two reflections, converge at its upper end. In regard to the oblique rays, this instrument possesses the same advantages or disadvantages as the one now in use.

The murmuring sound which is heard when hollow bodies are applied to the ear, may be diminished by covering the outside with some bad conductor of sound.

There will be some difficulty in turning the curves above described, so that they shall be perfectly accurate. I believe, however, that even an approximation to this form would render the instrument more serviceable than the one now in use.

I subjoin a diagram, and the dimensions which appear to me most convenient.

A, the parabola. B, the ellipsis. C, focus common to the two curves. The rays, $a a$, and all included between them, will pass directly to the superior opening; $b b$, which fall on the curve, will be reflected, and pass through the focus C, and ultimately converge at the focus F.

Major axis of ellipsis, 8 inches.

Minor ditto, 1.4 inches.

Latus rectum, or aperture, .25 inches.

Length of this part of the stethoscope, 7.9 inches, nearly.

Abscissa of the parabola, 1.2 inches.

Diameter of the lower end, 1.5 inches.

Latus rectum, .25 inches.

Length of the whole instrument, 9 inches, nearly.

The equation to the latter curve, $7^2 = 4ax$, becomes (since $4a = .25$) $2y = \sqrt{x}$, or the diameter of the lower opening = the square root of the length of this portion.

The diameter of the small apertures ($\frac{1}{4}$ of an inch) being smaller than that usually employed, it may be lengthened by rounding off the sharp edges.

Yours respectfully,

HENRY BARRETT,
Surgeon.

Watlington, Oxon.
Dec. 14, 1837.

FATAL DISEASE OF THE STOMACH.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think the following case worthy of being recorded in your Gazette, you will oblige me by giving it a place there.

Margaret B—, aged 18, had consulted me some months ago for occasional gastralgia, which was removed by mild aperients, a system of diet, and

the subnitrate of bismuth. Since that period she has appeared to be in perfect health, with the exception of habitual flatulence, and has been active in her duties as lady's maid. Yesterday, Dec. 22nd, whilst engaged in some domestic avocation, she uttered a violent scream, leaned forward over a table, and complained of acute pain in the umbilical region. It being the day on which the menstrual period should have occurred, I at first regarded the attack as arising from this cause, but inflammatory symptoms soon presented them-

selves, the pulse became extremely quick, small, and depressed, the abdomen tender, the extremities colder than natural, the countenance expressive of hopeless anxiety, and the stomach occasionally, but not distressingly, rejected its contents. Bleeding, instead of being followed by the satisfactory rise of the pulse, which we look for in ordinary cases of membranous inflammation, caused only greater rapidity and further exhaustion. The bowels were moderately moved, but from the moment of the seizure to its fatal termination, no remedy gave relief, and in twenty-four hours the poor girl was released from intense suffering.

Post-mortem examination six hours after death.—The body (which inclined to “*embonpoint*” rather than emaciation,) presented no mark of disease externally, excepting a tympanitic state of the abdomen, which had commenced slightly before death.

The abdomen contained some air, and from three to four pints of a turbid fluid. Recent and slight inflammation was evident on the peritoneal coat of the transverse colon: at its junction with the ileum, the inflammatory appearances were more decided, and at one or two parts had gone on to deposit of lymph; there were several recent adhesions in the vicinity of the duodenum, but the cause of death was apparent in an ulcer at the smaller arch of the stomach, near the *œsophagus*. At this spot the stomach was slightly adherent to the under surface of the liver, to the extent of a shilling, the corresponding portions of both organs being, as it were, shaded by ulceration. Here a circular aperture, about the size of a duck-shot, and having a well-marked gangrened margin, had allowed the contents of the stomach to escape into the abdominal cavity. The internal surface of the stomach presented a funnel-shaped ulcer through its coats, which would admit the end of the forefinger. I may here state that, in answer to my question, “have you any other pain than that in the bowels,” she said, “Yes, between my shoulders and here,” (pointing to the sternum), “but this is nothing compared to the other.”

I regard this case as illustrative of three points, namely,—1st, To what an extent disease of the cardiac extremity of the stomach may proceed without

apparent loss of health.—2ndly, How beautifully Nature makes her attempt to repair an injury, as in this instance, by the long-standing adhesion of the liver to the attenuated stomach: and, 3rdly, How completely and instantaneously she gives up the contest, when that injury becomes irreparable. Dr. Abercrombie, in his excellent work, cites a remarkably similar instance: and I have been the more induced to trouble you with this communication, in the hope that this similarity of symptoms may be considered practically diagnostic, although I need not say of a hopeless case.

I am, sir, with much respect,

Your obedient humble servant,

JOHN PRICHARD.

Leamington, Dec. 23, 1837.

MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo vendendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

POISONOUS CANDLES.

It has often been asserted that London is the healthiest of the great cities of Europe. Unfortunately, however, this boast is founded upon the Bills of Mortality; and the incorrectness of the Bills is but too evident to every one who has inquired into the subject. If we give up the position founded upon the “numerical method,” as untenable, and attempt to balance the destructive influences at work in London against those which harass other cities, the problem becomes too complicated to be solved.

It is clear that almost all the agents of death and disease are in full activity around us; spoiled provisions are the habitual food of large classes of the population; the air is deteriorated by noisome exhalations, from the decomposition of animal and vegetable matter; and the more indigent inhabitants of

London are crowded together in a manner incompatible with health, and almost with life. It may perhaps be urged that many, or all of these noxious agents, are to be found in still greater force in foreign cities; and that if the Londoner drinks opiated beer, the Parisian is obliged to swallow leaded wine. A new source of death, however, unknown to our fathers, has been introduced among us, to which this argument will not apply—we speak of the arsenical candles, by which one of the most fatal of poisons is spread in a gaseous form over the dwellings of thousands of families. The same deadly manufacture was, indeed, tried in Paris, but was put a stop to by the vigilance of the *Conseil de Salubrité* and the police.

The merit of discovering the presence of arsenic in candles, in London, is due to Mr. Everitt, who mentioned it about six months ago, in a lecture delivered before the Medico-Botanical Society. The subject has since been frequently discussed at the Westminster Medical Society, who appointed a Committee to investigate it. Their report, drawn up by Dr. Granville in a clear and judicious manner, is now before us*.

It appears that at the meeting of the 28th of October, a member informed the Society that a hypochondriac had supposed himself injuriously affected by the use of the candles supplied to him at an hotel; and had in consequence sent a piece of one to a professor of chemistry, who, on analysis, found that it contained a sufficient quantity of arsenic to account for the morbid symptoms described by the patient. After a protracted discussion, the Society, on the 4th of November, 1837, came to the resolution of appointing a Committee to inquire into the presence of the poison in candles, and to ascertain in what

proportion it was contained in them, as well as to consider the probable effect the arsenic might have on animal life during combustion.

The reporter observes that Chevreul, one of the most distinguished French chemists of the present day, in the course of an investigation into the nature and elementary composition of animal fats which lasted ten years, discovered that common tallow consisted of two distinct substances. The one was solid, and the other was of the consistency of olive oil: he called the former *stearine*, and the latter *elaine*.

Stearine possesses two great advantages over tallow; in the first place, it is almost free from smell, and, secondly, its melting point is much higher. The manufacture of stearine candles, however, presented some difficulties; these were overcome by a process which was kept a secret at Paris (where the candles were first made); and which was afterwards sold to a London manufacturer, who immediately introduced it into this country.

A man, moreover, who knew the secret, went about to the candle-makers in London, and sold them not only the mode, but the actual material by which stearine could be converted into marketable candles. This material was soon ascertained to be white arsenic; and the chandlers having now emancipated themselves from the tax which they had been obliged to pay for the purchase of the secret, the manufacture of arsenical candles soon became almost general. The stearine candles were sold cheaper than any others, except those of common tallow, and became so popular, that some of the most respectable manufacturers of wax and spermaceti candles were obliged to make the new stearine ones, in order to retain their customers, and indemnify themselves for the great diminution in the sale of candles of the superior kinds.

* See page 585 of our present No.

The manufacturers admitted that the candles in question contained arsenic, but the Committee resolved to ascertain this fact by chemical analysis, and also to determine the quantity contained in each candle; as this was of importance with reference to the probable effects of such candles on the human constitution. The chemical experiments were conducted by Mr. Everitt, Mr. Golding Bird, and Mr. Richard Phillips; the first of whom repeated some of the experiments at one of the meetings of the society. The water in which the suspected stearine had been boiled was tested with re-agents, which showed the presence of the white oxide of arsenic; and metallic arsenic was reduced from the precipitate obtained by sulphuretted hydrogen gas.

Mr. Everitt satisfied the committee that the quantity of arsenic varied in different samples, from ten to eighteen grains in the pound of four candles; and that the largest proportion, namely, four grains and a half in each candle, was found in the cheapest sample.

It was also found that the arsenic was only mechanically mixed with the stearine, and not dissolved in it; and hence a larger quantity was contained in the top of some of the candles than at the bottom, because in moulding the candles are reversed. Such a candle, therefore, when first lighted gives out a greater quantity of arsenical vapour, than when it is nearly burnt out. When glass vessels were placed over the candles, arsenious acid was deposited on their inner surface. Mr. Bird carefully examined the products of the combustion of arsenicated animal fats, and found "that according as the combustion is impeded or free, that is, according as more or less oxygen has access to the flame, metallic arsenic, or the so-called black oxide of arsenic (?)—or arsenious acid, is given out and deposited under their respective character-

istic forms. According to Mr. Golding Bird's experiments, there might be a point of such low combustion in the burning of arsenicated fats, as to give rise to that most deleterious and fatal gas, called arsenuretted hydrogen gas."

In the course of their experiments, the Committee received candles for examination from various sources, some of which were found to be arsenical, and others not. In wax, spermaceti, and composition candles, the poison was never detected.* Experiments were also tried on birds, with arsenicated and with ordinary candles. Several linnets and greenfinches were shut up in wooden chambers which were well ventilated, and contained food and water. In two of these chambers arsenical candles were kept burning, and the birds died; in another spermaceti candles were burning, and the birds remained perfectly healthy. The same experiment was tried with rabbits and guinea-pigs, and although the arsenical vapours did not kill them, they evinced signs of distress, particularly the rabbit. It became dull, "was constantly lying on its side, its flanks drawn in, and its breathing quick, accompanied with a tremulous motion." The rabbit in whose chamber spermaceti candles only were burned, did not exhibit these symptoms.

For the last thirty-six hours of the experiment, an earthen dish was fixed over one of the arsenical candles, at the height of two feet and a half, while shallow basins holding distilled water were placed on the floor near each

* Our readers must not suppose that stearine candles are always sold under that name. They are sometimes called German wax—imperial wax candles—French candles—pressed tallow—tropical candles—moulded wax—and Venetian wax.

We observe that one advertiser asserts that he makes them with what he calls "that harmless metal, bismuth."—Query, is it so?

They may also be made with one-thirtieth part of wax, which must be safer, we should imagine, than the most "harmless metal."

candle; and Mr. Everitt discovered ample traces of arsenic, both on the dish and in the water. Hence it appears, that when arsenical candles are burning, the vapours fall as well as rise.

The Committee then proceed to mention some recorded facts, showing the deleterious effects of arsenical vapours. There are two cases in which arsenuretted hydrogen gas has been fatal. One is narrated in the *Annales de Chimie* (vol. xcv. p. 110) in an extract of a letter from M. Ruhland to M. de Guyton Morveau.

Mr. Phillips told the Committee of a similar case which occurred in 1836, at Falmouth. Mr. Beard, who was delivering a lecture on the gases, at the Mechanics' Institute, inhaled a portion of arsenuretted hydrogen gas, and died some days afterwards, in spite of medical assistance*.

The second form of arsenical vapours is that in which they contain the black oxide; and in France, where the black oxide is employed under the name of *poudre à mouches*, to destroy flies, it is found to be fatal to them, if they but approach the atmosphere around the vessel containing its solution.

The third form of the vapours is that in which they consist of arsenious acid, and the pernicious influence of this gas is well known. The reporter cites several instances to this effect. Our readers will find two of them, and another case besides, in Dr. Christison's work on Poisons (p. 236.) In the mining districts of Cornwall, too, arsenical vapours are found to be injurious to animal as well as vegetable life.

To many it will seem a work of supererogation to prove the unwhole-

someness of arsenical candles; but such objectors are fully answered in the report before us.

The unwholesomeness of the stearine candles was, of course, quite clear from the moment that it was known that they contained arsenic; yet the perpetrators of these candles will, no doubt, complain of the Committee for shedding "intolerable day" upon the subject, and thus diminishing their gainful craft. Yet, what with the *auri sacra fames* on the one hand, and the desire to make a show at small cost on the other, we fear that even this unsparing exposure will fail of its due effect with some.

Whether it would be desirable to have a Board of Health in this country to which such points might be referred, is too weighty a question to be mooted at the end of an article; perhaps we may take some other opportunity of discussing it. Meantime the thanks of the community are due to the Society for the pains which they have taken in investigating a subject of such importance to the public welfare.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

The London Dispensatory. By ANTHONY TODD THOMSON, M.D., F.L.S. G.S. Professor of Materia Medica, Therapeutics, and Medical Jurisprudence, in University College, London, &c. London, 1837. 8vo. pp. 1164.

DR. A. T. THOMSON'S position, as professor of materia medica in one of our largest schools, as well as the popularity of his Dispensatory, are two manifest reasons why the accuracy of his works should be watched over with the most scrupulous care. Unfortunately, this care is not bestowed; and as on a former occasion it was our duty to point out some of the numerous errors in his *Elements of Therapeutics*, so it is now our disagreeable office to show how

* The account of this case, which is said in the report to be taken from a Cornish paper, states, that the lecture on the gases was delivered December 5th, 1836; that the experiments in illustration of that lecture were performed on the 19th, when the fatal inhalation took place; and that Mr. Beard "died on the 29th, that is, twenty-four days after the accident." It would seem rather to have been ten days after the accident.

frequently the author has slumbered in revising the ninth edition of his Dispensatory.

Before we enter upon the long catalogue of faults, let us preface our censures by declaring that we are by no means blind to the merits of the book. These merits consist in a generally good selection of matter, a happy amalgamation of facts drawn from a hundred sources, and a fluent, natural style. But as our author's faults must not make us unjust towards his brighter qualities, so these latter will hardly prove a sufficient answer to the numerous counts of our indictment, in which we accuse him of being one of the most careless of all writers; and that upon a subject in which accuracy is imperiously required. Let us proceed to substantiate what we have said.

Taking the articles in the order in which we have made our notes, we find that under *Ammonia liquor fortior*, our author says it "is chiefly employed by the retail druggists, for preparing the liquor ammoniac of a strength equal to that of the Pharmacopœia; for which purpose, one fluid ounce of it is mixed with three fluid ounces of distilled water." (p. 188.) Instead of *three*, he should have written *two*. The error unfortunately exists in both the original editions of the Pharmacopœia: Mr. Phillips, however, has given it in his table of errata.

Under the head of *Ipecacuanha*, he has omitted, among its official preparations, not fewer than three; namely, the Pulvis Ipecacuanhe et Opii of the Edinburgh Pharmacopœia, as well as the Pil. Conii Comp. and the Pil. Ipecac. Comp. of the London Pharmacopœia.

He says of *Digitalis*, that "by a proper exhibition of it, the frequency of the pulse may be diminished any number of pulsations, and regulated at the pleasure of the practitioner," (p. 380); an assertion in which we fear few physicians will agree with him. A few lines before, an instance occurs of almost miraculous carelessness, in connexion with the same drug. Our author had formerly said, "*Digitalis* is directly sedative," (4th edit. p. 321); and on the word *sedative* was the foot-note, "this term implies, as I understand it, any substance which diminishes the action of the heart and arteries, *without first increasing it*." The text has now, however, been altered to, "*Digitalis* is

directly stimulant, indirectly sedative," (p. 380); but the foot-note remains the same as before.

We fear that it is not yet known what doses of *digitalis* are effectual, without being poisonous, and that consequently it still remains the most dangerous of remedies. From two papers by M. Joret, in the Archives Générales for January and March, 1831, it would seem to be a common thing, in the hospitals of Paris, to give a patient ten or fifteen grains of powdered foxglove in a day. One of the physicians to the Hôtel-Dieu gave much larger doses to three patients under his care, and in two of them the treatment was followed by sudden death. In one case the patient drank an infusion made with four drachms of the dried leaves; and though this caused frequent vomiting, he was made, on a subsequent day, to take an infusion made with five drachms. He vomited again, but less than before, and the pulse sank from 120 to 45. The potion was discontinued, but two days afterwards he dropped down dead.

On the other hand, some very interesting remarks on *digitalis* were published, some years ago, by Dr. John Davy, in which he showed that it might be taken by persons of broken-down constitution, in much larger doses than was generally supposed. He gave it to soldiers who returned from tropical climates with diseased livers and dropsy, to the extent of 3ss., ʒj., and even grs. 105, of the pulv. *digitalis*, in 24 hours. To guard against being misled, he sent to Apothecaries' Hall for a fresh supply, but still found the same doses borne. He then gave the same *digitalis* to other patients not placed under similar circumstances, and found that it produced its usual effects in the usual doses. Of these cases Dr. Thomson appears to be ignorant, for no mention is made of them; and coming from such an authority as Dr. Davy, they are too important to be passed over in silence.

He says, that the strength of the infusion of *digitalis* is just one-half of that in the last Pharmacopœia (p. 897); but it is considerably less; for in the former one a drachm of the leaves was ordered to eight ounces and a half of fluid; and in the present one, twenty-one ounces of fluid are used with the same quantity of leaves as before.

At page 705, he ascribes the term *Vinum album Hispanicum* to the London College; the term they really use is *Vinum Xerium*.

At page 738, he says, that one fluid drachm of diluted hydrochloric acid contains about 32 grains of real acid; yet the diluted acid is but one-fourth of the strength of the strong acid, and the latter has a specific gravity of only 1.160!

At page 776, he says, in the note 2, "The title of this section in the London Pharmacopœia is, *Alkalies and their Salts*;" not so; the title *was*, but *is* no longer.

The London College order the Cataplasma Conii to be made with the extract; our author with *dried hemlock*, (p. 840)

The London College order the infusion of cinchona to be macerated for *six* hours; our author translates it *two*, (p. 895)

In the Inf. Rosæ Comp. the time of maceration is *six hours* according to the College, but *half an hour* in our author's translation, (p. 901.)

In the Inf. Scoparii, the time of maceration is *four* hours according to the College, and *two* hours in our author's translation, (p. 902;) and in the Inf. Valerianæ, *half an hour* according to the College, and *two hours* in Dr. Thomson's translation, (p. 904.)

He directs the liniment of opium to be made with *ten* fluid ounces of tincture of opium to six of liniment of soap (p. 908;) the quantity in the London Pharmacopœia is only *two* ounces of laudanum to six of the soap liniment.

The Linimentum Terebinthinæ of the London College is composed as follows:—

"R Saponis mollis uncias duas,
Camphoræ unciam,
Terebinthinæ Olei fluiduncias sedecim. Agita simul, donec miscantur."—8vo. edit. p. 168.

Dr. Thomson's translation (?) is as follows:—

"Take of cerate of resin, a pound; oil of turpentine, half a pint. Melt the cerate; then add to it the oil of turpentine, and mix them," (p. 909.) This is, as our readers may guess, the formula of the former Pharmacopœia retained by the most careless of men.

In the Liquor Aluminis Comp. our author has diminished the quantity both

of the alum and of the zinc, by one half.

The London College direct the Spirit of Rosemary to be made with two drachms* of oil of rosemary, a gallon of rectified spirit, and a pint of water: our translator orders two pounds of rosemary, a gallon of rectified spirit, and a gallon of water (p. 1044;) he afterwards says, "oil of rosemary is sufficiently volatile to rise in distillation with rectified spirit, which the Edinburgh College has, therefore, ordered to be used," just as if the London College did not order it likewise; and he then gives as the official preparations of Spir. Rosmarini in the London Pharmacopœia, the Linimentum Saponis Comp., and the Spiritus Lavandulæ Comp.; though the former is now called Linim. Saponis, and the latter Tinctura Lavandulæ Comp. These faults in nomenclature, indeed, are, singly, trifling; but when they occur frequently, they greatly diminish the value of a work of this kind.

In the Tinctura Camphoræ Comp. the London College have restored the oil of aniseed: Dr. Thomson omits it (p. 1062.)

In the formula for the tincture of black hellebore, the London College say—

R Hellebori contusi uncias quinque, &c.

Dr. Thomson, however, first mis-translates it *sliced*, instead of *bruised*; and then says, "the smallness of the fibres of the root of black hellebore renders it almost impossible to follow the direction of the London formula," &c. (p. 1070), whereas there is no difficulty whatever in following the directions actually given, but only in complying with the provisions of his false translation.

The *Mellita* and *Troches* are wholly omitted in the body of the work in their proper place, and appear in a supplement at the end of the volume, between the appendix and the index.

Our author continues to say of the Unguentum Piperis nigri of the Dublin Pharmacopœia, "We are ignorant of the purpose for which this irritating ointment is designed," (P. 1096.) Yet its use is mentioned in a book which Dr. Thomson *ought to have read*, as he *has edited it*; we mean Bateman on Diseases of the Skin. When speaking of Porrigo scutulata, Bateman says,

* In the octavo edition, *decem* has been misprinted for *duas*.

"There is an Unguentum Piperis nigri in the Dublin Pharmacopœia, of the efficacy of which Dr. Tuomy speaks highly. See his Essay on the Diseases of Dublin.* Moreover, Drs. Barker and Montgomery say of this preparation:—"This ointment was formerly in vogue as a cure for tinea capitis; and the powder of black pepper still remains an ingredient in the French *onguent pour la gale*†."

At page 1100 *et seq.* Dr. Thomson gives a "table shewing the proportion in which opium and certain preparations of iron, antimony, arsenic, iodine, and mercury, are contained in some compound medicines;" but it unfortunately contains several errors. *Pilula Saponis cum Opio*, Lond., stand instead of *Pilule Saponis Comp.*; *Pilula Syracis Compositæ*, Lond. are omitted; and the *Pulvis Cornu insti cum Opio* remains here, and also in the Index, though no longer in the Pharmacopœia. The *Liquor Potassæ Arsenitis* is stated to contain four grains of arsenic of potassa in the fluid ounce, though, in fact, each ounce contains this quantity of arsenious acid in combination with potass. But the most important error is in the statement that two fluid ounces of the *Liquor Hydrargyri Bichloridi* contain half a grain of bichloride of mercury: the fact is, that *one* fluid ounce contains this quantity.

In the posological table (p. 1143), the dose of aconitina is said to be from gr. $\frac{1}{4}$ to gr. ss.; at p. 780 the only dose mentioned is 1-16th of a grain.

The dose of tartar emetic is stated to be from gr. j. to 3ss. (p. 1143); any dose, however, beyond three grains, is hardly known in this country, the fl-lowers of Rasori in England being few and far between‡.

The dose of arsenic is said in the table (p. 1143) to be from gr. $\frac{1}{3}$ to gr. j. Surely this last is a monstrous and unheard-of quantity. In the account of the arsenical solution at page 529, the dose is

stated to be miv., gradually increased to mxxx. twice a day, while in the table (p. 1145) it is stated to be from mv. to f. 3j. Now mxxx. are only equal to a quarter of a grain of solid arsenic, and f. 3j. of course to half a grain. Thus the maximum dose at page 1143 is made double what it is at page 1145; while this, again, is just double the maximum dose given at page 929; and thus the largest quantity of arsenic which may be given is stated to be four times greater at page 1143 than it is at page 929.

The dose of the *Pil. Cambogiæ* [Comp.] is stated, at page 1145, to be from two to three grains; at page 1024 it was said to be from ten to twenty grains; *utri creditis Quirites?*

The dose of iodine is asserted to be from gr. $\frac{1}{4}$ to gr. iv. (p. 1144). We rather agree with those who think that the benefits produced by iodine are due to the long continuance of very small doses, and that large ones are inexpedient as well as unsafe. We would never give more than a grain in the course of twenty-four hours.

The dose of the *Spiritus Ammoniacæ succinatus* is said to be from mxx. to f. 5j. This medicine is now called *Tinctura Ammoniacæ Composita*; and as it has not only changed its name*, but trebled its strength, being now made with the *Liquor Ammoniacæ fortior* instead of *Liquor Ammoniacæ*, mxx. are a full dose, and f. 5j. an unbearable one. In the body of the work, the dose of the *Tinctura Ammoniacæ Comp.* is stated to be from mv. to mxx. (p. 1060). So that here, also, the quantities mentioned in different parts of the work as the proper doses vary exceedingly.

Strychnia is directed to be given in doses varying from $\frac{1}{3}$ of a grain to a grain (p. 1149). We more than doubt the propriety of ever giving grain, or even half-grain doses. In a very instructive case narrated in the second volume of the Transactions of the Provincial Medical and Surgical Association, the patient, after having taken half a grain of strychnia twice a day for five days without any sensible effect, was ordered to take a grain twice a day. He soon became apparently accustomed to this quantity, and was then ordered

* Bateman's Practical Synopsis of Cutaneous Diseases. Sixth edition, p. 173, note.

† Observations Chemical and Practical on the Dublin Pharmacopœia, &c. Dublin, 1839; p. 37c.

‡ At page 919 Dr. Thomson says, "Rasori gives at first grs. xij. during the day, and the same quantity at night, dissolved in a pint of barley-water, to be taken in divided doses, and carries it to doses of grs. ii. and a half." The same error occurs in the fourth edition, page 780, excepting that "ij. grs." stands instead of "grs. ij." Perhaps grs. stands for *gros*, the account having been taken from the Archives Générales.

* The old name is retained in Dr. Thomson's Index, which refers us to page 1041, where, however, it does not occur either under its old or new name.

to take a grain and a half night and morning; but the first dose produced fatal opisthotonos, the patient dying in less than four hours after taking the medicine.

The dose of *Uva Ursi* is stated to be from gr. x. to ʒj. , the last being, of course, a misprint for ʒj.

Lastly, the dose of *veratria* is said to be from gr. x to gr. ss! (p. 1146). The gr. x. is, no doubt, a misprint for gr. $\frac{1}{10}$; but even these quantities are too great; in proof of which we appeal from Dr. Thomson in his posological table, to Dr. Thomson in the body of the work, where he says, "If it be internally employed, the dose should not exceed one-twelfth of a grain; and the action of even this minute dose should be watched." (p. 821.)

Again, the dose of *vinum veratri* is said to be from m℥ to grs. xx; grs. being, we presume, a misprint for m℥ —but the constant repetition of such errors, in regard to the most powerful agents, evinces, to say the least, a most unpardonable degree of carelessness.

Among other tables is one setting forth the new names, which are placed opposite those of the former edition of the Pharmacopœia. Now as a list of this kind is given in the original work, published by the College, we should not have thought it very difficult for any one to avoid important errors. Alas! not so: we have observed not fewer than nine or ten in our author's list of "former names," which were not in the last edition of the Pharmacopœia; and what is more absurd, the names into which they are said to be changed are not always in the new one! We are told that *Aqua Calcis Muriatis* is now changed into *Liquor Calcis chloridi*, and so, likewise, four other *Aque*, which did not exist, are said to have been changed into *liqueurs*. We also have a set of *Spirits* which did not exist till Dr. Thomson made his list, and which he tells us are changed into *Tinctures*. Among others we find *Spirit. Rhei Comp.* given by Dr. Thomson, as converted into *Tinctura Rhei*; whereas the only Tincture of Rhubarb in the present edition of the Pharmacopœia is the *T. R. Comp.* Thus, the thing said to be changed did not exist in the former edition of the Pharmacopœia, and that said to have been substituted for it is not to be found in the present!

The number of articles omitted in this same Posological Table is rather considerable. Among the decoctions, for instance, we miss those of pomegranate, and *uva ursi*. Among the infusions, those of *diosma*, (*buchu*) *krameria* (*rhatany*), *hop*, and *parcira*; among the tinctures, those of *colchicum*, *eubebis*, *galls*, and the compound tincture of iodine.

Again, of the articles of the *Materia Medica*, Dr. Thomson has altogether omitted two—viz. *Brominium* and *Ergota*; while some which occur in the body of the work are excluded from the Index.

As to the misprints and orthographical errors with which the work before us teems, we hardly know how to manage them; to give six or eight is nothing, and to give all, we should require to have a supplemental sheet entirely devoted to them. We must, therefore, steer a middle course, and content ourselves with a dozen or so, by way of specimens.

Among the foreign terms for arsenic acid, we find (at p. 215) *Naturlicoer Arsenickhalk* given as the German one; the first word is meant for *natürlicher*; but what *halk* signifies, at the tail of the second, we know not.

The German words, or rather what are intended as such, are certainly extremely curious: we had made a list of *five and twenty* of the most remarkable, but omit them in mercy to our readers.

The Italian term for the same substance is said to be *Arsenico iuxneo*. There's a portent for you—a word to crack an Italian jaw—*IUXNEO*. It is not a little curious that these imaginary German and Italian words are precisely the same as in the 4th edition, p. 186; so that they seem to have been copied from edition to edition, with a constancy worthy of a better cause.

At p. 202, among the synonymes of sulphuret of antimony, we have, as the French one, *L'antimoine sulfure*, instead of *Sulphure d'antimoine*; and at p. 272, the French for cloves is said to be *Clousele Girofles* (it is just the same in the fourth edition, p. 327, excepting that there is no accent on the first word;) the real term being *Clous de girofle*.

Then we find, *ipecacuanne* for *ipecacuanha*, at p. 284; *leveure* for *levain* (yeast,) at p. 293; *Beaume* for *Baume*,

at p. 345; *semen* for *semence*, at p. 367; *digitalis* for *digitale*, at p. 378; and so on, without end.

The Greek and Latin words appear, we think, in rather better trim than our author generally allows them to do; yet even here the errors are far from being few: thus we have *Βωμός* for *Βράμος*—*χρεας* for *κρεας*, &c. &c.; and again, *sextus* for *sextis*; *ulceres* for *ulcera*; *spergatur* for *spar-gatur*; *caloric* latinized by *caloricus*; and *utitur* employed to signify *used*, &c. &c. &c.

As we would wish to part with Dr. Thomson on friendly terms, we will remind him, that had we not thought his Dispensatory a work of merit, and one which will be consulted as an authority both by the practitioner and student, we should not have taken so much pains to point out its errors; errors, many of which he must himself acknowledge are fraught with the utmost danger, and all of which might have been avoided by a very moderate share of attention.

WESTMINSTER MEDICAL SOCIETY.

EXTRACTS FROM THE REPORT ON ARSENICATED CANDLES.

ALTHOUGH stearine was prepared in London in considerable quantity, candles manufactured with it were not, at first, so numerous as they have become since; owing to the secret process employed, to render them fit for sale. Your Committee have been informed, by a very intelligent manufacturer of candles, who made use of, but has since given up, the process in question, that an individual, in possession of the secret, went about to the candle-makers in London, to sell, for a consideration, not only the mode, but the very material, with which stearine was to be made fit to be converted into showy and attractive candles for the market.

The material in question was very soon ascertained by some of the candle-makers to be powdered white arsenic; and thus having emancipated themselves from the tax which they formerly paid for what had now ceased to be a secret process, those persons were enabled to extend the field of their operations, whereby the practice of manufacturing stearine candles with arsenic became very soon almost

general. Nay, such was the effect produced on the market, by the appearance of this novel and extensive branch of trade (at a price lower than that of any other candle except those of common tallow), that some of the most respectable manufacturers of wax and spermaceti candles were compelled to resort to the making of the new stearine candles (according to the then well-known process, which, your Committee have learned, consisted in putting one pound of white arsenic in every hundred weight of stearine), in order to retain their customers, and, in some measure, indemnify themselves for the losses sustained in consequence of the great diminution that had necessarily followed in the sale of every superior sort of candles.

As is generally the case in all matters of this kind, notwithstanding the notoriety of the practice among the trade, the public, whose welfare was likely to be affected by it, remained in ignorance of the fact, that in using the new stearine candles they were burning arsenicated candles; until Mr. Everitt mentioned the subject in a lecture delivered in June last, before the Medico-Botanical Society—and again until Dr. Scott, in October, as stated in the introduction to this Report, brought it to the notice of the Westminster Medical Society, and led them to the present investigation.

The admission made by the parties themselves who employed it, that arsenic was contained in the candles in question, might have been deemed sufficient for the purpose of the present investigation: but your Committee could not rest satisfied without verifying the fact by chemical analysis, and still less without ascertaining the quantity present in each candle: as that point was held to be of great importance in determining the probable injurious effects of such candles on the human constitution.

Accordingly, a great many specimens of the candles in question were procured from several shops, under various denominations, and were submitted to accurate analysis. This was confided principally to Mr. Everitt, who repeated his experiments before several of the members of the committee, and whose results were afterwards corroborated by some fresh experiments made by Mr. Golding Bird, supported by the testimony of Mr. Richard Phillips.

The Society, through the kindness of the first of these three chemists, had an opportunity of witnessing, at one of their ordinary meetings, the repetition of some of the experiments in question, which consisted not only in testing the water (with which the suspected stearine had been boiled for some time) by proper re-agents

denoting the presence of the white oxide of arsenic, but also in reproducing the metallic arsenic from the precipitate that had been obtained in the liquid by means of sulphuretted hydrogen gas.

Through the various experiments which he made, and often repeated, Mr. Everitt satisfied your Committee that the quantity of white oxide of arsenic, or arsenious acid, contained in the candles submitted to analysis, varied, in different samples, from ten to eighteen grains in the pound of four candles, and that the largest proportion of it—namely, four grains and a half in each candle—was found in the specimen which bore the lowest price of sale.

By another set of very ingenious experiments, conducted with the greatest precision, it was ascertained that this quantity of arsenious acid is only mechanically mixed with the stearine, and not dissolved in it (the saponified stearine appearing to be scarcely capable of holding any portion of it in solution:) and it is worthy of remark, that a larger quantity was found at the top of some of the candles, which in the act of moulding forms the lower end in the mould, than at the bottom. The difference between the two ends amounted to nearly one-third of the whole; so that when such a candle is first lighted it must emit a larger quantity of arsenious acid, than when it is nearly burnt out. These several quantities of the poisonous substance are given out during the combustion of the candle, in the form of subtle vapours of arsenious acid, a fact which was proved by the deposits obtained on the inner surface of glass vessels placed over the lighted candle, and which deposits were carefully examined.

But in order to leave no vestige of doubt on this point, Mr. Everitt contrived a little apparatus, by means of which the vapours emitted by a suspected candle in a state of ignition, were obtained, partly in a solid form, adhering to the inside of the body of a retort, and partly dissolved in the condensed steam deposited in the horizontal tube of the same retort, which was kept, for that purpose, in a constant state of refrigeration. Under both those forms arsenious acid was detected.

It is to the interesting question of what are the productions of the combustion of arsenicated animal fats, that one of the members of your Committee, Mr. Golding Bird, chiefly directed his attention. He first experimented on arseniferous gases, and afterwards instituted some direct trials with a mass of fat, in which arsenious acid was mixed, and which by means of a wick was set on fire. In watching the operation in both cases, Mr. Bird convinced himself of the fact, that according as the combustion is impeded or free—

that is, according as more or less oxygen has access to the flame—metallic arsenic—or the so-called black oxide of arsenic (?)—or arsenious acid, is given out and deposited under their respective characteristic forms. According to Mr. Golding Bird's experiments, there might be a point of such low combustion in the burning of arsenicated fats, as to give rise to that most deleterious and fatal gas called arsenuretted hydrogen gas.

In the course of their analytical inquiries, your Committee received specimens of candles for examination from clubs, institutions, and private families, some of which were found to be arsenical, while others were not so. And in order not to leave any point undetermined, the analysis, in some instances, was extended to wax, spermaceti, and the old-fashioned composition candles, in none of which the noxious material was detected.

It would be superfluous to specify more minutely or technically to the Society, the several operations gone through by your Committee, with a view to settle the chemical question of the presence of arsenic in the above candles. It is sufficient to state, that the fact of its presence in such candles was established beyond all possible doubt, and that the quantity contained is considerable.

Your Committee next directed their attention to the best mode of ascertaining, as far as such an investigation can admit of demonstration, the probable effect which the respiring of the ascertained quantity of arsenical vapour might have on animal life; and after some consideration, it was determined to expose various living animals to an atmosphere in which arsenicated, or stearine candles, were burning, at the same time that an equal number of the same species of animals, and, as nearly as possible, of the same age and strength as the first set, were placed in an atmosphere of similar dimensions, wherein spermaceti candles only were used.

The Committee being anxious to convince the Society that every measure of precaution necessary to ensure accurate results in the physiological experiments about to be undertaken was adopted, have directed the apparatus employed on the occasion to be brought into the Society's apartment, at this meeting, in order that it may be examined precisely under the circumstances in which it was used, when the experiments were performing.

The apparatus represents two sets of two chambers each, made of deal boards, the one set measuring two feet by three and three feet deep, and the second two feet by two and three feet deep. Their interior is ventilated by contrivances simi-

lar to those which are recommended for large assembly rooms, namely, by several openings at the bottom and top; so arranged, that the whole, or only part of them; may be used. The top, or roof, of the chambers takes off to admit of the ready introduction and removal of the animals; and there is a glass-door in front, through which all that passes within can easily be observed. These wooden chambers stood at the height of two and a-half feet from the ground, supported upon wooden uprights, and they were fixed within a spacious and lofty apartment, well lighted and well ventilated. The two largest chambers were marked A and B, the smaller C and D.

Into the letter A two strong and lively linnets (*Fringilla Linaria*) were introduced, confined in a large cage together, raised on a stand, and placed in the centre, with two guinea-pigs and one rabbit in perfect health. In letter B a similar cage was placed with two guinea-pigs and one rabbit. Four arsenicated candles, one in each angle of the chamber, were lighted in A; and an equal number of spermaceti in B. In C two green finches, (*Fringilla Chloris*), and in D two other linnets, strong and lively, (particularly the birds in C,) were confined within a cage properly suspended, with three arsenicated candles lighted in the first chamber, and three spermaceti candles in the second.

The experiments in A and B began at two P. M. Monday, the 27th November, and those in C and D at half-after three P. M. Tuesday, the 28th November; and all of them were continued, from day to day, until Saturday evening, the 2nd December, beginning each day about ten o'clock A. M. and terminating at the same hour in the evening, when the cages were taken out, and all of them suspended in an ante-room, cleaned the next morning, and a fresh supply of food and water for the day administered, before they were again replaced in the experimental boxes.

A thermometer was suspended in each of these boxes, so as to be easily seen by the observer, and a strict watch kept by some member or other of the Committee, but especially by Dr. Scott, at whose house the experiments were made, respecting what was going on within the boxes in reference to the state of the animals, their movements, and power of feeding, the temperature and ventilation of the chambers, and the manner of burning of the candles. All these remarks were instantly committed to writing as soon as made; and your Committee beg to lay before you this curious register, which extends over a week's time, during which observations almost hourly were made for seventy-two hours. In the course of that

period several pounds of arsenicated candles were burnt in A and C. As a general statement it may be remarked that, with the exception of the first day, when it varied from eighty to ninety degrees, the temperature of all the boxes was kept, more or less, at the standard of summer heat, as the most congenial to the animals submitted to the experiment,—that ventilation was maintained as perfect as it could be,—and that in neither food appropriate to each, nor in drink, were the animals stinted in the course of the experiments.

In reporting the result of their observations made on the animals during those experiments, your Committee intend strictly and rigidly to adhere to a statement of the facts and phenomena observed, without venturing an opinion as to any relation which such facts for phenomena might bear to the vapours of arsenic, as a cause. Having once proved the presence of the poison in candles, and its volatilisation during combustion; and having faithfully reported in the register laid before the Society, what several of the members had an opportunity of repeatedly witnessing in respect to the progressive condition of the animals experimented upon, your Committee leave it to the Society, and to those who may peruse the present Report, to draw their own conclusions.

After exposure to the candles containing arsenic, for the space of three or four hours, one of the birds in A became visibly affected, but recovered in the night, on the experiment ceasing. At the termination of the first hour (on the resumption of the experiment on the following day, Tuesday), the same bird became again affected, and in an hour more it died. Its death was followed by that of the second bird half an hour later. These two birds had been in an arsenicated atmosphere for seven hours and a half altogether.

Three more linnets were immediately put into the cage of chamber A, with two arsenicated candles instead of four. In about four hours they became dull and stupefied on their perch, although, at first, they appeared particularly the reverse; they seemed much inconvenienced for the rest of that day. On Wednesday three stearine candles with arsenic were lighted, and the three birds who had recovered in the course of the preceding night, were not long in exhibiting symptoms of uneasiness. They drooped their wings, breathed laboriously, and kept their beaks constantly open; they continued so through that day. On the following day two of them became much more distressed three hours after exposure to the candles; an hour later one of them fell, as if from vertigo, from its perch, and in half an hour

it died. The day after witnessed the death of its two remaining companions, although when replaced in their chamber A, at ten o'clock that morning, they appeared to have recovered their usual state of health.

On that day, at twelve o'clock, one of these latter birds had been seen to gasp for life, unable to remain on the perch, and the other became equally affected by one o'clock P.M.

The bodies of five of these animals were confided for chemical examination to Mr. G. Bird, who reported, that distinct, though minute, traces of arsenic were found in them, under circumstances which led him to believe that the poison had been either inhaled or swallowed.

Your Committee have only to add, in respect to these experiments, that the two linnets, which had only been exposed to the burning of spermaceti candles, under equal circumstances of temperature, ventilation, space, and food, never exhibited the smallest deviation from health, and are now alive and well.

Of the larger animals, your Committee has only to report, according to the daily entries into the register, that those in the arsenicated chamber A evinced signs of distress from the second day; the rabbit in particular, which became dull from that time, was constantly lying on its side, its flanks drawn in, and its breathing quick, accompanied with a tremulous motion. These symptoms, which were not noticed in the rabbit of chamber B, kept increasing towards the end of the week, when the experiments were put an end to; at which time the eyes of the animal had become dull, the ears were drooping, yawning occurred frequently, and the guinea-pigs as well as their companion refused corn. They would take only green food, of which, however, they partook in diminished quantities; while they accepted eagerly of water twice in one day. The same species of animals, on the contrary, confined in chamber B, invariably refused the water; they seemed as lively and playful at the end of the week as when they were first put in; nor did they appear to have lost flesh like those confined in chamber A.

It had been arranged that, with a view to obtain some information as to what became of the arsenical vapours, when once they were dispersed through the chamber, an earthen dish should be fixed over one of the candles at the height of two feet and a half; and, also, that shallow basins, holding distilled water, should be placed on the floor near each candle. This arrangement, however, was not made until the third day of the experiments, and was therefore in force only for thirty-six hours altogether. Notwithstanding the short-

ness of the period, Mr. Everitt discovered both on the surface of the dish in question and in the distilled water, ample traces of arsenic; shewing, that when arsenicated candles are burning, the poisonous particles may fly upwards, or fall on the objects in the apartments near the candles.

CASE OF STRANGULATED HERNIA,

IN WHICH THE SYMPTOM OF VOMITING
WAS ABSENT BEFORE THE OPERATION
WAS PERFORMED—OPERATION—DEATH.

To the Editor of the Medical Gazette.

SIR,

If you think that the following case is of sufficient interest to hold a place in your journal, I shall feel obliged to you by its insertion.—I remain, sir,

Your obedient servant,

THOMAS MORTON.

University College,
Dec. 17, 1837.

Thomas Knight, admitted into the North London Hospital, at half-past two, P.M., January 7, 1837. The history of the case is as follows:—

He has been subject to inguinal hernia for twenty years, which was first induced after violent exertion. Since then the protrusion has much increased in size. For thirteen years after its appearance he wore no truss. Seven years ago the hernia descended more voluminously than before, and he was obliged to send for a surgeon to reduce it, as he could not effect its return himself. The hernia has frequently descended since then, but he has been always able to reduce it himself with ease.

Yesterday night, at twelve o'clock, he retired to bed as usual, laying aside his truss; soon after he was attacked with vomiting, during which the hernia descended. The tumor not yielding to his endeavours to reduce it, he was quickly seized with severe pain in his belly, which compelled him to send for professional assistance.

A surgeon attended, who, after trying the taxis for some time, without avail, recommended the man to come to the hospital, which he did. When admitted, there was a large scrotal hernia on the right side, which is tense and painful when it is squeezed. Colicky pains in the belly; nausea and retching; but *he has not vomited since the descent of the hernia*. The bowels have not been relieved since yesterday morning. The pulse is moderate; countenance is expressive of suffering. The taxis, cuemata, hot bath, and two

grains of tartar emetic, were employed, but without any good effect. Soon after the administration of the tartar emetic the muscular system was much relaxed, but he did not vomit. The operation was now recommended and performed. When the sac was opened a quantity of the small intestine was found in it, of a dark colour, but firm and glistening in its appearance. When the stricture, which existed in the neck of the sac, had been divided, the bowel was readily returned. Some omentum that was adherent to the sac was allowed to remain undisturbed. Not long after the operation had been finished, the man vomited for the first time. He had now several copious evacuations downwards from the bowels.

Jan. 8, 5 P.M.—Twenty hours after the operation, he appeared to be in a dangerous state. Has vomited several times during the last two hours. He died at two o'clock A.M., 9th January, 41 hours from the commencement of his seizure, and 29 hours after the performance of the operation.

Examination of the body, twenty hours after death.—Some vascularity of the small intestines in the pelvic region. Folds of small intestine glued together by recently effused coagulable lymph. The portion of the small intestine that had been included within the constriction was recognized by the constricted appearance which it presented at two places. The bowel was more engorged between these points than elsewhere, though the rest of the bowel for some extent was darker coloured than natural. The omentum was more vascular than is usual; the portion that had been left in the hernial sac was free from all stricture. Under the peritoneal coat of the intestine, where the constricted appearance alluded to was manifested, a narrow circular band of light yellow-coloured substance was deposited, and which was regarded as concrete pus; that had been produced in consequence of the injurious pressure to which the muscular and mucous coat of the intestine had been subjected to.

TREATMENT OF FRACTURES BY MEANS OF PLASTER OF PARIS.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel greatly obliged if you will do me the favour of inserting in your journal the following remarks on the treatment of fractured limbs, by incrusting them in plaster of Paris; which request I make be-

cause I believe that I may fairly claim to be the author of the plan, it having been proposed by me in the inclosed pamphlet between six and seven years ago; and besides which there has been for the same period in the Museum of the College of Surgeons, an apparatus invented by me for extending a fractured leg or forearm to its proper length, and for holding it so extended, and in a position neither everted nor inverted, during the deposition and hardening of the plaster of Paris around it.

Mr. Sweeting, whose communication on this subject appeared in the *GAZETTE* of last Saturday, mentions Messrs. Bond and Gale, of Glastonbury, as the parties to whom we are indebted for the plan; but I have been unable, after considerable inquiry, to ascertain the period at which these gentlemen published this plan of treatment, and should feel glad to learn whether it was before or after the date of my pamphlet, viz. September 1831.

In the *Medico-Chirurgical Review* for April 1834, the plan is spoken of as M. Dieffenbach's; but in the same journal for Oct. 1831, there is a review of my pamphlet on this subject, and the treatment is spoken of as my proposal, without any remark that it had ever before been employed or proposed by any other surgeon.

There was also a notice of my pamphlet in the *London Medical and Surgical Journal* for Oct. 1831, edited by Dr. Ryan, who condemned the plan most unequivocally, and concluded by saying:—"He has as yet tried it only on brutes, and we advise him to halt there." This journal likewise gave me credit for the originality of the plan, and for its presumed absurdity also; but Dr. Ryan, I think, must acknowledge, that he at least committed an error of judgment by condemning in so off-hand a manner a mode of treatment which experience has now shewn to be very successful.

The *London Medical and Physical Journal* for October, 1831, then edited by Mr. North, was the only other journal in which my pamphlet was noticed, so far as I am aware. The editor did me the favour to say, that where the patient is a restless child, or an irritable, or perhaps insane adult, Mr. Beaumont's plan would probably be more successful than any other yet devised. It was also stated in this journal, that though plaster of Paris might never have been employed in this country in the treatment of fractured limbs, yet that by the Arabians it had been so employed, and on inquiry, I found, in Dr. Dunean's *Medical Commentaries*, vol. ix., decade 2, for 1794, a detailed account of a case of severe compound fracture of the bones of the leg and foot so treated by the natives of Benderneck, on the Persian

Gulph. The essential difference between their mode of using plaster of Paris in compound fractures, and that described by me, consists chiefly in their using it only as a means of steadying the limb, whilst I proposed it, also, as a means of perfectly excluding the atmosphere from the injured surfaces of the bones and soft parts. The Arabians, also, employ no apparatus to extend the limb to its proper length, and to hold it so during the time of incrusting it in plaster of Paris, which is, of course, a very important point in this mode of putting up a fractured limb. The patient treated by the Arabs, it is stated, recovered, but with a leg considerably deformed.

May I beg you to do me the favour of looking over the inclosed pamphlet, and of giving your opinion as to the plan of treating fractured limbs therein proposed; and also as to whether I am, or am not, entitled to lay claim to the authorship of this mode of treatment.

I have the honour to be, sir,
Your obedient servant,
WM. BEAUMONT.

47, Berrers Street,
Dec. 19, 1837.

[We have looked over the pamphlet above alluded to. It appears to us fully to bear out the observations of Mr. Beaumont.—ED. GAZ.]

COX'S EDITION OF COOPER'S SURGERY.

To the Editor of the Medical Gazette.

SIR,
SHOULD the following seem to you a just cause of complaint, I should feel obliged by its insertion in your widely-circulated journal.

Some months ago a work was advertised, entitled, "Sir A. Cooper's Lectures on Surgery," published by Cox, of St. Thomas's-street. Now, neither in the advertisement nor in the title-page was there any thing to indicate that this was only the first volume of the work, whereas it is to consist of three; this appears to me to have been a complete trick. I have just purchased the second volume, which, in its title page, is marked as such, and in it are no less than ten superfluous explanations of the plates, so mixed up with the text of the work, that they must necessarily remain, while there are also proper explanations placed beside the plates. The following is a specimen:—

At page 62 is one headed, Explanation of Plate 6, containing a description of the five first figures in plate 3, and the six first in plate 4; also three other descrip-

tions of drawings of trusses, which I cannot find at all in the work.

Now, sir, is there no redress in such a case as this, where an expensive work is got up in such a careless and shameful manner? Surely the publisher should be compelled to give a new title-page with vol. i., and also to rectify the above ten mistakes, occupying twelve pages of the work, or to return their money to those purchasers who choose to demand it.

I am, sir,
Your obedient servant,
A STUDENT.

London, Jan. 3, 1838.

ON THE EMPLOYMENT OF GUNPOWDER AS A MEDICINE.

By ROBERT DICK, M.D., Glasgow,
*In a Letter to the Edinburgh Medical and
Surgical Journal;*

SIR,
I BEG to call, through your journal, the attention of the profession to the employment of gunpowder, as, in some cases, an useful addition to the already existing stock of medicaments.

I was induced, from theoretical considerations, lately to prescribe it, in certain cases, and had reason to be satisfied with the results.

The derangements for which it appears to me to be peculiarly adapted are morbid secretions of the gastro-mucous membrane, depending on a *sub*-inflammatory action, or accompanied by it.

In such cases, gunpowder, given in various doses, and with the occasional interposition of ordinary mild laxatives, has proved, in my hands, eminently serviceable.

Whether it may be appropriate in a greater variety of cases, or whether it may, if given in larger doses, and for a greater length of time, than I prescribed it, be found useful as a constitutional alterative, or as a cutaneous drug, I am unable to state. But I should not be surprised if it should be found so. I have administered from ten grains, indefinitely upwards, several times in the day.

I find the use of spirituous liquors, or of pungent condiments, &c. rather contraindicated during the employment of gunpowder. The gastralgic effects which I have found these produce, when used simultaneously with gunpowder, I ascribe to what I shall venture to designate the *detergent* effects of that substance on the mucous membrane, which, owing perhaps to its charcoal and nitre, it denudes of its attaching albumino-mucous secretion,

clearing, and seemingly attenuating that membrane, in some measure.

One advantage of this drug is, that it exists in commerce, ready for medical use.

The best form of administration of gunpowder is in the dry state. The liquid form does not suit.

No apprehensions need be entertained of the charcoal producing any unpleasant consequences. In *pica*, and in the chlorotic state, large quantities of this substance are eaten with impunity; and further, J. P. Frank [*De Curandis Hominum Morbis*] recommends it as an effectual remedy in flatulence.

The above notices are very general, as the remarks of an individual, who suggests a new drug, ought always to be.

I am, sir, yours, &c.

ROBERT DICK.

Kensington Place, Glasgow,
25th July, 1837.

In speaking of the therapeutic effects of gunpowder in various morbid states of the gastro-enteric mucous membrane and its secretions, it may be not unseasonable to add to the observations now made by Dr. Dick, the remark, that charcoal in its separate and pure state has been long used by various practitioners with similar intentions, and to fulfil similar indications in the treatment of ague with gastric, enteric, or dysenteric complication. As a short notice of the use of this substance is given in the Elements of the Practice of Physic by Dr. Craigie, without entering into all the details of the history of the introduction of this substance into the practice of medicine, the easiest way perhaps is to quote the account given in that work.

"The exhibition of charcoal for the cure of ague, as a substitute for bark, appears to have been practised in 1813 by Calcagno at Palermo, and afterwards by Dr. Calvert, Mr. Mackesy, Mr. Tully, and other English practitioners, in Sicily, (*Med. and Surg. Journ.* x. 15, 403); and it was used with that intention by Dr. Jackson in the West Indies. In simple ague it seems to produce little or no benefit. But in ague with affection of the gastric, or the hepatic, or gastro-enteric circulation, in ague with anguish at stomach, squeamishness, flatulence, or hiccup, and in dysenteric ague, its sanative influence is unequivocal and powerful. It may be given in doses of from ten to twenty grains in rice-water or arrow-root, either alone or with six or eight grains of rhubarb, and two or three grains of powder of ipecacuan. It appears to operate chiefly by rectifying disordered secretions of the stomach and bowels. It is probably by its charcoal, that the snuff of a candle, which has been alleged to be beneficial in curing ague, as mentioned by Lind, operates."—P. 137

NEW GERMAN WORKS.

Entwurf einer Bromatologie und Pomatologie für Kranke. Von Dr. C. F. L. WILDBERG. 8vo. Berlin, 1831; pp. 112. London: A. Schloss.

THIS is a compendium of dietetics, adapted for the guidance of invalids, and the instruction of young medical practitioners.

Zusätze zur Erkenntniss grosser Organization im Kleinen Raume. Von C. G. EHRENBURG. Folio. Berlin, 1836; pp. 30. London: A. Schloss.

Die Akalephen des rothen Meeres und der Organismus der Meduse der Ostsee. Von Ditto. Folio. Berlin, 1836; pp. 82. London: A. Schloss.

The author of these two memoirs is distinguished for his brilliant researches into the minutest structures of animated nature.

The former dissertation contains some novel observations relating to the duplicity of sex in the various Infusoria, the vascular system of the Rotatoria, together with a description of fifteen new kinds of Polygastrica, and one new kind of Rotatoria. The latter is an investigation into the anatomy of certain species of Medusa.

Über die Irren und deren Psychische Behandlung. Von Dr. BRAÜSLICH. 12mo. pp. 167. Meissen, 1837. London: A. Schloss.

This is, in a great measure, a psychological inquiry into the nature, causes, and treatment of insanity. It is addressed to non-professional as well as to professional readers. The author states, in the preface, that the number of insane persons in Germany ranges from 20 to 30,000.

Repertorium für Anatomie und Physiologie. Von G. Valentini. 8vo. Berlin, 1836. Bd. I. H., 1, 2, 3, 4. London: A. Schloss.

This work embodies some of the most interesting researches which have recently appeared in the domain of human, comparative, and vegetable anatomy, physiology and pathology. It moreover professes to furnish from year to year a retrospective glance of all that is being done in these different branches of science.

Medicinischer Almanach für das Jahr, 1838, von Dr. J. J. SACHS. Dritter Jahrgang, 12mo. Berlin, 1838, pp. 626. London: A. Schloss.

This work, which, properly speaking, is rather a medical annual than a medical

almanack, is edited by a physician already known by his writings on the *Materia Medica*. It is replete with useful information. The first portion comprises some original contributions; among the rest, an interesting account of a recent visit to the medical institutions of Erlangen, Nürnberg, Fürth, and Bamberg.

The next part (nearly 300 pages) is occupied with details of the latest discoveries in anatomy and physiology, and of the last improvements in pathology and therapeutics; systematically arranged, according to the plan adopted by the late Dr. Bluff, in his "*Leistungen und Fortschritte der Medicin in Deutschland*."

The work concludes with an elaborate digest of medical statistics, which, although relating chiefly to Germany, includes, nevertheless, other European states; and an obituary of distinguished German physicians.

De Animalculis Infusoriis.—J. A. LORENT Phil. Doct. 4to. pp. 40; Manheim, 1837. London: A. Schloss.

This dissertation contains a succinct account of the *infusoria*, more especially in relation to their mode of development. The subjoined table exhibits the recent advances of microscopical discovery, in this field of research.

"Linnæus described 3 genera 21 species
Müller..... 17378.....
Lamarck..... 23241.....
Ehrenberg.....125410"(p.11.)

Analekten der speziellen Pathologie und Therapie. Herausgegeben von Dr. H. BRESSLER und Dr. J. JACOBSON. 8vo. Berlin, 1837. London, A. Schloss.

In a former number of the *GAZETTE*, we noticed the German *Analekten* for Surgery and for the Diseases of Women. We have now before us the first number of a similar publication, devoted to practical medicine. These contain, *inter alia*, Sir B. Brodie's observations on local hysteria, and Dr. W. Stokes' investigations concerning vesicular emphysema.

British Medical Almanack.
Churchill, 1838.

This very useful little work again claims our attention. It contains almost every kind of information capable of being brought into an almanack, to which the medical practitioner can wish to refer.

While we thus do full justice to the Editor, we must add, that we do not feel much flattered by the total disregard of some hints we ventured to give last year; the imperfections then pointed out remaining unchanged.

APOTHECARIES' HALL.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE XI.

Examination of the Chest through the vital properties or functions—Analysis of the General Symptoms (concluded)—Symptoms connected with the Circulation—Analysis of the Pulse—Varieties of the Pulse explained—State of the Pulse in Diseases of the Organs of Respiration—Symptoms from the Venous and Capillary Circulation—Symptoms of Fever, or increased heat; Perspiration—Symptoms from the state of the Secretions and other functions—Respective Value of the Physical Signs and General Symptoms.

WE come now to examine shortly the nature and value of the symptoms which diseases of the organs of respiration develop in other functions.

We have noticed, in the physiological part of this course, the close relations which subsist between the organs of respiration and those of circulation; and you will be prepared to expect that disease in the former should disturb the latter, and develop symptoms in the function of circulation. Accordingly we find such symptoms in the state of the *arterial pulse*, and in that of the *superficial capillary and venous* parts of the circulation.

528.—XXI.

You know how much the pulse has for ages been relied on as a guide in the diagnosis and treatment of all diseases; but if you have had much experience, you must know how fallacious it sometimes proves; and if you have had little experience, you will acknowledge that it is very difficult to distinguish the varieties of the pulse from one another. Now I cannot help thinking that some of the fallacies and difficulties connected with the pulse as a sign, arise from our studying it too empirically,—from our not rationally considering those elements on which its varieties depend, and a knowledge of which would enable us to understand and to foresee the circumstances which are capable of producing these varieties. As the subject of the action of the heart will more fully come under our notice in the latter part of this course, I shall now only detain you with a brief analysis of the nature and varieties of the pulse of arteries.

The arterial pulse, you know, is caused by the jets of blood thrown at certain intervals of time into the arteries by the contractions of the ventricles of the heart. The motion originates exclusively in these contractions, although it may be modified by the blood which is moved, and by the tubes which convey it. Now here you have three elements:—1, the heart; 2, the blood; and 3, the arteries;—and variations in the condition or action of each of these cause varieties in the arterial pulse. Let us consider a few of these variations.

1. Without noticing the modifications in the action of the heart resulting from disease of that organ—a subject to be considered hereafter—it is plain enough, that if the other elements be equal, the strength and frequency, or rhythm, of the contractions of the left ventricle of the heart, will determine the *strength* and *frequency* of the arterial pulse. But the contractions may have another quality—that of abrupt-

ness : being rather brisk and short than strong and complete, they communicate to the pulse that character which is called *sharp*. Now what property in the heart gives it this abruptness of contraction? what but an extreme irritability? There is sometimes this irritability in inflammations and fevers; but you may find it also in conditions of mere nervous irritation, of which it is more distinctive. And it is when these co-exist with inflammation or fever, that the pulse presents a sharpness, in addition to other qualities more peculiar to inflammation. In sthenic irritations, or those connected with fulness and tone of the vascular system, which may tend either to acute inflammation or to active hæmorrhage or other discharge, the heart's contractions are strong as well as sharp; and so is the pulse. In these cases, although the original irritation were local, it has now reached the centre of the circulation, and thence, distributed through the whole system, becomes general. But let us see how the other elements modify the pulse.

2. There can be no doubt that the blood in the heart and vessels determines by its *quantity* the character of the arterial pulse: very possibly it does so by its *quality* likewise; but this is not so easy to prove. The fulness and strength of the pulse in the arteries depend materially on the quantity of blood in them; and when the pulse is frequent as well as full, there is the greater proof of plethora, inasmuch as it shows that there is a considerable jet thrown into the arteries at each contraction, notwithstanding that the contractions are so frequently repeated. But you may have a full system of blood-vessels without a large or strong pulse,—as when the heart is acting feebly or faintly; and where its irritability is lowered, such a mode of action may be actually caused by the congestion or distention which for a time oppresses the function until it is roused into reaction. Under these circumstances, blood-letting will often increase the fulness and strength of the pulse. The opposite condition—a defective quantity of blood—will modify the pulse differently according to the state of the other elements, the action of the heart, and the arterial tubes. When the irritability of the heart is reduced, together with the quantity of blood, the pulse will become softer, weaker, and less frequent. But it frequently happens, especially in nervous temperaments, or where the depletion has been carried to excess, that the diminution of the blood is accompanied with an augmented irritability of the heart, and the pulse becomes not only quicker, but sharper than usual; and the effect of the abrupt jets into a small bulk

of blood, contained in imperfectly distended tubes, is to give to the pulse that jerking or bounding character, as if a mere ball of liquid were suddenly shot through the empty tube,—which is so remarkable in the irritation of inanition and chlorosis.

3. But we cannot fully understand the variations of the pulse without attending to the properties of the tubes in which it is felt. If the arteries were tubes of an unyielding or an unvariable character, then the pulse in them would more uniformly represent that of the heart, which would be transmitted through them unmodified. But you know that they are not so: they possess properties of *elasticity* and *tonicity*, which vary according to circumstances, and which modify the pulses from the heart, by changing the size of the tubes, and the yielding or the resisting nature of their walls. Now just think how differently the impulse of a jet of blood must be transmitted by vessels when they are large and yielding, and when they are contracted and tense: in the first case the pulse would be *soft* and *full*, in the latter *hard* and *small*. What are the circumstances which affect the tonicity and elasticity of the arterial coats, and thereby the pulse? We know these but imperfectly; further experiments are wanted to elucidate them: but the following are pretty well ascertained, and they should not be forgotten in estimating the signs of the pulse. Cold causes the arteries to contract, and therefore renders the pulse smaller. You know how a cold lotion will often diminish the fulness and throbbing of the arteries of an inflamed part; and I have seen the same effect of cold more strikingly produced in the large arteries. In the experiments on the sounds of the heart which I carried on in the room below in February 1835, I repeatedly observed, that when the aorta of an ass, recently killed, was plunged into cold water, it contracted, so as not to permit the introduction even of the little finger, and its coats acquired an increased thickness and rigidity; the pulmonary artery did not contract near so much. The circumstance of temperature must therefore be taken into account in judging of the pulse; for cold may render the pulse of an artery small and hard, or if severe, small and weak, when the action of the heart and the condition of the system would give it the reverse qualities. Heat, on the other hand, within certain limits, tends to diminish the tonic contraction of the arteries; so that under its influence they receive more strongly and fully the pulse from the heart. You know how warmth restored to a limb makes it throb with these expanded pulses.

But there is another circumstance that

may modify these actions of heat and cold on the pulse, besides proving by itself a cause of modification—the condition of the capillary circulation. When this is not free, the artery will be more distended, and therefore the pulse harder and stronger than usual; and thus in fevers, where the surface is pale and constricted in the cold stage, and dry and unrelaxed in the hot stage, the pulse often preserves through these changes of temperature a hardness and strength, which would be much more varied were the capillary vessels free and exhaling their usual excretion, and which is actually diminished under the influence of a warm bath or temporary moisture of the skin, although the fever still continue. Again, whatever view we take of the nature of inflammation, we cannot, in the present state of pathological knowledge, doubt that the circulation through the inflamed vessels is to a certain degree obstructed; whilst, either as a consequence of this, or from some co-operating influence, the vessels leading to the part become dilated, and being thus more open than others to the pulse-wave from the heart, they become the seat of that throbbing hard pulse, that has been mistaken for increased action of the vessels themselves. And there are many other variations in the pulse explicable on these principles, but we really have not time to consider them further in detail, as they might occupy two or three lectures.

There is, however, one more cause of variety connected with the arteries, so frequently occurring, that I must mention it;—I mean the difference in the arteries of different individuals. Without any adequate difference in the action of the heart, in the quantity of blood, or in the temperature, you will find a very remarkable variety in the character of the pulse in different healthy individuals, and the same difference extends to the modifications of disease. Some have always a soft large pulse; others a small feeble one; others small and hard; others, again, have habitually a hard strong pulse, which scarcely becomes soft under any circumstances. The first depends on the arteries being large with thin elastic coats. The small feeble pulse may result from their small size and thin coats: this is common in females, and may co-exist with inordinate action of the heart. The hard wiry pulse is connected with small arteries with rigid coats; and the same rigidity or deficiency of elasticity in the coats of arteries of larger size gives that unvarying hardness and strength to the pulse which we so often meet with in old people, and which renders it so uncertain a sign in these cases. You may often, in the radial artery, feel the per-

manent thickening and hardness of its coats, which thus, like a tube of glass or metal, rigidly transmit the heart's pulses, without tempering them by any yielding or spring. With these peculiarities of pulse there are often connected characters of constitution or temperament, and propensities to disease or health, which are of great importance in guiding us in practice.

I cannot attempt to go into many interesting details which this subject presents; but I hope that the elementary view which I have given may prove something of a key or guide, and that you may now see (for instance) why you are to depend more as a sign of inflammation on a pulse which continues quick and strong, or hard, with permanent heat of the skin, or with perspiration, or through varying circumstances of temperature, than on one which, although very quick, sharp, and jerking, yet without fullness or permanency of character, obviously depends on an irritation more mobile and transient than that of a fixed inflammation. What a capital example of the fallacies of the pulse have we witnessed in many cases of the influenza that has been lately infesting this quarter of the globe! Here you would have a pulse as sharp and frequent as at the commencement of an exanthematous fever; and this with the local symptoms betrayed many practitioners into the supposition that a most serious inflammatory or febrile disease was commencing; but, perhaps, the very next morning you would find the pulse weak, unsteady, and with a moderate degree of frequency; and if as often happened, an exacerbation took place again at night, the pulse and circulation exhibited the same excessive disturbance, quite disproportionate to the ephemeral character of the fever, and to the degree of the local affection. You would have been tempted by these signs, to use, at one time of the day, active antiphlogistic treatment; at another, stimulating remedies; so rapidly were the functions overbalanced from one extreme to the other, by the excitement and depression which this morbid influence caused in the system.

Besides the general causes which modify the pulse, which we have now briefly considered, there are some specially connected with diseases of the pectoral organs. Those arising from diseases of the apparatus of the circulation will be treated of hereafter. But severe affections of the respiratory organs also sometimes signally modify the pulse, and that in a manner which may tend to confuse its indications. You know how closely the heart is linked with the lungs; by the circulation even more closely than by mere position; for the lungs may be said to lie between the two

compartments of the heart; and any considerable obstruction in the lungs will derange the usual relations of these compartments. There is then a distention or over-stimulation of the right side of the heart; while the left, receiving a diminished quantity of blood from the lungs, and that not thoroughly aerated, is less excited than usual, and may give to the arterial pulse a character of weakness and smallness that by no means represents the condition of the whole vascular system, and which often is remarkably contrasted by the action of the right side of the heart, as felt or heard under the sternum. These varieties are produced by any of those affections of the chest which infringe far on the respiratory function. These are more commonly those of the bronchial and parenchymatous kind, which have accordingly been described to be accompanied by a softer and weaker pulse than those affecting the serous membranes. But you may have a pleurisy also with a small weak pulse, when the effusion or pain is such as to interfere largely with the function of the lungs. Neither are you to suppose that the pulse in severe pneumonia or bronchitis is always weak, even when these affections infringe considerably on the function of the lungs. Even under asphyxiating influences the left ventricle may sometimes become excited, together with the right, and give a sharpness to the pulse, which, combined with the arterial tension of fever, may be readily mistaken for hardness and strength. But this character is seldom permanent; and you will generally find in all diseases, when the function of respiration is much impaired, that the pulse soon loses its body and strength. These considerations suggest the expediency of examining the state of the circulation not only by the arterial pulse, but also by the pulsations of the heart itself, and by the condition of the veins and capillaries.

Under the circumstances just mentioned, when the indications of the arterial pulse are most variable and deceptive, you may often find useful signs in the condition of the *venous* and *capillary* part of the circulation. The distention of the more superficial venous trunks, especially the jugulars, in which a double pulsation often shews also the retropulsive action of an over-distended right ventricle; the fulness of the capillaries of the lips, tongue, throat, cheeks, eyelids, nails, and other parts, at first having a florid and flushed appearance, but afterwards, as the respiration becomes more injured, assuming a purple or livid hue,—are signs of great practical importance, and of a constancy more approaching to that of the physical signs. They do not, however, present

themselves in the early and more tractable stages of disease; and they are always less distinct in pallid persons with small superficial vessels.

Intimately connected with the state of the circulation is the symptom of *general fever*, or *increased heat*, which attends many diseases of the chest. It depends on increased force and rapidity of the circulation, with diminished perspiration. When the perspiration is restored, the heat always falls. This exhalation of fluid not only lowers the temperature by its physical agency of evaporation, but being in itself a sign of a relaxing of the superficial vessels, it implies an abatement of the vital irritation. In the more transient forms of fever, such as the intermittent and hectic, the profuse perspiration sometimes reduces the animal heat to below the natural standard, just as the circulation is proportionately enfeebled; and you have the same chilling influence illustrated by the cold sweats which succeed to temporary and irregular excitement. There are degrees of vascular irritation in which the increased heat of skin is partial, and determined by the structure of particular parts. Thus in the asthenic excitement of hectic fever, the heat is most felt in the palms of the hands and soles of the feet, because the circulation is not strong enough to drive the perspirable excretion through the thick cuticle of those parts, which become consequently dry and hot. The same thickness of cuticle, on the other hand, when once imbued with perspiration, often keeps these parts soft and moist, when there is no sensible perspiration on other parts. Not unfrequently the unequal state of the circulation is exhibited in febrile and inflammatory disorders by the heat of the abdomen, back, chest, or head, whilst the extremities are cooler than usual; and occasionally the same locally increased action is manifested by partial sweats, which prevent the increase of heat, and tend to reduce the excitement. I have known a patient with pleurisy perspire profusely only from the affected side, for several days; and nothing is more common, in slight abdominal inflammations, than to find the pungent heat of the belly relieved by a perspiration equally confined to that part. But you know how we practise on the same principle, in applying to irritated or inflamed parts poultices, fomentations, and partial baths, which tend to bring the skin and superficial vessels to the same relaxed and expanded state which they have in a perspiring part.

I think, then, that it will be plain to you that heat of skin must be an uncertain symptom; for it depends on a condition of the superficial circulation that is

by no means constantly associated with disease of the internal organs. When present, it may as much result from a general cause—an idiopathic fever—as from a local inflammation; and cases are not uncommon in which severe, and even fatal, visceral inflammations are attended, through a great part of their course, by free perspiration; nay, the same may be said of some fevers which are called idiopathic. Still the heat and condition of the skin become valuable guides, when taken in conjunction with other signs, inasmuch as they indicate the constitutional disturbance, which is an important part of the disease, and which is sometimes as much to be considered in the treatment as the local disease which has excited it. So, likewise, when the presence of a disease has been established by other signs, the condition of the skin may prove a measure of its increase or diminution more delicate and sooner appreciable than can be found in the physical signs. Thus an increased heat of skin, coming on during a bronchial or pulmonary inflammation, either indicates an increase of that inflammation or the addition of some abdominal or other irritation, which tends to aggravate the condition of the patient. So, too, perspiration breaking out in the hitherto dry and hot skin of a pleuritic patient, occasionally does prove *critical*; whether that word be applied to the excretion as a cause or as a sign of the amendment.

Where there is disorder of the circulation, especially of a febrile kind, you may well expect alteration of the *secretions*, which are so intimately connected with it: hence you find the urine is scanty and high coloured, and the secretions of the liver and intestines variously deranged. As a natural consequence, too, there will be disorder of the digestive and nutritive function: the tongue will be furred, or florid; the appetite will fail; the stomach will cease to digest; thirst will torment; the blood, no longer fed with chyle, will not duly nourish the textures, nor support the functions; the strength will fail; absorption continuing active, if time permit, emaciation will ensue; and various complications of these disturbances may differently modify the character of diseases of the chest. The sensorial functions, too, may be deranged, either in consequence of the secondary visceral disturbances, or more rarely by a more direct influence of the imperfect respiration on the brain and nervous system. You need only recollect our views of asphyxia, to perceive also how certain states of the nervous system may tend to develop disease of the lungs. Thus insensibility, or coma, causes imperfect respiration, and

consequently congestion of the lungs; and, as we shall hereafter see, a long-continued congestion of the lungs only requires the addition of vascular reaction to convert it into inflammation. Persons rarely recover from an asphyxiated state, without suffering more or less from the injury which it leaves in the vessels of the lungs; and not a few who have been recovered from suspended animation, have sunk under the pneumonia, or bronchitis, which supervened.

I have been thus rapidly glancing at some of the pathological relations of the organs of respiration to other functions, to give you an opportunity of considering rationally the nature and value of general symptoms. We have said enough of those more nearly related to the chest—dyspnoea, cough, pain, and signs of the circulation, with its concomitant, temperature: although often equivocal, yet when strongly marked, they sometimes assist us in diagnosis. Now it is just the reverse with the symptoms arising out of disorder of the other functions. The altered secretions of the kidneys, the liver, and the intestines, cannot inform us of the nature or presence of a disease of the chest; and still less will gastric derangement or sensorial disturbance. Nay, not only will they not direct, but they tend essentially to blind us to the presence of pectoral disease; for they set up prominent symptoms of a new character, that may take the attention entirely from the real source of disease, and fix it on the brain, the liver, the stomach or intestines, the affections of which are only secondary, and often trivial. How often do we find a peripneumony, or a bronchitis, disguised by delirium or stupor, or by vomiting, a loaded tongue, or diarrhoea. How often a pleurisy, masked by a jaundiced skin, a tender right hypochondrium, and clay-coloured feces; or by a lumbago, or a nephralgia! How often tubercular consumption, obscured by sundry bilious, dyspeptic, or nervous symptoms! It will be happy for us, for our credit at least, if not always for the success of our practice, if we detect the enemy through its false colours, ere it triumph, and before the scalpel shall proclaim the delusion of our unwary minds! The physical signs will enable us to do this, and again I commend them to your most attentive study. We have been occupied for three lectures with the general symptoms, and I trust not unprofitably; but on taking a rational review of them, in comparison with the physical signs, I think you must come to the conclusion to which my reason and experience have long brought me, that as diagnostic means, the general symptoms fall far short of the physical signs.

But do not suppose, that because the

general symptoms are often comparatively of little aid in diagnosis, we are to neglect the study of them. They are almost always of great importance in prognosis and practice. The physical signs more surely show how the pectoral organs suffer; but having discovered this, to the general symptoms we must look for how the system suffers; and as the system often closely sympathizes with the injured organ, we may, through them, often watch the first turns of the disease before the change in the organ becomes physically appreciable. In the general symptoms we seek for those *critical* phenomena, which, although sometimes deceptive, yet generally announce the tendency of the disease to one or other mode of termination. In them we study the vital forces and properties with which nature works, and the signs of what nature can do; and in our methods of treatment these become the standards to which we direct, and by which we modify, our remedies. When we treat a patient with peripneumony or catarrh, we do not apply our remedies merely to the local lesions, inflamed vessels, or a discharging membrane; we study the system at large, we examine other functions through the general symptoms, and we direct our treatment with due reference to indications from all these several sources. You see, then, that the mere stethoscopist is but ill fitted to practise medicine. He may justly boast of his skill in diagnosis: his place of triumph will be the dissecting-room, where he can shew the lesions that he had detected; but his practice at the bed-side will be unsuccessful in proportion as local lesions vary in their general relations, and in the conditions of the constitution, or of other functions that may accompany them. The judicious physician will not omit to study the condition of the vital properties, which are exhibited in the general symptoms, as well as the local physical changes which have been already produced; and whilst he chiefly confides in the physical signs to indicate and measure the present local lesions, he carefully watches in the general symptoms the tendencies of those properties and functions which are capable of increasing or modifying these lesions, and are equally liable to be affected by them. The general symptoms being less intelligible and certain than the physical signs, need more experience to enable us to appreciate them; but I hope that you now think that even these also may be *rationally* studied, and may derive a light from a knowledge of physiology and the physical signs, which experience alone could never throw on them.

LECTURES
ON THE
ENTOZOA,
OR
INTERNAL PARASITES OF THE
HUMAN BODY,

Being Part of a Course on Morbid Anatomy,
delivered at the London Hospital,

By T. B. CURLING, Esq.

LECTURE II.

WE now come to the consideration of the second class of the Entozoa, the Protelmintha. There are two kinds, the *Cercaria Seminis*, and *Trichina Spiralis*.

3. *Cercaria Seminis*, Zoosperms, or Spermatozoa.

These names are applied to minute animals which exist in the secretion of the testicle at puberty. They resemble tadpoles in shape, and when placed in the field of a microscope they are seen moving

about, often with considerable rapidity, apparently by means of a caudal appendage or tail, which varies in length in the spermatozoa of different animals. Mr. Owen classes them with the entozoa; but as they are proper to health, and are usually treated of in connexion with the subject of generation, I shall not dwell further upon them here.

M. Donné, of Paris, who has been much engaged in the examination, both chemically and microscopically, of the various secretions, has very recently announced the discovery of an animalcule which he has detected in muco-purulent discharges from the vagina. It is termed the *Trichomonas vaginale*, and varies from $\frac{1}{150}$ to $\frac{1}{30}$ of a millimetre in diameter. Its body generally appears round, but assumes various forms. At its anterior extremity the animal is provided with a filiform appendix, double the length of the body, which it has the power of moving freely. On one side there are several shorter appendices, which are more difficult to be perceived. These animalcules have never been observed in the simple mucous discharges, and M. Donné is inclined to regard them as characteristic of gonorrhœal matter. M. Donné has likewise noticed a number of animalcules, having the form of the Vibrions, described by Müller under the name of *Vibrio lineola*, which he has observed constantly in the pus of chancres on the glans penis and vulva. He states that they do not exist in non-syphilitic pus, nor in that of buboes, but are only found in the matter of the primary sores. Should the accuracy of these observations be confirmed by further researches, the discovery must be regarded as of an interesting and important nature, and as calculated to suggest many curious speculations and inquiries respecting the development of these diseases.

4. *Trichina Spiralis*.

This is a minute worm, infesting human muscle, which has recently been discovered by Mr. Owen. Anatomists had occasionally observed, in dissection, the muscles presenting a peculiar speckled appearance. The nature, however, of the white specks which are found thickly studded upon and between the fibres of the various voluntary muscles, escaped detection, until a portion of muscle thus beset was transmitted to Mr. Owen for examination, in 1835. The specks were then ascertained to be produced by cysts containing a worm. The cysts vary in distinctness according to their degrees of

Cysts of the *Trichina*, in situ.

opacity, whiteness, and hardness. They are of an elliptical figure, and the extremities are attenuated, elongated, and more opaque than the intermediate part. They measure generally about $\frac{1}{50}$ th of an inch in length and $\frac{1}{150}$ th of an inch in breadth, and they are adherent to the surrounding cellular substance by the whole of their external surface; being attached loosely at the middle dilated part, but more closely at the extremities. These cysts, like those

Separate Cyst of the *Trichina*.

A separate cyst, with the worm coiled up in its interior, and seen through the transparent walls.

containing the acephalocysts and echinococci, are composed of condensed cellular tissue, and are of a laminated texture. Occasionally they become hardened by the deposition of earthy matter, feeling gritty upon pressure. On tearing open the cyst, which may be done with a cataract needle, in the field of the microscope the worm is discovered within, disposed in two or two and a half coils, and surrounded by a transparent fluid. The trichina measures from 1-25th to 1-30th of an inch in length, and 1-700th of an inch in diameter. It is cylindrical and filiform, termi-

Trichina magnified.

nating obtusely at both extremities, which are of unequal sizes; tapering towards one end, but continuing of uniform diameter to the opposite extremity, which Mr. Owen regards as the head, in consequence of the constant appearance of a transverse linear mouth. The worms appear to consist of a smooth transparent exterior skin, inclosing a fine granular and extremely fragile parenchyma. Dr. A. Farre has ascertained that they possess

an intestinal canal, with distinct parietes; and Mr. Owen has more recently perceived a transverse slit close to the small extremity, which he regards as the anus.

The *trichina* appears to be chiefly, if not entirely, confined to the muscles of volition; and those which are superficial, such as the pectoralis major and platysma myoides, usually contain them in greater abundance than the muscles which are deeply seated. In addition to the larger voluntary muscles, they have been detected in the muscles of the external ear and of the soft palate; also in the constrictors of the pharynx and in the levator and sphincter ani. They have not yet, however, been found in the heart, in the muscular tunic of the alimentary canal, or in the muscular fibres of the bladder. It is an interesting fact, noticed by Mr. Owen, that all the muscles infested by the *trichina* are characterized by the striated appearance of the ultimate fasciculi; while the muscles of organic life, in which they are absent, have, with the exception of the heart, smooth fibres, not grouped into fasciculi, but reticularly united.

The presence of these worms in the system does not appear to be connected with age, sex, or any peculiar form of disease. They have been found in the bodies of persons who have died of tubercles in the lungs, aneurism of the aorta, and hectic fever. No painful or inconvenient symptoms were present, in these cases, to excite any suspicion of a morbid state of the muscular system, and it is probable that, in all instances, the patient himself is unconscious of the presence of the microscopic parasites which are enjoying their vitality at his expense. Although they are so minute in size as scarcely to be perceptible to the naked eye, yet, when present, they exist in such countless numbers, and their distribution throughout the muscular system is so extensive, that it was imagined they must occasion debility, from the quantity of nutriment required for their support. This opinion, however, is not sustained, for I have found the *trichina* in the muscles of two robust men, who were killed while in the apparent enjoyment of good health; one by fracture of the skull, the other by fracture of nearly all the ribs, with laceration of the lungs: the first was 58 years of age, the other 60.

The occurrence of the *trichina* is certainly rare, but they were found during the last winter, once or twice, in most of the dissecting-rooms in London. I have myself observed them three times, whilst conducting post-mortem examinations, and I have met with them once in dissection. It is, however, a curious fact, that my brother, Henry Curling, who was constantly engaged during last season, in

FIG. 2.

FIG. 1.

FIG. 1.—Worm extracted from cyst, shewing the alimentary canal. (f) A small body regarded by Dr. Farr as the ovary.

FIG. 2.—Portion of worm shewing the alimentary canal protruding from the cut surface.

Clamart's large dissecting-rooms, at Paris, where the number of bodies admitted exceeds those dissected at all the schools in London, did not hear of any instance in which this worm was discovered; though having been but recently described, it would not have been liable, if present, to have escaped detection. The only specimen seen by Giralddi, one of the most diligent of the prosecutors there, had been brought over from England. The distinguished physiologist, Müller, who visited this country in the autumn, informed me that he had met with it in Germany.

The *Sterelmintha*, or third class of the Human Entozoa, contains five genera. We shall speak first of the

5. *Cysticercus Cellulosæ*,

(from *κυστις*, a bladder, and *κερκος*, a tail). It consists of a head, neck, and dilated cyst, of a spheroidal form. Of the genus *Cysticercus* there are several species, distinguished for the most part by the forms and proportions of the neck, or body, intervening between the head and the cyst. The only species known to infest the human body is the *Cysticercus Cellulosæ*, which

Cysticercus Cellulosæ.

is developed like the trichina, in the cellular tissue between the fibres of the muscles, and is also included in a similar adventitious cyst. The head of this parasite is furnished with a beak, or proboscis, armed with a double circle of hooks, for irritation and adhesion, and four promi-

Magnified head of *Cysticercus Cellulosæ*.

nent suckers, for imbibing the surrounding nutriment, the fluid secreted by the adventitious cyst in which they are lodged. The head and neck are usually retracted within the cystic pouch, their situation

being indicated by a white opaque spot in the transparent vesicle.

The occurrence of this entozoon in the human subject appears to be rare, especially in this country. It is less uncommon on the continent. Rudolphi relates, that out of two hundred and fifty bodies dissected annually at the Anatomical School of Berlin, from four to five were found, through nine consecutive years, to be infested more or less abundantly with the *Cysticercus Cellulosæ*. Bremser, however, endeavoured for ten years to procure them at the Great Hospital, and in the Anatomical Amphitheatre of Vienna, but in vain. The development of these animals is not limited, like the *Trichina*, to the voluntary muscles, for they have been discovered in the heart and œsophagus, and also in parts not muscular, as the brain, especially the plexus choroides, and in the eye. The muscular tissue around the cyst is not otherwise diseased.

Portion of Human Muscle with *Cysticercus Cellulosæ*.

Soemmering first observed this parasite in the anterior chamber of the eye, in the case of a young woman aged 18. In the course of seven months it became twice as large as when first observed, and attained the size of a pea. On being extracted through a small incision in the cornea and put into warm water, it continued to move for more than half an hour. It then became gradually opaque and white; and with the microscope the four suckers and the double circle of hooks, forming the head of the animal, were plainly discerned. The *Cysticercus Cellulosæ* has been detected since, in the anterior chamber of the eye of a lively healthy child, seven years of age, after an attack of ophthalmia, by Mr. Logan, of Scotland, in 1833. It floated unattached in the anterior chamber, was about two lines in diameter, and of a spherical form, except that a slender process was seen to be projected or elongated from time to time, and again retracted, so as to be completely hid within the cystic portion. It interfered with vision, more or less, according to its position, and the form which it assumed. As it subsequently enlarged in size, so as to impede the motions of the iris, and excite inflammation in the sclerótica and conjunctiva, it was extracted through the cornea, at the Glasgow Eye Infirmary. The animal was torn in shreds in the operation, but the

result was satisfactory as regards vision. Cysticerci sometimes occur in the brain in considerable numbers. Treutler once found fifteen in one plexus choroides, and two in the other. They are not, however, so common as the simple serous cysts, for which they may be mistaken. In the brain of an epileptic patient, who died in the Bicêtre at Paris, Cruveilhier found at least a hundred of these animals. Some were seated in the sub-arachnoid cellular tissue of the brain and cerebellum; others occupied the substance of the convolutions, and central part of the hemispheres. As many as fifty were observed in the structure of the cerebellum, and others were discovered around the spinal cord.

I know of no symptoms by which the presence of these parasites in the muscles can be recognised, nor any mode of treatment by which they can be expelled the system.

The *Cysticercus Cellulose* likewise occurs in quadrupeds, and is found most commonly, and in greatest abundance, in the hog, occasioning that state of the muscles which is vulgarly termed "measly pork." In two measly pigs dissected by Andral, cysticerci were found in the subcutaneous

and intermuscular cellular tissue, in the different folds of the peritoneum, and in the liver, lungs, and substance of the heart.

The *Cœnurus*, or *polycephalous hydatid*, which is so frequently developed in the brain of the sheep, and is the cause of the affection known under the denomination of the "staggers," does not occur in man.

6. *Tania solium*,

or common tape-worm of this country. The *Tania solium* consists of a flat, elongated, articulated body, varying in breadth from one-fourth of a line at its anterior part, to three or four lines at its widest, from whence it again diminishes to its termination. The head, which is so small that it cannot well be seen without the aid of a strong lens, is somewhat hemispherical, and provided on its anterior surface with a prominence, encircled by a double row of minute recurved processes or hooks, which are surrounded by four suckers or mouths. The circle of minute hooks are not constantly found, and Bremser supposes that they disappear with age. The anterior joints of the neck are very short; those immediately follow-

Tania solium, two-thirds the natural size.

ing are nearly square, their length scarcely exceeding their breadth; the remaining ones are long, the last series of the segments being sometimes twice or three times as long as they are broad. The first articulation is received into the base of the head, and each subsequent joint is let into the one in front of it. Both longitudinal and transverse fibres may be observed in the larger specimens of the *Tænia*. Each segment possesses distinct and separate motions, the fibres not being continued from one joint to the other. A *tænia*, when recently expelled, is occasionally contracted to the length of a few inches, the segments appearing as close-set transverse striæ; but after remaining for a few hours in water, it may be found to measure as many feet. Werner states, that a *tænia* which extended from the anus of a patient to the length of three feet, returned itself almost entirely into the intestine. Other and still more extraordinary instances of the powers of motion possessed by *tæniæ* have been noticed; and it is without doubt to this cause that we must attribute the circumstance, that a part of the body of one of these worms is sometimes found to be tied in a complicated knot, a specimen of which is preserved in the museum. From the four

Tænia tied in a knot.

months already described proceed two vessels, which run along the whole length of the animal, near the margins of the joints. These, which are the nutrient vessels, are united by transverse canals at each joint; and they terminate, according to Rudophi, in a common orifice in the last joint. In a large specimen of tape-worm, in which the nutrient vessels were injected with quicksilver, they were found to pursue a regular serpentine course; and as in repeated trials the mercury could only be made to pass in one direction, viz. towards the posterior extremity, I

Portion of a *Tænia* magnified, shewing the Nutrient Canals and Generative Organs.

conclude that they are furnished with valves. All the articulations have marginal foramina which open alternately, that is to say, on the opposite edges of two contiguous joints. Thus, of the two free margins of each articulation, commonly one only possesses a pore; this, however, is by no means invariable, and in some instances there are two pores on each joint. In each joint there is a large branched ovary, from which a duct is continued to the marginal opening. The ova are crowded in the ovary; and in those situated in the posterior segment, of the

body, they generally present a brownish colour, which renders the arborescent form of the ovary sufficiently conspicuous. A duct more slender and opaque than the oviduct, and containing a gummy secretion, may be traced extending from the termination of the oviduct at the lateral opening, to the middle of the segment, where it terminates in a small oval vesicle. This is the male duct and gland, and the ova are impregnated in their passage outwards. The structure, therefore, of the generative apparatus in the *Tænia* is androgynous, each segment of the individual being sufficient for reproduction.

It has been a question whether the nutriment of the tape-worm is imbibed through the pores which I have described at the sides or margins of each joint, or whether the entire body is dependent for its nourishment upon the four mouths from which the lateral canals commence. Rudolphi and Mr. Owen are of opinion that the lateral or marginal orifices of the segments are exclusively the outlets of the generative organs. In some species of tape-worm, in which no ovaria have been detected, there has been a corresponding absence of the marginal pores, while the lateral longitudinal canals have been present and of the ordinary size. In other species the generative pores open upon the middle of one of the surfaces of each segment, and in these it is plain that the lateral nutrient vessels have no communication with the central pores. The orifices of the segments correspond, in short, with the modifications of the generative apparatus, while the nutrient canals undergo no corresponding change. We may conclude, therefore, that the head of the *tænia* is the sole natural instrument by which it imbibes its nutriment, and it is to the expulsion of this part that our attention should be chiefly directed in endeavouring to relieve a patient from these injurious parasites.

The *tænia solium* measures usually from five to ten feet. It has often been found much longer. Tape-worms twenty feet long are by no means rare. Robin relates in one of the French journals that he once found one extending from the pylorus to within seven inches of the anus, which would make its length at least thirty feet. Cases, however, are recorded in which they have attained the length of a hundred feet, and even more. Some of the accounts, such as a case mentioned in the Copenhagen Transactions of a worm measuring eight hundred fells, are not perhaps altogether worthy of credit. The name of *tænia solium*, or *solitary worm*, is not strictly applicable to it, as it is well known that it may co-exist with several others of its own or even different species.

Bremser has frequently known two or three worms to be passed simultaneously by the same individual. As the joints are very readily separated, you must be careful not to mistake several portions of one worm for different parasites. It is, indeed, rather rare to find a *tænia* of any size entire, the larger tape-worms being found almost always torn across, and deprived of the final articulations. Sir A. Carlisle conceived that the detached joints were capable of becoming distinct animals, but later investigations have shewn this opinion to be erroneous.

The *tænia solium* is met with in the principal countries of Europe, but not in all with equal frequency. It is common in England, Holland, and Germany; and travellers relate that it infests the inhabitants of Egypt.

Tapeworms generally reside in the small intestines, where it does not appear that they produce any important lesions. It is not often that we have an opportunity of ascertaining the state of the intestinal canal when they are present. I examined the body of a female twenty-three years of age, who had passed portions of tapeworms by stool for several years, and who had voided part of a very large one by the mouth the day before death, but although a large *tænia* was found in the ileum, the only lesion in the intestinal canal, which was examined carefully throughout, was a very slight hypertrophy of the follicles, chiefly of the *glandulæ solitariae*. There was no preternatural injection of the vessels. They have been found adhering pretty closely to the mucous membrane by means of the circle of hooks, and it has been imagined that they might occasion ulceration and even perforation of the intestine; but I do not know of any well-authenticated case in which they had produced so unfortunate a result.

The statements of various writers respecting the effects of tape-worms upon the œconomy differ considerably, some representing them as exciting scarcely any disturbance, whilst others regard them as the source of very serious mischief. Rudolphi speaks of them as existing in very healthy individuals, and only being detected in consequence of portions being found in the stools. Such may sometimes be the case, but there can be no question that in general they occasion more or less derangement in the system and impairment of the general health. The best account of the symptoms occasioned by these animals is by Louis, and it is drawn up with all the care and accuracy which characterize the productions of that distinguished pathologist. It results from his observations, that the origin of *tænia* cannot be ascribed to bad nourishment, a weak state

of the constitution, previous disease, or a sedentary life, and that they occur at all ages. The greater number of the ten patients who were the subjects of his observations, had evacuated fragments of tape-worms almost daily for several years, and sometimes in the intervals of the stools, portions having been observed in their beds and amongst their clothes. In none of the cases were the functions of the body perfectly healthy, though the degree of derangement varied much in different individuals, being very inconsiderable in some, and yet so distressing in others, that they took every means within their power to rid themselves of the disease. The chief symptoms were colicky and other kinds of pain in the abdomen, itching about the anus, and at the end of the nose, more or less derangement of the appetite and digestion, and pain at the epigastrium. Headache was rare, but pain and lassitude in the limbs frequently existed, and to so considerable a degree, as to prevent the patients from continuing their occupations. Other symptoms less constant and of an anomalous character are described; but he remarks that when there is pain in the abdomen, colic more or less severe and frequent, but unaccompanied with diarrhœa, and itching at the anus and at the extremity of the nose, we may then conclude almost with certainty that there is a worm existing in the intestinal canal.—In the case of the female already alluded to, whose body I examined, there was a remarkable prolapsus of the uterus, an occurrence rare at so early an age as twenty-three, and before the organ had been impregnated. It is questionable, therefore, whether the prolapsus was not in some degree the result of the irritation occasioned by the worm.

I shall leave what I have to say, as to the treatment which should be pursued for the removal of tæniæ, until I have spoken of other worms which infest the intestinal canal.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

BY WILLIAM GRIFFIN, M.D.

Limerick.

The Cholera at Limerick.

No. II.

THE cholera, after spreading terror and death throughout numerous towns in Scotland and England, reached Dublin about the latter end of March, and broke out destructively in Cork before

the middle of the ensuing month. From the miserable condition of the people in this country, their want of sufficient food and clothing, and their habits of living together in dense masses in the narrowest and filthiest streets of large cities, it was long anticipated that a disease, dreadful every where, would assume some new features of malignity, and leave a memory of its desolation amongst us, surpassing any thing that had been known of it in other kingdoms. This sad presentiment was very general, but in Limerick it was felt with peculiar force, from the conviction that the crowded state of the old town, the closeness of the streets and lanes, and the utter destitution of the great majority of its inhabitants, had no parallel within similar limits in any other city.

As Cork, perhaps, approached near to it in this respect, the greatest anxiety was evinced in ascertaining its daily mortality, and when, at the latter end of the month, the reports gave, as the hospital deaths alone, the frightful amount of fifty in one day, a sensation of mingled apprehension and astonishment pervaded all classes. People felt as if it was already at their doors; inquiries were daily and hourly made of the medical practitioners, whether a case had yet occurred, or whether there were any symptoms in the prevailing complaints which could be considered indicative of its approach, and a deep interest was now for the first time observable, in the general preparations to meet the calamity. Within ten or twelve days afterwards two persons died of the disease in Boherbuoy, and on the 26th of May eight more were admitted into St. John's Hospital, of whom seven expired within a few hours.

Very soon after their admission I went to visit them, in company with Dr. Geary, who was senior physician to the hospital. The outer gate was thronged with crowds of people, whose panic-stricken faces were sufficiently expressive of the occurrence of some catastrophe which had never been witnessed in their age before. The relatives of the sick were in the van of the crowd, lamenting loudly, and watching anxiously for the opening of the door in the portal, to make inquiries of those within. As we passed through the yard, silent fear was seen in every countenance; the servants, the nurses, the strangers, who had come in to assure

themselves of the presence of the disease, all looked anxious and depressed, as if some new mystery in human nature had just been unfolded to them.

The habit of meeting disease in almost every form that could awaken feelings of awe and terror in the mind, and a general immunity even in the midst of the worst contagion, protects the physician, in some degree, from those apprehensions of which others are so naturally susceptible. His interest in the study of the science to which he is devoted, his curiosity to witness a train of morbid phenomena without counterpart in any thing that he had yet seen in the diseases of the human frame, and perhaps a faint hope that he might light upon some remedy capable of arresting its progress or diminishing its fatality, tend also to divert his mind from those depressing reflections so universally consequent to the incursion of cholera. With all this, I must confess I felt a shock on entering the ward of St. John's Hospital, for which any thing I had heard of the disease had not prepared me. On the right as I entered were two young men, of robust frames, apparently asphyxiated; they had been, it was said, at their work in the morning, but they were now laid in the bed, cold and pulseless; their breathing oppressed, their faces shrunk and livid, their eyes with a dark areola around them, their hands and arms blue and sodden, and a clammy moisture exuding every where from the skin. To the left was a pale and cadaverous-looking figure, flinging his arms about, complaining of the burning within him, and craving for cold water. This was, indeed, the general cry amongst them when any one approached or passed the beds; and the deep hoarse whisper in which the supplication was uttered, was one of the most startling as well as characteristic symptoms of the malady. There were others vomiting, and some were screaming with the cramps, while the attendants were busily engaged in rubbing them. Altogether, a scene was presented to me of which any thing I had known in the practice of medicine, except from the direct administration of poison, had not the remotest resemblance. My mind was so strongly impressed with this conviction, that I could scarcely repress my surprise at the statements which had appeared from many physicians on the first irruption of the

cholera in England. It was said that it was not a new disease, and that it had prevailed in many places as an epidemic repeatedly before. There is not, perhaps, a single symptom attendant on it which may not have been met with in an isolated form in other maladies; but viewing them all connected with one another, as they were in cholera, their commencement, their progress, the frightful spectacle of disease they present to us in a few hours, and the rapidity of their termination in death, I venture to affirm no medical man has, in these countries, before witnessed their likeness, much less the identical complaint they constitute.

When the bodies were, one by one, taken out for interment the next day, the scene at St. John's gate was beyond description. Many more patients had been admitted during the night, and all the friends and relations of the sick, with crowds of persons attracted by intense curiosity, choked up the street. There was no ingress or egress except through the centre of a dense mob; and whenever the gates were opened, and a death was announced in reply to any inquiry, wild screams were heard along the market-place, mingled with the subdued cries of those who had learned the fate of their friends in the morning.

Towards the close of the day, however, the expression of complaint among the people was gradually altering its tone. Of the first seven who had been admitted, four or five had been already removed to the burial-ground, and but little hope was given to those inquiring respecting the rest. Such an unprecedented and rapid mortality was altogether unaccountable, and strong suspicions began to seize upon the minds of many, as it had done in almost every place which had been visited by cholera, that the physicians were poisoning the patients. At first, exclamations of astonishment were heard in the midst of the wailing as a coffin passed out, "What! no one recovering? all, all dead!" But as the belief grew stronger, little scruple was made of directly charging the medical attendants with the deaths which had occurred. It was not until long afterwards, when the character of the disease became thoroughly known to the poor in their own cabins, and under their own management, that they became convinced of the injustice of these ridiculous suspicions.

Although the two first instances of the complaint appeared in Boherbuoy, parish of St. Michael's, it did not spread in that district for some days. The cases already admitted into hospital were from the parish of St. John's, and seemed to have no connexion either with those that had first taken ill, or with one another. It now, however, burst out almost simultaneously in all quarters of the old town, and was so destructive in the parish of St. Mary, that it was apprehended it would become utterly depopulated. The published reports gave the hospital admissions to the 30th of May at fifteen or twenty a-day. On the 1st of June there were fifty-five new cases, and on the 10th one hundred and twenty-three, up to which period there had been altogether nearly six hundred in hospital, of whom two hundred were already dead.

Commodious houses were at this time opened in the several parishes for the reception of patients. The Christian Brothers or Monks' School was obtained for St. Michael's, a small house on the North Strand for St. Munchin's, and the school of the convent of St. Clare for St. Mary's. The last is one of the poorest parishes in the city; the population exceeds 14,000, and as they were for the most part panic-stricken at the number carried off in the first burst of the disease, and thus generally predisposed to the attack, even the spacious school-rooms of the nunnery became too narrow for the sick.

I had been appointed, with other physicians, to the Strand hospital, but as this was not yet prepared for patients, and the medical men at the nunnery were worn down with fatigue, I was requested by the Board of Health to relieve them. I shall never forget the impressions which that night's attendance left on my mind. Those who have never visited a cholera hospital during the early ravages of the disease, can form but a feeble idea of its horrors from the most vivid description. The field of battle at the close of day presents scenes, perhaps, as shocking; but the constant presence of the relations or friends at the bedside of the cholera patient, gives rise to many touching circumstances which can seldom occur at the lonely death of the soldier. I repaired to the hospital about eight or nine in the evening; the windows were bright with lights as I approached, but

there was a bustle within, a confused din of voices or cries, a trampling, and hurrying to and fro, that gave sufficient announcement of the fearful struggle with death which was going on.

A few miserable wretches hung round the gate; they seemed to have been there for the greater part of the day, and were only sobbing quietly; but on its opening as I entered, they started up, to make inquiries of the porter. The yard was strewn with straw; there was a heap of coffins piled at one side, against the wall, and the cholera cot was at the stair-foot, with a patient waiting to be removed up stairs.

As I ascended, the full horror of all I was to meet came upon me; the moans of the dying, the screams of those in cramps, the cries for assistance, the vomiting, the hiccup, the prayers for a drop of cold water, came mingling with the heavy sobs or unrestrained lamentations of the attending relatives. It was not inaptly said, by a friend who was with me, that it went nearer to realize one's imagination of the place of future torment than any thing he had ever witnessed. The apartment was long and lofty; the beds were arranged in three rows, and so crowded together that there was merely room between them for the attendants to move about. Here and there, from the walls and pillars, dingy lights gleamed across the ward, bringing into indistinct view the upturned ghastly countenances of those near the door. Further on, as the rays fell fainter and more obscured by the smoke and the steam of the water used in filling tins, little could be seen but struggling movements of the patients as they lay, or the figures of persons hurrying backwards and forwards from bed to bed; and yet onward, at the extremity of the room, all was mist and gloom, from the depth of which was repeated back, like distant echoes, the horrid sounds and cries that assailed me on entering. I was particularly struck by the first object I happened to encounter near the door. An old man, perhaps 80 years of age, lay in the nearest of the central beds; his head was unusually large, and his whole frame of colossal make, though gaunt and bare. He was partly bald, but whatever hair remained was snow white, and his thick grey beard, descending from an immense jaw some inches on the chest, gave to a visage,

otherwise sufficiently proportioned to the rest of the person, an appearance of gigantic magnitude. He was supporting himself on his elbow, after a severe fit of vomiting; his features were of a ghastly blue; a glairy fluid was flowing down his chin and beard, and his large, sunk, dilated eyes, were fixed and staring. He was evidently dying. This herculean form, which had resisted the vicissitudes of fortune and climate, and the attacks of all common diseases, for eighty winters, sunk in a few hours under the stroke of the pestilence. Within a few beds of him, as if in horrid contrast, a little infant, of a year old, was lying cold and pulseless. It appeared to be dead, but on my raising its little head, it started up and looked about for cold water, which it drank ravenously from the hands of the nurse. In a few moments it began to vomit; between each fit of which it looked about in piteous wondering, as if to know whether we could conjecture what was the matter with it. There was little time, however, for reflecting on individual portions of a picture which was altogether new and appalling. The physician I was come to relieve was in the middle of the ward, taking his round; the apothecary following him with a tray of medicine. He was now prescribing, now issuing orders, now crossing here and there, as the cries or calls of the sufferers demanded. At times all seemed in utter confusion, some running with sinapisms, others with tins full of hot water, others with liniments, and the doctor was frequently arrested by the friends of the sick, each endeavouring with the most earnest supplications to call his attention wherever they were most interested. "Doctor! my mother, my dear mother! she is gone, if something is not done for her."—"Oh, sir, what will become of my brother, with the cramps?—do look at him; one look, only one look!"—"Doctor, is my child to die; is nothing to be done for him? Heavens bless you for ever, sir, and give me something to stop the vomiting." With these distracting appeals were mingled the ever-during cries for cold water, or the screams of some miserable creature whose cramps had abated a little, to have the sinapism removed.

Occasionally the startling shout of "a case, a case!" reached us, from the door-way; a heavy trampling on the

stairs succeeded, and, in a moment after, a figure tottered into the ward, supported by the porters, with a countenance sunk and death-like, the lips blue, the eyes glassy, the voice hoarse and sepulchral. I saw a stout young man brought in in this state, and struggling violently with cramps, who had but two hours before, on the preceding watch, been refused admittance by the physicians, on the supposition of his not being in cholera: but even scenes like these soon grew common-place, and it was only where one's attention was caught by some extraordinary display of patience or passion in the passing tragedies, that they excited any deep interest. A mother's motionless figure, kneeling at the feet of her dead son, with hands clasped and tearless eyes, uttering, in whispering accents, "The Lord gave him to me, and the Lord has taken away;" or a daughter, with hysterical screams, claspings the limbs of her breathless parent, as the heavy steps of the porters coming to remove the body to the dead-house, were heard passing along the ward.

There had been a great mortality the night before in this hospital, and I believe about 37 patients were still living when I took charge of it. Feeling much indisposed and exhausted, I returned home at four o'clock in the morning, after admitting nearly forty new cases, and witnessing eleven deaths. There had now been 312 admissions since the commencement, and 111 deaths; and as the disease seemed still on the increase, and the sick were accumulating to so frightful an amount in the wards that it was impossible to attend to them, it was found necessary to remove the patients from the General City Hospital (Barrington's), to the County, to make room for the admission of cholera cases.

On the 12th it also began to spread rapidly in St. Michael's parish, where it had hitherto extended itself rather slowly. On the 13th the admissions into the hospital opened in the Monks' School were immense, and were chiefly from Little Anne-street and Market Alley. The cases in the other hospitals were also numerous, and those among the wealthier classes vastly exceeded any which had occurred in one day since the commencement of the pestilence.

At length the mortality seemed to

have attained its maximum, sixty deaths having taken place in and out of hospital within twenty-four hours. Nothing could now exceed the still and forlorn state of the city, or the dismay of its inhabitants. The deserted streets were white with lime, which was abundantly scattered through them, with the hope of decomposing the infectious poison in the atmosphere. Silent and almost deserted, they presented at noon, in the midst of summer, an appearance sometimes seen at day-dawn in the depth of winter after a hard night's snow; in itself sufficiently startling if only for its strangeness, but rendered infinitely more so by the gloomy countenances of the lonely individuals who now and then hurried past, or the solitary hearse moving slowly on, with no other attendant than the driver. St. Munchin's parish, at the opposite side of the river, had been hitherto comparatively free from the disease; but on the night of the 15th and 16th of June, as if it had suddenly crossed the river, a vast number were taken ill at Thomond-gate, and conveyed to the Strand Hospital, to which I was now attached.

For several days the disease spread extensively in this new direction. As the population of the parish, however, was small, and such as were unable to resist the pestilence were soon struck down, it declined almost as suddenly as it commenced, and on the 22d both the North Strand and Nunnery Hospitals were closed.

I was immediately transferred to St. Michael's Hospital, where I found the severity of the disease unabated. The deaths, which had from the beginning exceeded those of any other hospital, were still so numerous, and the supply of coffins so deficient, that the bodies of those who died during the night were often thrown in heaps in a corner near the gate, to await the arrival of the burial cart in the morning, or the claims of friends or relatives, who chose to inter the deceased themselves. It was a shocking sight to witness the business-like indifference with which the cotmen turned over these ghastly remains in search of any particular corpse, when it was demanded for interment, and from the recklessness of these men, and the confusion often incidental to sudden incursions of cholera, or to an unexpected mortality, mistakes no doubt occasionally occurred, and bodies were

consigned to the grave amidst the wailings of those to whom, while living, they were wholly unknown.

It was at this period I first had an opportunity of classifying the patients accurately as they were brought in, and noticing whether in the early or late stage of the malady the treatment adopted was more or less successful. At the termination of a month, by a simple calculation made by the clerk or registrar, I was furnished with inferences worth all the medical opinions which had been broached since the disease had reached these kingdoms, and only not in every respect indisputable, because not founded on more extensive premises. To these inferences I shall have to refer more particularly hereafter.

In the beginning of July there was a very perceptible decrease in the total amount of new cholera cases and deaths in the city; and towards the end of the month the complaint had nearly ceased. It had, however, so universally returned to every place once visited by it, that the people were for some time in no way disposed to feel at ease on the subject; and the result proved their apprehensions were but too well founded. On a beautiful warm evening in the latter end of August, when even the most apprehensive were beginning to forget their fears, the medical officers of Barrington's Hospital (the only one kept open for the disease) were a little alarmed on finding that two or three cases had been just brought into the house; and while they were yet conjecturing as to the probability of a new irruption, the tramp of crowding feet, and the well-known cries and sounds of cholera, were heard in the hall. Within an hour or two the wards were full; and as beds could not be procured with sufficient readiness, the patients were stretched on the floors side by side, with just room enough for the medical attendants to pass between them. Three-fourths of those brought in were pulseless, cold, and livid; and of 73 admitted on this and the succeeding night, 52 expired—a mortality far exceeding that at St. Michael's Hospital, which had previously occasioned very general remark. Nothing, indeed, seems so singular in this disease as the suddenness of its onset, and the apparently inevitable death of those first struck with it. This great mortality was even observable when it moved to a new street

or quarter of the city, as if it always assumed fresh energy when it changed its locality. The attack in this instance, though more violent than even on its first invasion, was happily of very short duration; and we had the happiness, within a few weeks, of declaring the city perfectly freed from the pestilence.

The total number of persons attacked in Limerick from the commencement of the epidemic until its termination, including private cases, at a rough estimate, was over 2500; the number of deaths about 1000. The population of the city, by the census in 1831, was 66,551; but it was supposed to be then very much underrated, and was more generally estimated at from 70,000 to 75,000. The hospital cases reported to the Board of Health to the 18th of July, when the complaint had nearly ceased, were 2125; the deaths 760. There were a considerable number afterwards on its second irruption in August, of which I have the reports only for the three first days, during which the admissions were 73, the deaths 52, as already stated.

[To be continued.]

ON

"REVERBERATION" OF THE VOICE IN DISEASES OF THE CHEST.

To the Editor of the Medical Gazette.

SIR,

I HAVE frequently noticed the fact, that a reverberation of the voice is communicated to the hand if applied to the chest of a healthy person during the time he is speaking; but the application of this circumstance as a diagnosis of disease did not occur to my mind until Dr. Chambers stated, while examining a patient at St. George's Hospital, that no "reverberation" of the voice was felt by the hand in cases of effusion of fluid into the chest. These may not be the precise words employed by Dr. Chambers, but the principle is correct. Since then I have made a few observations on this subject, which, if not very important, will probably be the means of calling the attention of others to a symptom which may often be found of some practical utility.

The word "reverberation" strictly means, a beating back, an echo; nevertheless, I will endeavour to explain, as clearly as possible, the phenomena to which this name has been applied.

If the hands be placed on either side of the chest of a healthy individual in the submaxillary region, while he is speaking, a tremulous motion is felt, as if the sound of the voice was conducted to the walls of the chest, and gave a mechanical stroke or impression to the hand*, just as the waves of air conduct sound up the meatus auditorius, and cause an impression on the auditory nerves; only in one case the sense of feeling, in the other that of hearing, is used. I have remarked, if the tone of voice be rather high, that the impression is not conveyed to the hands; and consequently in women, who generally speak in a higher tone of voice than men, the reverberation of the voice is not so frequently felt. If, however, much effusion of fluid exists in the cavity of the thorax, this impression is not propagated to the hands; or if fluid is contained only in one cavity of the chest, the reverberation is felt on the walls of the healthy and not on those of the affected side. I have also reason to believe, that in cases of partially condensed lung, the reverberation of the voice is much modified; and when one lung is entirely condensed, that no sensation of the voice is produced on the hand applied to the affected side.

I remain, sir,
Your obedient servant,
C. J. B. ALDIS, M.D.

13, Burlington-street,
Dec. 9, 1837.

PERFORATION OF THE STOMACH.

To the Editor of the Medical Gazette.

SIR,

MR. SAMUEL SANDYS has desired me to forward to you the inclosed case, and to request your insertion of it at an early time, as a companion to that of Mr. Prichard, of Leamington, published last week.

It occurred some months since in a patient attending our local dispensary,

* Any person can verify this fact on his own chest.

and is principally copied from notes taken at the time.

I am, sir,
Your obedient servant,
WILLIAM WHITEHOUSE.

4, Francis Terrace, Kentish Town,
Jan. 8, 1834.

A young woman, aged about 22, unmarried, of a pale and somewhat chlorotic appearance, yet naturally plump, and in *embonpoint*, requested my advice for a pain at the region of the stomach, accompanied by a loss of appetite (especially as regarded solid food,) with a sensation of weight and fulness after each meal. This distaste for solid food, and some other dyspeptic symptoms, have existed for some months.

The treatment adopted was cupping and blistering over the region of the stomach, the exhibition of the vegetable tonics with soda,—an occasional aperient,—and lastly, a course of steel. From none of these did she experience any marked benefit.

After persevering in this treatment for some weeks, she went out one morning, having taken a single cup of tea for her breakfast. She had proceeded about a mile, when she was suddenly seized with violent pain in the lower part of the abdomen, recurring in throes like labour pains,—so much so, that a stranger, into whose house she was taken, expected nothing less than an “accouchement” every moment. A chaise was procured, and she was quickly brought home;—my attendance was now requested, and I found her extremities cold, her pulse 120, low and feeble; there was constant urging to make water, a continual retching, with ineffectual efforts to vomit; great tenderness of the abdomen, the pains increasing in violence, in duration, and in frequency, till at length they became incessant, with a most urgent and distressing bearing down of the womb.—The bowels were moderately open.

Bleeding being contra indicated by the extreme lowness of the pulse, and the great prostration of strength, a full dose of *Liq. opii sedat.* was given, and warm fomentations sedulously applied to the abdomen.

From these measures she seemed to experience some benefit, the retching being moderated, and the pain somewhat relieved; but in the evening she

became thirsty, and indulged largely in lemonade, when the previous symptoms returned in all their violence. Her thirst now became incessant, and she drank at least five pints of acid drink during the night. I was summoned at 7 o'clock in the morning, but before I arrived she had expired, about twenty-one hours after the occurrence of the first alarming symptom.

Examination about eleven hours after death.—The body, externally, was plump and well-formed. There was evident fluctuation in the abdominal cavity. On making the first incision through the skin, there appeared a layer of fat at least three-fourths of an inch in thickness over the whole of the abdomen and thorax: the cavity of the abdomen was filled and distended with a mixed and turbid fluid, to the extent of more than a large wash-hand-basin full. —There was a circular perforation of the stomach, of the size of a shilling, in the lesser curvature, about midway between the cardiac orifice and the pylorus; the edges of this were smooth, stiff, and almost cartilaginous; it had evidently been, and was still, partially adherent to a thickened and solidified portion of omentum. There was no appearance of ulceration on the internal surface of the stomach, and no other apparent lesion of its mucous coat, if we except two or three minute points of a vivid scarlet near the cardiac orifice. The intestines, in several parts, were slightly adherent, from the effusion of coagulable lymph.

Such other parts as were examined, presented no unusual appearances.

REMARKS CONNECTED WITH MIDWIFERY.

To the Editor of the Medical Gazette.

SIR,

BE kind enough to give insertion, in your valuable periodical, to the following observations, in answer to the remarks of Mr. H. Coles, which appeared in a late number of your journal.

It is well known to every one acquainted with the principles of midwifery, that women have from time to time been delivered in almost every

position that could be mentioned, and frequently in very odd ones, from their inability to change it on the unexpected occurrence of *spontaneous evolution* supervening. Though women have from necessity or superstitious habits, preferred being delivered in certain positions rather than others, yet that never can be a reason for continuing the practice in opposition to all delicacy and mature reflection, neither can the vague and indefinite remarks of Mr. H. Coles be a motive for changing the position at the period of parturition, from the left side, which is the established, to the right. There are many special reasons of the highest importance for delivering on the left side. First, it is the most becoming and suitable, both for the patient and accoucheur. Secondly, it is the best for making examinations (in all common cases), applying instruments or performing operations, without the patient seeing either the practitioner, or what he is about, which is of the greatest consequence. Thirdly, it is superior to every other for the application of manual aid for the safety and support of the perineum during the second stage of labour, a circumstance which all must admit to be of great importance, frequently calling for our undivided attention. Fourthly, it is the position of all others in which a woman can be delivered in accordance with that high and sensitive feeling of delicacy which at all times, and more particularly at this, pervades the female breast.

I think it would be absurd going on multiplying proofs of the advantages of the left side in preference to every other position, as I imagine if what I have said does not convince, nothing would. The experience of ages, and unanimous consent of all the professors and teachers of the obstetric art, after repeated discussion and mature deliberation, have been in favour of the left side. If there was nothing else, the *relative position* of the attendant and patient condemns and forbids us ever once delivering on the right side, if it can be avoided. Rare cases, no doubt, do occur in which the right side holds out advantages, but these are the exceptions to the rule, and will not happen more than once in five or six hundred cases. There are also forceps cases where the back will be found the best position, particu-

larly where the difficulty arises from extreme rigidity of the external parts in the first labours of women advanced to the age of forty or upwards.

INTRODUCING THE FEMALE CATETER.—This is an operation that ought to be performed with great gentleness and courtesy, neither doing any thing rude, nor making use of any expressions that would wound the most sensitive ear. One attendant is enough to be present. The room ought to be darkened; the curtains of the bed drawn, and the patient's face covered. The back, with the thighs drawn up, is the best position, next to which is the left side. It is the only operation in which you require to make your examination from before: laying your hand gently on the hypogastric region, feel the distended bladder, and make some inquiries about the seat of the pain, to carry off the alarm and attention of the patient: take care you use no pressure on the distended organ, as it gives rise to acute pain: pass the index finger of the left hand down over the pubis, between the nymphæ; carry it down in a perpendicular direction, about an inch below them: at this point, and immediately above the orifice of the vagina, you will feel the meatus of the urethra in the shape of a small protuberance resembling a flattened pea: having placed your finger on the meatus, carry the catheter in your right hand *to it*, your finger will then be able to direct it into the urethra without the slightest difficulty, if you hold it in the proper direction, with the other extremity pointing up over the pubis, towards the umbilicus, having the catheter either armed with a bladder or a vessel applied to receive the urine on the bed, opposite the right groin, which is the most depending and convenient direction for the escape of the urine, without either wetting the female or soiling the bed, which ought never to occur, as it can with ease be avoided. You will be able to tell by the length of the catheter introduced if it has reached the bladder. The urethra is about an inch and a half long; never more than two, except in extraordinary cases, where the bladder has been pushed up, and the urethra stretched, distorted, or forced to one or other side, out of its natural course, by the pressure of the gravid uterus and distended rectum behind it. In some of

these extreme cases great difficulty is experienced, and sometimes all our efforts fail in introducing the catheter. The plan I have found to succeed best in these cases is simply to empty the rectum by the gentlest means, then raise the nates and lower the shoulders of the patient considerably, to allow the pressure of the distended uterus to fall back off the urethra; you will then be able to pass the catheter with comparative ease, and relieve the patient from excruciating torment. If the case is very bad, keep in the catheter for some time, and do not empty the bladder all at once, but by degrees, or very slowly, stopping a little now and again, that it may contract upon itself. If bland, or comparatively mild injections, thrown up, do not empty the rectum, the scoop will be found the most convenient. I have said little of the position of the patient during the operation of introducing the catheter, as in all ordinary cases the accoucheur ought to be able to perform the operation with facility, ease, and delicacy, in any position which he may chance to find her in, as it ought to be done with the least possible preliminary ceremony, as it would multiply her fears, increase her alarm, and make the operation appear doubly terrible to her already excited imagination.

No one who has studied the anatomy and relative position of the parts, and practised sufficiently on the dead subject, will feel any difficulty: practice itself will never teach a man to pass the catheter with grace and gentleness without the above-mentioned preparatory study and practice: certainly no one is justified in exposing the patient, and still less in looking, and then apologising by saying she was not conscious; just as if it was possible, which I maintain it is not, for the accoucheur to tell whether the patient was or was not conscious of being exposed. Women do not make known all the wounds they receive on those occasions from imprudence. Mr. H. Coles, I perceive, has forgot to inform us of the length of his catheter, as well as the direction he makes it assume, whether between the abdomen and thigh, over the acetabulum, or down between the legs and round the nates. I am inclined to think his instrument must be very long, if it reaches from the interior of the bladder

out of the bed into a receiver, which he leads us to believe.

Your obedient servant,

W. H. M'IVOR.

pulchrum sit, dicendi periculum non recuso."

CICERO.

CASE OF SUPPOSED IDIOCY.

THE difficulties which we meet with at every step in forensic medicine do not differ in kind, and perhaps not even in degree, from those which are found in the therapeutic division of our art. The practical difference in the difficulties of the two branches seems to be, that in the one where law and medicine come in contact, each slight distinction is of importance; whereas, in the practice of physic, though the same shades necessarily exist, they are ranked together under a few bold divisions, and the minor varieties are passed over. Thus, to take an instance, scarlet fever may vary through a thousand grades from the most malignant forms of the disease to perfect health; and it would surpass the skill of the most acute physician to decide which are the precise forms where danger begins, and, on the other hand, which are those that can become fatal, as Sydenham expresses it, only by the *nimia medici diligentia*. Nicety of distinction, however, is not here of much importance; the milder cases, in this, as in other diseases, recover under any, or no treatment: and the only inconvenience resulting is, that the medication which allows the lesser degrees of the malady to get well, is often spoken of as having a really curative power. Examples of this error will occur to every one among the thousand-and-one remedies

extolled in the treatment of Asiatic cholera. But let us suppose that the possession of a civil right depended on the claimant's being affected with scarlatina or not; how nice and how disputable would be the line drawn between the slightest case of the disease, and perfect health! How many and how vain would be the attempts to distinguish between some varieties of scarlatina and certain other eruptions! Who would be able to settle whether roseola is scarlatina at a minimum?

The circumstances under which these fine distinctions are every day laid down by one party, and contradicted by another, is unsoundness of mind; for here the boundaries of health and disease are as undefined as in either of the maladies we have mentioned, but with this additional circumstance, that to decide whether the supposed patient is one or not, is often to decide whether he is to enjoy his property at large, or be a prisoner for life.

Hence the repeated but vain attempts which have been made to define unsoundness of mind with precision, and hence the conflicting verdicts of juries in commissions *de lunatico inquirendo*. A remarkable instance of this kind took place in Scotland about a year ago, of which an elaborate report is now before us*.

The circumstances of the case were as follows:—

David Yoolow, the son of a farmer, at Mill of Peattie, in Forfarshire, was struck with paralysis, at the age of nine years, from which he never altogether recovered. From this time to the holding of the inquest, a period of about forty-three years, he had led the life of an invalid. He spent his time in his room, where his chief employment was

reading the Scriptures, though he occasionally had recourse to other religious books, and even glanced at the newspaper, in which, however, he did not seem to take much interest. His extreme debility hindered him from personally superintending the concerns of his farms, and his knowledge of rustic matters was, of course, far from deep. Such as he was, however, he seems to have been a man of plain common sense, not wholly indifferent to what was going on around him; and considering his very limited opportunities of acquiring information, he answered many of the questions put to him with something more like shrewdness than idiocy.

In England, says Blackstone, a man is not an idiot if he has any glimmering of reason—if he can tell his parents, his age, and the like common matters.

Similarly in Scotland, those are idiots, says Erskine, “who are entirely deprived of the faculty of reason, and have an uniform stupidity and inattention in their manner, and childishness in their speech, which distinguishes them from other men; and this distemper of the mind is commonly from the birth, and incurable.”

With this definition by the highest legal authority staring him in the face, how any one could have ventured to assert that David Yoolow was an idiot, is almost inconceivable.

We find in Mr. Colquhoun's book, that a remedy is provided by the Scottish law for those cases where persons are not idiots, but from profuseness, or the too great facility of their tempers, might be too easily induced to make hurtful conveyances. This remedy is called an interdiction, and makes all deeds voidable which are subsequently executed by the party interdicted, affecting his heritable estate, without the consent of the interdictors, “unless it shall appear that such deeds have truly

* Report of the Proceedings under a Brieve of Idiocy, Peter Duncan against David Yoolow, tried at Compar-Angus, 28—30 Jan. 1837. With an appendix of relative documents, and an introduction, by Ludovic Colquhoun, Esq., Advocate. Edinburgh, 1837. 8vo. pp. 116.

been of an onerous and rational character, and that the grantee has suffered no prejudice through them."

Whether such an interdiction would have been thought sufficient for the protection of the property of Yoolow we know not; but it is clear that the evidence would not have borne out the jury in laying even this limited restraint on him; nor does it appear, indeed, that there was the slightest danger of his losing his property in any manner.

This inquiry into the state of mind of David Yoolow was held at Coupar-Angus, in Forfarshire, Jan. 28—30, 1837; the question proposed to the jury being the supposed idiocy of the defendant. The proceedings were opened by speeches from the counsel for the plaintiff and the defendant, after which Yoolow was visited at his dwelling by the Sheriff, accompanied by the jury and the counsel. The answers given by Yoolow to the questions which were put to him might alone have been sufficient to settle the point of his imaginary fatuity. "Being asked whether he read the newspapers? he answered that he did—the *Weekly Journal*. He was asked what it was that he read in the newspaper? he answered that it was the price of grain. Being asked what is the price of wheat? he answered, thirty-eight shillings a quarter. Being asked how much is in a quarter of wheat? he answered, eight bushels. To the question whether he read his bible? he replied that he did. Being asked if he understood what he read? he answered, "I think I do." He was asked whether the soul perished with the body? he answered that it did not. Being asked what became of it? he answered, "If you are good, it goes into happiness; if not, into misery." He was asked how many ploughs he had labouring, and how many horses? which he answered correctly. Being asked who were his

sister's trustees? he named them all. Being asked what he would do with his money at his death? he answered, "I cannot take it with me." He was asked, if he were dying, would he not think it right to leave some part of his money to his relations? he answered, "Part of it." He was asked, if a deed were offered him to sign, giving away his property, would he sign it? He said, "I should like to know what was in it*."

We can only say, that if these are the answers of an idiot—nay, even of one against whom "a brieve of idiocy" could with any decency be levelled, that we know plenty of people who might shake in their shoes; and that the whole population of the country might be divided into juries, and defendants accused of idiocy.

Some of your signers of blank acceptances might take a lesson from David Yoolow's proviso—"I should like to know what was in it."

The first witness on the plaintiff's side was Dr. Christison, the author of the treatise on poisons. He gave an account of the questions which he had put to Yoolow, together with his answers, from which he inferred that he laboured under a great degree of imbecility, and was unable to manage his affairs. Many of the questions put by the learned professor were very strange, if we consider them as addressed to a supposed idiot;—*e. g.* "Although you do not meddle with politics, there are some branches of them which, as a farmer, you should know about; for instance, what is your opinion of the Corn Law Bill?" He answered, "I ken naething about that." I asked "What is it intended for?" he answered, "To sell the corn, I fancy†."

If he had read all the folios that have been put forth by committees on the

* Report, p. 11.

† Ibid. p. 13.

corn-laws, he could hardly have given a more shrewd reply.

When asked "if he knew who was prime minister just now, he answered, "No;" and this we suppose was considered as a proof of fatuity; though even the counsel for the plaintiff acknowledges in his second speech that "it is often difficult to answer who is prime minister. Whether it be Lord Melbourne, or the Duke o' —,* or any other O', may be at times a puzzling inquiry to wiser men than Yoolow†.

Dr. Christison says, "an uncommon degree of memory sometimes accompanies persons of unsound mind, particularly memory of the contents of the Scriptures, which I was informed Mr. Yoolow possessed. It was partly on that account, and partly because I was otherwise satisfied that he was of unsound mind, that I refrained from asking him any questions upon the subject of the Scriptures‡.

In the celebrated case of Miss Bagster, on the contrary, Dr. Monro deposed that "many insane persons have good memories, but I have not known imbecile patients have good memories§."

Almost the only answer in which Yoolow apparently broke down was the following one:—"I asked him how much wheat should be used per acre in sowing?" To which he answered, "a boll." "Then I asked him what would be a good return?" He answered, "Twa (two) bolls;" and this he repeated on being asked the question again, and said "it would be a very good return||."

A return of two for one would certainly not be considered good by any one acquainted with agriculture; but the constant mistake committed by the

witnesses for the plaintiff throughout this inquest was to suppose that Yoolow was a farmer; whereas he was a trembling invalid confined to his room by incurable disease, and though in possession of several farms, he necessarily transacted everything by deputy. Hence he could hardly be expected to have a ready acquaintance with these matters; far less could such an answer be considered a proof of fatuity.

Moreover, it was suggested by his counsel, with great probability, that Dr. Christison had misunderstood the answer, and that Yoolow had really said "twal bolls," *i. e.* twelve bolls, though the Professor fancied he said "twa bolls," *i. e.* two bolls*.

We shall give the remainder of this interesting trial, with some further observations, next week.

CLINICAL LECTURE

ON

THE VENEREAL DISEASE.

Delivered at St. Bartholomew's Hospital,

BY WM. LAWRENCE, ESQ. F.R.S.&c.

THEY who wish to learn the nature of the venereal disease may choose between two modes of proceeding. One is, to read books on the subject; the other, to enter the wards of an hospital, and study the facts there presented to observation, with a mind as free as possible from doctrines and preconceived notions. The two methods ought to coincide; but they differ widely in their results. There cannot be the slightest hesitation in determining that the latter is preferable for the purpose of gaining correct knowledge. If you expect to find what you read confirmed by what you will observe for yourselves in this hospital, you will be disappointed: the two modes of study do not differ more essentially than the conclusions to which they respectively lead. The statements in books are to the effect, that there is a certain virus or poison, which, when applied

* A witness "asked him, at different times, who was prime minister, when he said, 'The Duke o' —,' and then looked to Charles Scott; but on the last visit he told me it was Melbourne."—Report, p. 25.

|| Report, p. 13.

* At least three Englishmen out of four, in pronouncing French, confound the sounds of the *eu* and *ou*. Hence, if a Frenchman says *deux sous*, they are apt to mistake it for *douze sous*, or *vice versa*, which produces exactly the same misapprehension as the one in the text.

to the human body, produces effects so well marked in character, and so regular in progress, that we may by them easily distinguish syphilis from all other forms of disease. Thus, we should expect to find the great pox as definite in appearance and course as the small-pox or cow-pox. Again, it is represented that other morbid phenomena, apparently produced in the same manner as this supposed regular syphilitic disease, are not venereal, do not result from the application of a poison, and require a different mode of treatment from true syphilis.

When, on the contrary, we look over the several cases presented to our observation in a large hospital, we see affections very different from each other in appearance, and in other essential characters, yet coming under the common denomination of venereal disorders. Different as these are, they seem all to arise from a common source; they owe their origin to promiscuous sexual intercourse, and are, therefore, justly denominated *venereal*. I know no reason why any one of these varieties should be called *true syphilis* rather than any other. We may, therefore, abandon the attempt to distinguish between syphilis and the diseases resembling it, and discard from our vocabulary the terms *true syphilis* and *pseudo syphilis*, and the others founded on the hypothesis just noticed; terms which have either no clear meaning or an erroneous one, and are only calculated to introduce confusion and obscurity into a subject sufficiently difficult in itself. If, then, you wish to learn the nature of syphilis, dismiss from your minds the speculations of authors, and observe the phenomena, progress, and treatment of the venereal cases in this hospital.

I now direct your attention to the case of William Smith, a tailor, in Lazarus ward, who has already been in the hospital more than once. This is a well-marked example of phagedenic venereal disease, and it shows a correspondence in character between the primary affection and its secondary or constitutional consequences.

He was first admitted into the hospital on the 19th of May, 1836, with a phagedenic ulcer of the prepuce, by which the upper half, or two-thirds of the part, had been destroyed to the basis of the glans. The ulcer had an irregular ragged surface and edge, small portions of the latter being livid; there was no appearance of reproduction. The discharge was thin and ichorous; not abundant nor offensive. There was not much pain. The ulcer had existed eight weeks, during which time he had taken twelve pills, and employed a lotion, which caused considerable pain. A few large brownish-red cutaneous tubercles had appeared recently on the fore-

head and face. He was directed to take two grains of calomel with one-third of a grain of opium, three times daily, and to apply the black wash to the sore. He continued this treatment till the 6th of June, when the mouth had become considerably affected: he then left off the calomel and opium, and took five grains of the blue pill every night. During this time he was kept in bed, and confined to milk diet. Under this plan the ulceration was quickly arrested; and the sore, which had been spreading for eight weeks, healed rapidly: the tubercular eruption disappeared from the face.

The original sore, however, did not heal completely at the middle of the dorsum penis, where the ulceration had extended a little under the integument: it continued to burrow in this direction after it had cicatrised soundly elsewhere, and at last extended so far that it was necessary to lay open the undermined skin by a free incision on the 13th of June. The unhealthy surface thus exposed was dressed successively with black wash and with the balsam of Peru. The sulphate of quinine, and the compound decoction of sarsaparilla, were administered internally. The patient left the hospital in the middle of July, freed from the local complaints, and in excellent health.

The case, thus far, shows the natural progress and the destructive effects of phagedenic ulceration, when unchecked; for, if we suppose the twelve pills taken before admission to have been mercurial, they had produced no sensible operation on the system. It shows that phagedena, although essentially destructive, eating away the affected part by ulcerative absorption, as its name implies, is not necessarily active in its progress. It had here gone on uncontrolled for eight weeks, and merely destroyed a portion of integument. The effect, indeed, would have been more serious, if the disease had been seated in the glans. The present case is an example of what might be called chronic phagedena. It demonstrates further the powerful influence of mercury over the disease, and its unequivocal instrumentality in effecting a cure. Some have believed that the use of mercury is capable of giving the phagedenic character to an ulcer. Here, however, the primary form of the complaint was phagedenic: this character rapidly disappeared under the use of mercury, being succeeded by a healthy restorative process.

W. Smith returned to the hospital on September 10, 1836, with a relapse of ulceration on the penis: I was absent from London at the time, and he consequently came under the care of my colleague, Mr. Lloyd. I understand that the

whole dorsum of the penis was occupied by a foul phagedenic sore of circular figure, which extended a little in the direction of the pubes. The surface was so foul, and it had extended so rapidly, that Mr. Lloyd had thought it proper to apply the strong nitric acid. The sore, when I saw it, was covered by the brown crust which follows the effective application of that escharotic. The separation of the eschar was followed by a clean granulating surface, and cicatrisation was soon completed. On this occasion no mercury was used, either externally or internally, and the patient was discharged perfectly well in October.

On January 6, 1837, he was again admitted with phagedenic ulceration of the fauces and face, and inflammation of the periosteum. The *velum palati*, *uvula*, and tonsils, the upper and back part of the pharynx, were occupied by an irregular ulceration with a lardaceous surface, ragged edge, and bright red margin; deglutition was performed with difficulty and with great pain. There were three or four circular phagedenic sores on the face. There was a soft fluctuating swelling over the left superciliary ridge, and another on the os male of the same side. The carpal extremity of the left ulna presented a large painful swelling of the periosteum. All these affections were of painful character; they had interrupted rest, and impaired appetite, causing emaciation and great weakness. These evils were aggravated by great alarm respecting the nature and progress of the disease, and depression of spirits. I found, on inquiry, that he had never been affected with syphilis before; that he had been of regular habits; and that he had been particularly careful of himself since his first admission into the hospital. The painful nature of the symptoms, and the enfeebled condition of the patient, required narcotics, and strengthening means, both medical and dietetic, and presented a strong contra-indication to the general use of mercury, although the influence of that remedy was required to check the progress of disease, particularly in the throat. He was ordered to fumigate the throat with cinnabar every night and morning; to take the concentrated compound decoction of sarsaparilla three times a day, and 5 gr. of the *pil. saponis c. opio* at night; and to feed on milk and broth, or on meat, according to his powers of swallowing. On the 9th eight ounces of port wine ordered for him daily, and the dose of the *pil. saponis c. opio* was increased to 7½ gr. On the 24th the fumigation was continued once daily, the month having become sore, and linetus was ordered for a cough. Under this treatment, the local symptoms and the health

improved rapidly; the ulceration of the throat lost its phagedenic character, and soon healed; the ulcers of the face cicatrized; the swelling of the ulna disappeared, and those of the frontal bone and os mala broke and discharged, the openings subsequently scabbing over. With the abatement of pain the rest and appetite returned; the flesh and strength were restored; and the patient left the hospital in the middle of February, not only free from disease, but stout and in excellent health.

On this occasion mercury was only used locally, viz. in the form of cinnabar fumigation; but, as it happens not unfrequently under such circumstances, the specific action of the remedy on the constitution was produced, and pytalism ensued. The rapid cicatrization of the ulcers in the fauces and in the face, and the corresponding dispersion of the periosteal swellings, were probably owing in great measure to this operation of the remedy. The soothing and restorative medicine, and the generous diet, which were necessary on account of the pain, emaciation, and weakness, were advantageous in enabling the patient to support the action of mercury.

Smith seemed completely restored when he left the hospital; but the cure was not yet permanent, for he is now again in Lazarus ward, affected with disease of the nose, ulceration of the throat, enlargement and induration of the right testicle. He came in on the 23d of this month (June.) There is a large ulcerated opening in the septum narium, forming a free communication between the two nostrils, both of which are in great measure blocked up with bloody scabs and stinking matter. A most offensive fœtor is diffused to some distance round the patient. The bridge of the nose has partially sunk, and has become turned to one side. The integuments are swelled, of dull red colour, hot, and painful. There can be no doubt that the bone is diseased, from the yielding of the septum, the offensive stench, and the inflamed state of the external coverings. The affection of the mucous membrane is probably secondary; the seat of disease in the pharynx is its upper and back part, so high up that the lower portion only of the ulcer comes into view; it has the same phagedenic character as on the former occasion. This position of the ulcer in the pharynx, if not peculiar to phagedenic syphilis, is very common in that form of the disease; the testicle is moderately enlarged, hard, somewhat irregular and knotted, painful on pressure; the scrotum is red, and rather warm.

The remedies ordered were, solution of corrosive sublimate (half a grain to the

ounce) in lime water, to the nose, previously clearing it of scabs and matter by means of tepid water; five grains of hydriodate of potash in an ounce and a half of compound decoction of sarsaparilla, three times a day; mercurial liniment to be rubbed on the testicle. The patient has now been in the hospital a week under this treatment, and already feels much better.

The foregoing is a striking case of primary phagedenic ulcer, followed by the constitutional effects which are observed in this form of syphilis more particularly, viz. tubercular eruption, and phagedenic ulcers of the skin, fauces, upper and back part of the pharynx; disease of the nasal bones and membrane, and affection of the testicle. It shews the rapid succession of the various secondary symptoms, which is usually observed in this form of the complaint.

Mercury is of great service in the treatment of phagedenic syphilis; but it must not be employed indiscriminately. If we proceed on the old notion of its being the specific and sole remedy for such complaints, employing it freely at first, recurring to its use when the disease appears again, and so on, *toties quoties*, we shall seriously damage the constitution, aggravate the patient's sufferings, and increase the liability to relapse. The disease itself is of painful nature; it causes loss of flesh and general depression: repeated and long courses of mercury act like a poison in this dilapidated state of health. It is necessary to check the destructive progress of the primary affection; and this object sometimes cannot be accomplished without the full action of the remedy on the month. Its local administration is of great service in phagedenic secondary symptoms; but I avoid, if possible, its internal use, especially when the powers of the constitution have been impaired by the painful nature and the duration of the disease.

[Smith remained in the hospital four or five weeks on the last occasion. Before he went out the whole septum narium came away in several pieces. The discharge ceased, and the nostrils became clear, but the deformity of the nose was increased; the throat soon got well, and the swelling of the testis subsided. He showed himself at the hospital from time to time during the autumn, continuing free from disease and in excellent health. It may be concluded that he continues well, as he promised to return in the event of any relapse.]

There are at present other cases in the hospital, illustrating the various effects produced by what appears to me a common cause, promiscuous sexual intercourse;

and clear evidence to the same point may at any time be obtained by looking over the patients in any one venereal ward.

James Wood, admitted June 15, has six or eight small circular sores on the lining of the prepuce, at its orifice. These sores are a little elevated, so that the entire ulcer is in slight relief; they are of florid red. This is a common form and situation of primary syphilis. The sores, which are numerous, present a little ulcerative excavation; they then become raised as you see them in this patient, and of florid colour, and subsequently cicatrize. From four to eight weeks not unfrequently elapse before the healing process is completed. This must be the kind of affection which has been denominated *ulcus elevatum*. Remember that this elevation belongs to one period only in the progress of the affection. These cases shew that excavation and a foul tawny surface are not essential characters of a syphilitic sore; also, that primary sores may be numerous as well as single.

Thomas Haley, in the same ward (Lazarus), has a sore, not excavated, seated on an indurated basis, at the root of the prepuce, just behind the glans. The induration, as large as a horsebean, feels like a lump of cartilage under the skin. In this and the preceding case black wash is applied to the part, and five grains of blue pill are taken twice daily.

Mr. Hunter's description has led to the belief that a venereal sore is circular, excavated, foul or tawny on the surface, and with an indurated base and edge. A little observation will be sufficient to shew that the latter character is not essential, and that it is not seen in the majority of venereal sores. The subcutaneous hardness, which is certainly very peculiar in indurated chancres, depends in some measure on the texture of the affected part; its development requires the existence of loose cellular tissue under the skin. It is not seen in ulcers of the glans, where that tissue exists sparingly: we meet with it in the prepuce, and especially at the angle between the lining of the latter and the body of the penis, where the cellular tissue is abundant. An ulcer sometimes occupies the corona glandis and the basis of the prepuce, in which case the preputial portion of the sore may be indurated, while that on the glans possesses no such character.

Another patient in Lazarus has a sore as large as a sixpence on the integuments of the prepuce. The ulceration is superficial, with a clean smooth surface, affording a thin discharge in small quantity, which concretes into a slight closely-adhering scab. The margin of the sore is a little raised; there is a bubo in the right

groin, while the sore is on the left side of the prepuce. This occurrence of glandular affection on the side opposite to the ulcer is occasionally noticed. This case is treated in the same manner as the two preceding.

Thus these four cases of disease arising from promiscuous sexual intercourse, present to your observation four primary affections essentially distinct; and I know no reason why one of these should be called true syphilis more than the others. Hence syphilis, whatever may be the nature of its unknown cause, and whether that cause be one or many, produces phenomena considerably varied. They who have been endeavouring to find out true venereal disease, in the expectation of finding, as in small-pox or cow-pox, an affection of determinate character, commencing at a regular period, running a certain course, lasting a certain time, and coming to a definite conclusion, have been pursuing a chimera; they have been seeking for what does not exist. The whole phenomena of syphilis, the characters of the primary disease, the constitutional effects, the duration of both, the intervals between the primary and secondary affections, and between the successive manifestations of the latter, present numerous and striking differences.

FURTHER REPORT OF

CASES OCCURRING IN THE CLINIQUE OF M. LOUIS,

At the Hôpital de la Pitié, Paris.

By HENRY CURLING, Esq.

CASE VII.—*Typhoid Fever with Eruption— Recovery.*

A YOUNG man, aged 23, of a strong constitution, with black hair and eyebrows, well developed, came to the hospital March 9th. For six or seven days previous to his illness he had had diarrhoea, but had paid no attention to it. He has been obliged to keep his bed the last fortnight. His illness commenced with shivering, cough, and headache, followed by excessive heat and great prostration of strength. The diarrhoea has continued except during the last two days; the fever has not ceased, but he has had no return of the rigors. Anorexia and tinnitus aurium are to be added to the symptoms. The sight has been troubled, and he has felt giddy; but

he has had neither pain in the abdomen, nor epistaxis.

March 10th.—Lies on his back; face covered with red spots, and has an expression of anxiety; answers questions rapidly and sensibly; sight troubled; eyes injected; nostrils dry; feels giddy; tongue dry in the centre, moist and natural in its circumference; no meteorism; no gargonillement in the right iliac fossa. The chest, axilla, and abdomen, covered with numerous vesicles, half a line in diameter; perspired a little in the night; several rose-coloured spots are seen on the chest and abdomen; pulse 96 yesterday evening; 100 this morning. A bitter taste in the mouth; no nausea; respiration vesicular; much thirst.

Antim. Tartariz. gr. j. in die sumend.

11th.—Countenance less injected; has not vomited; pulse 92 yesterday evening, 88 this morning; tongue dry in the centre, but trembles less; tinnitus; fresh vesicles on the chest and neck; desquamation of the skin; four stools; spleen cannot be distinguished.

Eau de Seidlitz, half a bottle to be taken during the day.

On the 14th the sudamina were still more numerous, and confluent, particularly about the axilla. The tongue began to clean, and to become moist.

On the 17th he felt a little appetite, and from this period he became rapidly convalescent.

REMARKS.—The last three cases afford examples of two diseases, enteritis and typhoid fever, which by inattentive observers are often confounded. Though several symptoms of typhoid fever were absent in the last case, those that were present were sufficient to announce its nature. The diarrhoea and excessive prostration of strength at the commencement, the headache, the giddiness, and tinnitus, the presence of sudamina and rosé-lenticular spots, could, when combined, be attributed to no other disease.

In like manner, in the second case, the nature of the disease was denoted by the very numerous stools, the little fever, the pulse being only 50; the little prostration of strength (for although the patient ceased working the second day, he never kept his bed); the advanced age of the patient (53); the absence of giddiness, tinnitus, and spots. These symptoms are only observed in enteritis. Pain in the abdomen and diarrhoea, though sufficiently frequent in typhoid fever, are still more constant in enteritis. Headache occurs in forty-nine cases out of fifty of fever, but in not more than two of the same number of

cases of enteritis. Among a great number of cases of enteritis observed by M. Louis, only one quitted his work the day of the attack, while the contrary happens in typhoid fever. The rosé-lenticular spots, the sudamina, epistaxis, meteorism, are rare in enteritis; not more than one in twenty-three had epistaxis. Vomiting is also rare in enteritis; but it does not often occur in fever before the eighth or ninth day, the period when most of the complications of fever are developed. Enteritis may occur from infancy, may be repeated several times, and may complicate other diseases. Typhoid fever rarely attacks very young or very old individuals. When M. Louis wrote his work on Fever, 25 was the mean age of the cases he had observed. From a more recent analysis of a still greater number of cases, he finds 23 to be nearer the truth. He has never seen it after 60 years, and very rarely after 50. M. Louis has only seen five fatal cases of enteritis; and, considering its frequency, he does not view it as a dangerous disease.

Though it is impossible to confound well-marked cases of enteritis and typhoid fever, yet as a disease is more denoted by the combination of certain symptoms than by the presence of any one particular sign, so, when some of these symptoms are absent—when they occur in a different order, the diagnosis is often rendered difficult. This occurs in enteritis and typhus fever, slight cases of which are often confounded. And the distinction between them is more important than is generally thought, particularly as regards the prognosis. All the cases of perforation of the intestines which have fallen under M. Louis' notice were at the commencement very mild, and comparatively trifling.

In the first case the diagnosis was doubtful: the disease commenced by a shivering fit, fever, diarrhœa, pain in the abdomen, succeeded on the second day by epigastric pain and vomiting, and on the fourth by a little catarrh.

The diarrhœa, the depression of strength, and the vomiting, would seem to indicate fever, whilst the slight headache, the absence of giddiness, of spots, and of pain confined to the right iliac region, would rather indicate enteritis.

A white exudation on the mucous membrane of the mouth was considered by the ancients as a very fatal sign; but that it is not always so the first case proves. It certainly is only developed when the patient is very weak, whether from the effects of an acute or chronic disease, and depends upon an inflammation of the mucous membrane. In like manner sudamina are often looked upon as a very dangerous symptom, whereas only one-half of the

patients in whom this symptom is present die.

CASE VIII.—*Typhoid Fever—Erysipelas of the Face—Acute Peritonitis from supposed perforation of the Ileum—Recovery.*

A cook, aged 33, had resided in Paris three weeks, when, on attempting one morning (March 22) to get up, she was attacked with vertigo, pain in the head, buzzing in the ears, and chilliness, which obliged her to keep her bed. She arrived in Paris in perfect health, and had not been exposed to privations. These symptoms continued till the 25th, when, being obliged to go out, she fell down from weakness. The next day she vomited for the first time, and had diarrhœa, with pain in the abdomen. On the 31st she entered the hospital, having walked there with difficulty, supported by two persons.

April 1st.—Memory exact; lies on her back; eyes sunk; cheeks of a livid red colour; vision troubled; tinnitus aurium; great prostration of strength, but not complete; tongue dry and red, not pointed; pulse 120, small and feeble; great thirst; abdomen soft; the spleen cannot be distinguished; pain in both iliac fossæ increased by pressure; no pain in the epigastrium; twenty stools yesterday; respiration healthy.

Diet: ptisan. Antimon. Tart. gr. j. in die sumend.

2d.—Has had three stools, and vomited four times. Yesterday afternoon the nose became red and swollen; the left cheek soon became in a similar state, and during the night the right cheek. The erysipelas extends as far as the chin; the occiput is painful when pressed, but is not œdematous; pulse 112; other symptoms continue the same.

Eau de Seidlitz, half a bottle.

6th.—The erysipelas has subsided considerably, and there is abundant desquamation of skin; her menses returned yesterday; no headache; pulse 104; no thirst; feels very weak.

7th.—At half-past six yesterday evening she was attacked with an acute pain in the right iliac fossa, accompanied by nausea and vomiting and rigors. At midnight the abdomen was universally painful, the pulse 116, weak and feeble. The pulse is now 140, and very small. Some laudanum was immediately given her. The tongue is projected with difficulty; the cheeks are of a deep violet tint; 40 respirations in a minute; she cannot bear the least pressure on the abdomen; pulsations of the heart imperceptible; two stools after a lavement; only took three spoonful of soup and a biscuit yesterday.

Three oranges. Acet. Morph. gr. j. in Mist. Mucilagin. sum. Strict diet.

8th.—Pulse 152 yesterday afternoon; now 116. Countenance improved; no nausea; circumvolutions of the intestines can be distinguished; abdomen soft, and without pain, except when pressed; no stool. Tongue slightly moist; red in its circumference, white in the centre.

Three lemons, and a little ice. Rep. Mist.

10th.—Checks red; abundant desquamation; no pain in the abdomen, except in the right iliac fossa; tongue red, not very moist; small white spots on the mucous membrane lining the lips, and a white exudation at the roots of the teeth.

Rep. Mist. Fomentations to the abdomen.

For several days she continued in a very precarious state, the pulse being very quick and small; but by persevering in the administration of opium, and in complete abstinence from all food, she was, towards the end of the month, enabled to get up, although very weak. In the course of another month she left the hospital.

REMARKS.—The symptoms at the commencement bore some resemblance to those of ramollissement of the brain. Indeed, it has twice happened to M. Louis to confound typhoid fever with that disease, which he has seen at the commencement attended with no other symptom than excessive prostration of strength. On the fifth day the nature of the disease was announced by the diarrhœa, abdominal pain, vomiting, &c., although many other important symptoms of fever were absent. It is by no means rare to see erysipelas of the face developed during the course of a typhoid fever; whereas it is very rare to see erysipelas preceded by cerebral and abdominal symptoms for twelve days; so that this complication would rather tend to confirm the diagnosis. On the 7th instant evident symptoms of acute peritonitis were present, which M. Louis believed to be caused by a perforation of the small intestine caused by ulceration, and situated about the junction of the ileum with the cæcum. Peritonitis so rarely complicates acute diseases, that it may almost be laid down as a law, that if in the course of an acute disease there suddenly comes on a sudden pain, if this pain is increased by pressure, and accompanied by a rapid alteration of the features, and more or less promptly by nausea and vomiting, a perforation of the intestine exists. The probability becomes still greater if the disease is typhoid fever, as it is always accompanied by some degree

of ulceration of the intestine. This is the first case of perforation of the intestine, occurring in the course of a typhoid fever, which M. Louis has seen recover. Would not the peritonitis be considered by many physicians, and perhaps justly so, as a metastasis of the erysipelas of the face?

CASE IX.—*Scirrhus of the Pylorus—Death.*

A sempstress, aged 69, previons to the month of November, 1836, enjoyed excellent health; her digestion had always been good; she had never experienced pain in the epigastrium; had always been in easy circumstances, and enjoyed the necessities of life without having committed any excesses in drinking, &c. &c. In that month she was troubled, for the first time, with a pain in the epigastrium, and her appetite at the same time diminished. In December she was attacked with frequent vomitings, and often brought up her food thirty-six hours after eating it. On that account she took hardly any nourishment, and became very thin. The pain in the epigastrium increased during the months of January, February, &c., and came on generally two or three hours after a meal; the vomiting also became more frequent, the food which had been eaten three or four days before being often rejected unaltered. In the month of April she was admitted into La Pitié, under M. Louis, and presented the following appearance:—

April 22.—She is in the last stage of marasmus; cheeks purple, and very hollow; superior limbs of a purple hue; pulse very small; pulsations of the heart well marked; tongue villous and white; no diarrhœa or cough; a depression in the epigastrium; pain upon pressure $1\frac{1}{2}$ inches to the right and a little below the umbilicus; also a little above and below the umbilicus a projection having the form of the little curvature of the stomach. Upon pressure being applied, a species of gargouillement is heard; has vomited four times since yesterday a clear fluid; continual eructations of gas; respiration healthy. She remained in the hospital about a fortnight; at the expiration of which period she died. Extensive scirrhus of the pylorus was found to be the cause of the symptoms, but I unfortunately was not present at the examination.

Pain in the epigastrium and anorexia are by no means always the signs of an organic disease of the stomach. They occur also in chronic gastritis, a disease which has not yet been well described, and of which M. Louis has seen but few examples; that is to say, in healthy persons, and occurring as a primitive disease; for nothing is more common than chronic gastritis in the course of phthisis and other similar diseases. But in the latter disease

there is seldom vomiting of food taken two or three days before, as in this case. The vomiting was, however, by no means pathognomonic of organic disease; it was composed solely of the food, and was never mixed with blood, so that there was no reason to suspect ulceration of the mucous membrane. The depression at the epigastrium, the projection above and below the umbilicus, and the gorgouillement, indicated a distended stomach; the projection being chiefly caused by the lesser *cul de sac*. The situation of the pain seemed to indicate the pylorus as the part diseased, which was the case. M. Louis does not consider scirrhus an inflammatory affection, or to be a sequel of inflammation. Cancer seldom occurs before the age of fifty, whereas gastritis occurs at all ages. Men are less liable to cancer than women, though they more frequently commit excesses. This, however, proves nothing; for, according to the same authority, women are more subject to acute gastritis than men. Cancer has a predilection for certain parts of the stomach. Thus out of 33 cases

In 16 the cancer occupied the epilorus.
 11 small curvature.
 6 the large do.

The cicatrices of ulcerations of the stomach are never observed in the epilorus; they more usually occupy the posterior surface of the stomach. The parts of the body most subject to cancer, are less liable to inflammation. Out of 55 cases,

21 consisted of cancer of the stomach.
 22 uterus.
 10 liver.
 5 lung.
 2 rectum.

No account is here taken of the mamma or testicle. In the lung, which perhaps is the viscus most subject to inflammation, it only occurred in five cases, and in none of these primitively.

CASE X.—*Cancer of the Uterus—Death.*

A woman, aged 40, the mother of six children, was attacked with hæmorrhage from the uterus fourteen months ago, which lasted seven days, and has frequently recurred. She commenced menstruating at 16; her menses were not very abundant, and were always preceded by pains in the loins, which ceased on their appearance. She has had leucorrhœa from the time she first commenced menstruating. Her accouchements have all been natural, and she has generally kept her room five weeks after each. Since the first hæmorrhage, the leucorrhœa has been more abundant. She has continued her work, except during the last two days.

The hæmorrhage was preceded by pain in the loins, extending round the sacrum. She has had a difficulty in making water since her first accouchement, and passes it very slowly and frequently. The pain in the loins and sacrum has augmented during the last week, and the discharge has been red. She has had scarcely any rest during this time, on account of the great pain at the anus. Her bowels are relaxed. She has but little appetite, and is considerably emaciated. Her abdomen is well formed, but pressure in the left lumbar and iliac regions causes pain; pulse 84; chest healthy.

Pulv. Opii, gr.j. nocte sumend.

Inject. Calcis Chlorid. ʒij ad ʒj.

January 23d.—Has suffered much from pain; less discharge, passing her water with facility; no sensation of weight at the uterus; pulse 88; no headache; above the left clavicle are situated several small round spherical tumors which have existed for months; they have caused no pain, and had existed some time before they were discovered; several of the glands in the inguinal region are enlarged.

During the month of February she was examined with the speculum; the neck of the uterus was found indurated and enlarged on the right side, and of a livid tint, presenting a very unequal appearance. She complained greatly of a pain at the arms, which ceased after the application of leeches. Having obtained admission into Salpêtrière she soon after left the hospital.

The symptoms were quite sufficient to denote the nature of the disease. The hæmorrhage occurred at the commencement, was considerable, and was repeated four times. In inflammation of the uterus there is often hæmorrhage, but it is very slight. When fibrous tumors exist in the uterus, there is also hæmorrhage, but by no means so abundant; and it occurs at a later period. Out of twenty-one cases of cancer of the uterus, all of whom died and were examined, in two only was hæmorrhage not present, and in one of these there was a rose-coloured discharge. Out of the nineteen, in which hæmorrhage formed one of the principal symptoms, in 13 it was developed 3, 4, and 5 months after the commencement of the disease. In the remaining six it was the first symptom that was observed, preceding or occurring at the same time as the pain. Age had no influence upon it, for it occurred at the various ages of 23, 60, and 70. The two in whom this symptom was absent, were between 30 and 40. Hæmorrhage accompanies organic diseases of various organs, and in none is it so frequently present as in cancer of the uterus. The mucous

membrane is frequently found quite healthy: the bleeding often precedes the pain. The sensation of weight at the anus, which had lasted a considerable time, and was relieved by leeches, most probably depended upon a swelling of the neighbouring parts. The mean duration of cancer of the uterus is about two years or two years and half. Cancer of the stomach causes death in a much shorter period, in eight or ten months; the great importance of the functions of the organ fully accounts for this.

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine.

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE VI.

Restrictions on the Deposition of Evidence in the English Courts of Law—The sanction of an Oath necessary in all criminal cases—None but an Original Record admissible—Self-criminative Evidence not demanded—Hearsay Evidence not admissible—When Medical Opinion is admissible—Conditions on which Dying Declarations are admissible—Confession—Penalties impossible on the medical witness for non attendance—Courts of Law in which the medical witness may be called to give Evidence—Constitution of the Court of the Coroner—Object of the Coroner's Inquest—Duties of the Coroner—Distinction between the Verdict of the Jury of the Coroner's Court and the Verdict of the Jury of the High Criminal Court—Recent Act providing for the Attendance and Remuneration of Medical Witnesses at Coroners' Inquests—Special object of the Medical Witness at the Coroner's Court—Effect of Evidence given before the Coroner's Court in case of the sickness or death of the witness—Special object of the Medical Witness at the High Criminal Court.

Restrictions on the deposition of evidence in the English courts of law.—In the preceding lectures I have entered fully into the consideration of the nature of evidence. I now proceed to make you acquainted with the restrictions which the mode of procedure in the English courts of law place upon the deposition of evidence. With

these restrictions it is important that you should be familiar, because if you are not cognizant of them, you may ignorantly do too little, or too much; neglect to do that which is essential to the admission of your deposition as evidence, or do that which will disqualify you, perhaps, on an essential point, for becoming a witness. Not only will ignorance of this subject be disreputable to you as men of education and science, whose peculiar knowledge is continually required in the courts of law, but it may be the means of defeating the ends of justice.

The sanction of an oath necessary in all criminal cases.—With the exception of dying declarations, to which I shall direct your attention immediately, no evidence can be given in any criminal matter unless upon oath; and therefore any one, unless he be a Quaker or a Moravian, who, on any account, scruples to take an oath, should be careful when employed on a case likely to come before the criminal tribunals, to have some person associated with him who may supply his place in court.

None but an original record admissible.—I have shewn how important it is, in every judicial case in which you are called to take a part, that you should immediately place upon record all the material circumstances which come under your observation. The record in which you originally note down the circumstances of the case you must carefully preserve. Of this original record you may avail yourself, for the refreshment of your memory; but you will not be allowed to make use of any copy of it. Any paper of this kind, to be of service, must be the original record.

Self-criminative evidence not demanded.—If you have yourself taken a part in any transaction by which you have become liable to a criminal prosecution, you will not be required to give evidence in that case. If, as a surgeon, you go out with parties about to fight a duel, with a view

of affording your professional assistance, you are liable to be prosecuted criminally if you knew that a duel was to take place. Should one of the parties be killed, and the surviving party be prosecuted for murder, and should you be summoned to give evidence in this case, you are not bound to answer any questions which may tend to criminate yourself.

"Mr. Pettigrew," said Mr. Justice Bailey, "I think it necessary to give you this caution: if you think the evidence you are about to give, likely to expose you to a criminal prosecution, you are not bound to give it.

"My Lord," said Mr. Pettigrew, "I am not competent to form any opinion of my legal guilt. I have not taken the part of principal nor second. The part which I have taken was merely to exercise my professional duty; in that I do not think there was any moral guilt."

"If," replied the judge, "you went, knowing a duel was to take place, for the purpose of giving professional attendance, I apprehend you are liable to a criminal prosecution.

"Then, my Lord," answered Mr. Pettigrew, "I must decline answering any questions.

"I recollect," continued Mr. Justice Bailey, "having seen a surgeon of eminence tried in this court on a similar occasion."

Neither Mr. Pettigrew nor his assistant were examined.

Hearsay evidence not admissible.—You will not be allowed to bear testimony to any thing which you have not yourself seen or observed. Any thing which you have merely heard from others is not evidence as coming from you. Hearsay evidence is peculiarly liable to the imperfections of incorrectness and incompleteness; there is no possibility of bringing it to the test of cross-examination; there are no means of sifting it in any other mode, and there is no responsibility attached to the statement of it. The English courts peremptorily reject it on the twofold ground, that "matters of fact must be tried only by proof of witnesses personally cognizant of such fact, upon oath before the judge, and that the party making the declaration must be subjected to cross-examination."

The exception to this is the account given by a patient to his medical attendant of his own state and feelings; such a statement is admissible as evidence. "In an action on a policy of life insurance, the account which the deceased gave to the medical witness some days after she had obtained the certificate of health, respecting her state on the former day, was admitted as evidence. The account which a person gives of his bodily feelings, in an-

swer to questions put to him by the surgeon with a view of ascertaining what he has suffered by reason of assault, is also admissible as evidence. It is the duty of the medical practitioner, in all such cases, to examine at the time the correctness of the statement, to sift its truth, and to declare to the court the conclusion at which, from a consideration of all the circumstances which he was enabled to observe, he arrived. "This kind of evidence," says Professor Amos, "of a person's own statement of complaints and symptoms, is admitted on the ground of its being part of what the lawyers call the '*res gesta*,' being not evidence of a by-gone fact, but part itself of the fact which it accompanies, and necessary to shew the true character of that fact."

When medical opinion is admissible as evidence.—Not only are the inferences you deduce from the facts you have ascertained admissible as evidence, but in certain cases even your opinion also. You may be called upon to give your opinion of the representation made by other medical witnesses, relating, for example, to the conduct, manner, and general appearance of an alleged lunatic. In like manner, in trials relating to policies of insurance on life, you may be called to deliver your opinion of the state of health of the deceased from the statements of others at the time of effecting the policy. In all this, the principle is precisely the same as that on which the reception of medical evidence in general is founded. In these as in all other cases in which the medical man is called to give evidence in a court of justice, he is a skilled witness; it is conducive to the ends of justice that the court should receive the advantage of his peculiar experience; and under all the circumstances in which the statement of that experience has a tendency to shed light on the facts of the case, the statement is admitted as evidence.

Conditions on which dying declarations are admissible as evidence.—You will often be called upon to state to the court words uttered in your presence by deceased persons in the immediate view of death, dying declarations as they are termed. Statements made in the immediate view of death are admitted as evidence, although no oath has been administered to the dying person, and although his declarations have not been subjected to cross-examination, on the ground that the solemnity of the occasion is a guarantee of the truth. The dying declarations of a person supposed to have been murdered, or who has sustained any kind of violence, are taken as evidence for or against the accused. But to give validity to such declarations, it is necessary that the person should be-

lieve himself to be actually dying; nay, that he should apprehend recovery to be impossible. Consequently the suggestion on your part of the hope of recovery to the dying, will, if there be evidence that the deceased paid any regard to your suggestion, completely invalidate his dying declaration. "The deceased asked me if his wound was necessarily mortal, (said Dr. Darling,) on a trial in a case of duelling; upon which I told him that his case was one of extreme danger; but that there had been instances where persons had recovered under such a wound; to which the deceased replied, I am satisfied." This conversation took place before the statement made by the deceased, which Dr. Darling was called to declare in evidence. Both Lord Tenterden and Mr. Justice Parke considered that this statement could not be admitted as evidence, because the remark of the physician was calculated to kindle a ray of hope in the dying man, and consequently his declaration could not be said to have been made in *articulo mortis*.

A female died by taking poison at the instigation of the father of her child, which was illegitimate. She related all the circumstances shortly before her death; but her declaration was not admitted as evidence, because, after it was made, she had requested that more medicine might be sent for; thus affording a presumption that the hope of recovery existed in her mind; and consequently that the declaration was not delivered after *every ray* of hope was extinct.

Not only must all hope of recovery be extinguished in the mind of the dying person, to give validity to a dying declaration, but the statement must be strictly voluntary. If you should be selected as the depository of the communication, and your character and office, as well as your situation about the patient, will be likely to suggest to his mind that you are the most fitting person to receive it, you should be merely the recipient of his communication; you should put no leading question; you should suggest nothing, do nothing, but simply receive the statement; excepting, indeed, it be to obtain an explanation of any thing that may be vague, doubtful, or liable to misapprehension. The exact words uttered by the deceased you should record. When there is time for it, you should take the deposition down on paper, read it over to the dying person, and obtain his signature to the document. If you should be unable to do this, on account of the rapid death of the deponent, you should make a memorandum of the conversation at once, while every syllable is fresh in your memory, and to this document you will be allowed to refer in giving your evidence in court.

In every case of this kind it is your duty to endeavour accurately to ascertain the state of the patient's mind at the moment he makes the declaration: whether he be collected; whether he be in the full possession of his reason; whether he be calm, coherent, clear; or agitated, confused, and incapable of sound judgment; whether his mind be under the influence of any particular bias; whether he be labouring under emotion, good or bad, in favour of or against the accused. Malevolence does not always fly from the human heart when death is felt to be at hand. Several appalling instances are on record of a determined purpose on the part of a dying person to attach the guilt of a capital offence to one known by the accuser to be innocent. In such a case you may have the satisfaction of being the safeguard of the innocent; your observation and sagacity may enable you to seize upon some circumstance capable of proving the falsehood of the accusation: it may thus be in your power completely to rescue the intended victim from the snares which are spread around him; snares from which it may be impossible that he should emancipate himself; and if ever you discern the slightest indication of a malevolent feeling or a vindictive purpose, you should use your utmost art and skill to elicit and establish the fact.

Confession.—If, as may sometimes happen, you are called upon by an accused person to receive a confession, take care that you do not hold out to him any inducement of any kind to make the communication; receive what is said to you without comment; reduce it to writing as soon as possible; read it over to the prisoner, and get it signed by him, and counter-sign it yourself, if you are the surgeon acting officially.

In the case of voluntary confession on the part of a person unaccused and unsuspected, while you make an accurate record of all that is stated, do not yield implicit credence to the story, but examine carefully into the state of mind of the deponent, and as far as you are able compare the particulars of the statement with all the notoriously true facts with which they purport to stand related. False self-inculpatory evidence, sometimes obviously resulting from mental disease, at other times induced by motives not at first view apparent, is by no means uncommon. Peculiar circumstances, and more especially such as are capable of producing disease, acting on persons of a certain mental conformation, may induce in them a real and firm belief that they have been guilty of crimes which they never committed, and these crimes they may confess with sincere contrition. About four or

five years ago, a very handsome young man, who resided at a town twelve miles distant from London, was attacked with fever, and lay at the point of death, being given over by his medical attendants. He was conscious that his end approached; but his spirit was so oppressed with guilt that he could not depart in peace without disclosing the dreadful secret that weighed upon his conscience. The curate, at his request, was sent for, to whom he confessed a criminal conversation with no less than six young ladies in the town, all recently married. The curate promulgated the confession, and threw the rural community, husbands, brothers, and fathers, into the most violent commotion. The young man recovered, and solemnly protested his utter unconsciousness of what he had confessed, and with like solemnity protested, that at all events there was not one word of truth in the statements. He was, however, obliged to leave the country, for no one would ever again admit him into their house or society; whereas the person who really deserved banishment was the curate.

In the war of the French revolution the *Hermione* frigate was commanded by Captain Pigot, a harsh man and a severe commander. His crew mutinied and carried the ship into an enemy's port, having murdered the captain and many of the officers, under circumstances of extreme barbarity. One midshipman escaped, by whom many of the criminals who were afterwards taken and delivered over to justice, one by one, were identified. Mr. Finlaison, the government actuary, who at that time held an official situation at the Admiralty, states, "In my own experience I have known, on separate occasions, more than six sailors who voluntarily confessed to having struck the first blow at Captain Pigot. These men detailed all the horrid circumstances of the mutiny with extreme minuteness and perfect accuracy; nevertheless, not one of them had ever been in the ship, nor had so much as seen Captain Pigot in their lives. They had obtained, by tradition, from their messmates the particulars of the story. When long on a foreign station, hungering and thirsting for home, their minds became enfeebled; at length they actually believed themselves guilty of the crime over which they had so long brooded, and submitted, with a gloomy pleasure to being sent to England in irons for judgment. At the Admiralty we were always able to detect and establish their innocence, in defiance of their own solemn asseverations."

Penalties impossible on the medical witness for non attendance.—Since it is often of the last importance to the interests of indi-

viduals, and of the community, that the information which you, as medical witnesses, are capable of affording, should be given in the courts of justice, the legislature has made effectual provision for causing your evidence to be forthcoming. It has armed the Courts with the power of compelling your attendance. Medical witnesses are summoned by a writ of subpoena, which commands them to appear at the trial at a fixed time, to give testimony in the case, under a penalty of one hundred pounds to be forfeited to the king. If the parties suffer from the non-attendance of a medical witness, unless he can show a lawful and reasonable cause to the contrary, he may be compelled to pay such reasonable compensation to the party aggrieved as by the discretion of a jury, under the direction of the Judge of the Court out of which the process issues, shall be awarded. This is effected either by an attachment, that is, seizure of the person, for a contempt of the process of the Court, or an action of common law. But this cannot be done unless it be in proof that the witness was *personally* served with the subpoena, and that his reasonable expenses were tendered or paid at the time of the service. On this account a guinea is usually paid when the subpoena is delivered to the medical man, whereas to an ordinary witness a shilling only is given. This relates to civil cases. In criminal cases attendance is compelled, either by the process of subpoena, or the witness is bound over when first examined either by the justice or by the coroner, and, as in the former case, he is liable for disobedience to an attachment or to a committal for contempt.

Courts of law in which the medical witness may be called upon to give evidence.—The courts in which, as medical witnesses, you may be called to give evidence, are five: the High Court of Parliament, the Ecclesiastical Court, the Civil Court, the High Criminal Court, and the Coroner's Court. I have already stated the several classes of subjects upon which you may be required to give evidence in these different courts. The questions which you may be called to elucidate in the High Court of Parliament, and in the Ecclesiastical and Civil Courts, are sometimes questions of the utmost delicacy and difficulty, the true solution of which will require, on your part, the most accurate and comprehensive knowledge, and the exercise of the most cautious and sagacious judgment. To these questions a full consideration will be given in a subsequent part of the course. But it is in the Court of the Coroner, and in the High Criminal Court, that you will be most frequently called to appear; here the questions on

which you will have to decide are often those of life and death; questions on which you cannot decide safely, justly, without putting into requisition diligently and skilfully the utmost resources of your art and science.

Constitution of the court of the coroner.—

In accordance with the value which is attached to human life, in every civilized community, and the sacredness of which has been shown to increase with the progress of civilization, no human being, however low his rank, is allowed to die in a sudden and unknown manner without the institution of a solemn inquiry into the cause of such death. In every country in which civilization has advanced beyond a state of barbarism, this inquiry is not left to chance, but devolves upon an authority legally appointed and duly constituted for the express purpose of examining into every circumstance connected with the fatal event, not only when the cause of it is altogether unknown, but also when the cause of it is either doubtful or of a suspicious nature. In our own country this authority is vested in a special court, called the court of the coroner. The court of the coroner consists of an officer called the coroner, and of a number of persons who are termed jurors.

The coroner (*coronator*), so called because he has principally to do with pleas of the crown, or such wherein the king is principally concerned, was, in ancient times, an officer of great dignity. By the statute of West. 1, it was enacted that none but lawful and discreet knights should be chosen; and there was an instance in the 5 Edward III. of a man being removed from this office because he was only a merchant. "Now, indeed," says Blackstone, "through the culpable neglect of gentlemen of property, this office has been suffered to fall into disrepute, and get into low and indigent hands; so that, although formerly no coroners would condescend to be paid for serving their country, and they were, by the aforesaid statute of Westm. 1, expressly forbidden to take a reward, under pain of a great forfeiture to the king, yet, for many years past, they have only desired to be chosen for the sake of their perquisites; being allowed fees for their attendance by the statute of 3 Hen. VII. c. 1., which Sir Edward Coke complains of heavily; though, since his time, those fees have been much enlarged."

There is no good reason why a public servant should not be paid for his public service; payment for the performance of the duties of an office is the only ground of responsibility universally recognized, and it does not follow that because a person "condescends to be paid for serving his

country," he is necessarily "low and indigent." For the proper performance of the duties of the coroner, which are extremely arduous, and which occasionally occupy large portions of time, the requisites are not wealth and rank, but education and skill; an acute and sagacious mind, thoroughly imbued with legal and medical science, and well practised in the business of life. To render the office efficient for its object, it is clothed with considerable authority and power. The court of which the coroner is president may consist of an indefinite number of persons, among whom it is not necessary that there should be an absolute unanimity of opinion, but twelve of them must agree in opinion, to constitute a verdict. The individuals composing the coroner's court are all severally sworn to the due performance of their duty, as in the high criminal court.

Object of the coroner's inquest.—The object of the coroner's court is to make inquiry concerning the death of any person who dies suddenly, under unknown, doubtful, or suspicious circumstances; who is found dead in any unusual situation, or who has come to his end by violent means; whether from accident, from the action of any external physical agent, or from intentional human agency. A person unknown is found dead in the street, or in a field; a person well known retired to rest in apparent health, but is found dead in his chamber; a person drops down dead unexpectedly and suddenly, in the midst of his friends, no cause of death being apparent; such a body ought not to be removed from the place in which it is discovered—ought not to be so much as stirred, unless for the purpose of resuscitation, until it has been viewed by the coroner and his jury. It is a misdemeanor to bury a body, under such circumstances, until the coroner has made his inquest into the cause of death; and after such a body has been interred, it is in the power of the coroner to order its disinterment, for the purpose of judicial examination.

It is the duty of the persons who discover such a body, to apprise the coroner of the event; who must summon his jury, inspect the dead body, inquire into the cause of death, record the verdict of his jury, and act upon that verdict, if it be of a nature which requires any further proceeding—that is, if the evidence adduced show that the death has been caused by violence produced by intentional human agency.

Duties of the coroner.—The coroner can make no inquiry of death without a view of the body, both by himself and his jury. The inquest must be *super visum corporis*; for if the body be not found, the

coroner cannot sit." Any inquisition taken without an actual view of the body is void; but after the body has been viewed, the inquisition may be carried on in any convenient place.

The coroner can summon witnesses, and compel their attendance. His authority may be enforced by the power of the Lord Chief Justice of the King's Bench, who is the principal coroner of the kingdom, and may, if he please, exercise the jurisdiction of a coroner in any part of the realm.

Every witness examined by the coroner is examined on oath; and no evidence can be taken but on oath, excepting in the case of Quakers and Moravians. By a recent act, these two denominations of dissenters are allowed to bear witness, even in criminal cases, on their solemn affirmation, instead of on their oath; a privilege which the Quakers had previously enjoyed in civil cases only.

The coroner's inquest is generally an impartial inquiry into the facts of any event which may come before the court: but such an event may assume a form which changes the ordinary functions of the coroner into those of a judge. The friends of the deceased may become accusers; some suspected person may stand in the coroner's court in the condition of a defendant. In such a case, the coroner is bound to hear counsel and evidence on both sides, and if he refuse to do so, the inquisition may be rendered void.

It is the duty of the coroner to take notes of the evidence. The evidence of the medical witness, more especially, is taken down with extreme care; and if the case be referred for trial to the high criminal court, the record of the coroner is presented at that court, and the evidence which you have already given before the coroner will be compared with that which you now give before the higher tribunal.

If the coroner's jury decide that the death in question has been produced by violence, and that there is reasonable ground of suspicion that a particular individual, or individuals, have been concerned in producing it, the coroner must arrest such persons and place them in prison, where they must await their trial in the high criminal court.

The coroner must enrol the verdict of his jury, return the inquisition to the justices of the next gaol delivery of the county, or certify it to the King's Bench, and bind over the witnesses to appear at the trial, to give in the higher court the evidence which they have given before his.

Distinction between the verdict of the jury of the coroner's court and the verdict of the jury of the high criminal court.—The verdict of a coroner's jury against an individual is,

then, sufficient legal ground for sending that individual to trial before the high criminal court, and therefore for his arrest and imprisonment, that his appearance may be compelled in that court. The verdict of not guilty, by the high criminal court, constitutes legal innocence. Whatever evidence of his guilt it might be possible subsequently to adduce, no further proceedings can ever be taken against him for an offence of which he has been declared innocent by the highest tribunal.

But this is by no means the case with the verdict of the coroner's court. The object of that court is to make inquiry, to investigate circumstances, to obtain evidence, to secure the person of an individual when suspicion falls upon him; but nothing is decisive, nothing final, in that court; consequently, although the verdict of the coroner's jury be that death has arisen from a natural cause, or (as they commonly call it) from the visitation of God, yet, should circumstances subsequently occur which beget a suspicion of murder, the former coroner's verdict is not sufficient to prevent further investigation.

In like manner, if the coroner's jury find the case in question to be one of murder—if suspicion have fallen on a particular individual—if the coroner's court, after the most careful and protracted investigation, decide that there is no real ground for suspicion in regard to that individual, and consequently this court take no proceedings against such individual, that person is not in a legal sense acquitted—not safe from any subsequent proceedings; but if strong grounds of suspicion again arise, he may at any time be arrested, imprisoned, and brought to trial in the high criminal court.

Recent act providing for the attendance and remuneration of medical witnesses at coroners' inquests.—The court of the coroner, then, is one merely of inquiry, not trial—of investigation, not decision. Still this inquest can seldom proceed many steps without the assistance of a medical man. Commonly, indeed, for obvious reasons, some medical practitioner is sent for in the first instance, and thus necessarily becomes a principal witness; and if, on the assembling of the coroner's court, no medical man be found in this position, one of the first steps of the coroner usually is to call to his assistance some medical practitioner. The court of the coroner has to determine whether the death in question has been produced by a natural cause, or whether it has been produced by violence of any kind; and if by violence, whether there be ground for suspecting that such violence has been produced by intentional human agency. The former fact can seldom be ascertained without medical investigation. A post-mortem

examination is usually indispensable, and it is often necessary that the contents of the stomach and intestines should be analyzed. Without such investigations, carefully and skilfully performed, the decision of the coroner's jury must often be to the last degree vague and uncertain. But no man can carry on such investigations without bringing to the inquiry much professional knowledge, and devoting to it a considerable portion of time. For the time and skill thus devoted to the public service, it is but just that the public should provide reasonable remuneration. Until very recently, though the coroner might summon to his assistance the medical witness, he had no power to recompense him for his services. Now, however, the case is completely altered. By an act which bears date the 17th of August, 1836, entitled "An Act to provide for the Attendance and Remuneration of Medical Witnesses at Coroners' Inquests," (for which the profession and the public are chiefly indebted to Mr. Wakley, one of the members for Finsbury), the medical witness is expressly entitled to a fee of one guinea for simple attendance, and of two guineas for a post-mortem inspection, or for a chemical analysis. By this act it is provided, that "whenever, upon the summoning or holding of any coroner's inquest, it shall appear to the coroner that the deceased person was attended at his death, or during his last illness by any legally qualified medical practitioner, it shall be lawful for the coroner to issue his order, in the form marked (A) in the schedule hereunto annexed, for the attendance of such practitioner as a witness at such inquest; and if it shall appear to the coroner that the deceased person was not attended at or immediately before his death by any legally qualified medical practitioner, it shall be lawful for the coroner to issue such order for the attendance of any legally qualified medical practitioner, being at the time in actual practice in or near the place where the death has happened; and it shall be lawful for the coroner, either in his order for the attendance of the medical witness, or at any time between the issuing of such order, and the termination of the inquest, to direct the performance of a post mortem examination, with or without an analysis of the contents of the stomach or intestines, by the medical witness or witnesses who may be summoned to attend at any inquest; provided that if any person shall state upon oath before the coroner that in his or her belief the death of the deceased individual was caused partly or entirely by the improper or negligent treatment of any medical practitioner or other person,

such medical practitioner or other person shall not be allowed to perform or assist at the post-mortem examination of the deceased." It is further provided that "whenever it shall appear to the greater number of the jurymen sitting at any coroner's inquest, that the cause of death has not been satisfactorily explained by the evidence of the medical practitioner, or other witness or witnesses, who may be examined in the first instance, such greater number of the jurymen are hereby authorized and empowered to name to the coroner in writing any other legally qualified medical practitioner or practitioners, and to require the coroner to issue his order, in the form hereinbefore mentioned, for the attendance of such last-mentioned medical practitioner or practitioners as a witness or witnesses, and for the performance of a post-mortem examination with or without an analysis of the contents of the stomach or intestines, whether such an examination has been performed before or not; and if the coroner, having been thereunto required, shall refuse to issue such order, he shall be deemed guilty of a misdemeanor, and shall be punishable in like manner as if the same were a misdemeanor in common law."

The act then goes on to provide for the enforcement of the attendance of the medical practitioner, in the terms following:—

"And be it further enacted, That where any order for the attendance of any medical practitioner, as aforesaid, shall have been personally served upon such practitioner, or where any such order not personally served shall have been received by any medical practitioner in sufficient time for him to have obeyed such order, or where any such order has been served at the residence of any medical practitioner, and in every case where any medical practitioner has not obeyed such order, he shall for such neglect or disobedience forfeit the sum of five pounds sterling, upon complaint thereof made by the coroner, or any two of the jury, before any two justices having jurisdiction in the parish or place where the inquest under which the order issued was held, or in the parish where such medical practitioner resides; and such two justices are hereby required, upon such complaint, to proceed to the hearing and adjudication of such complaint; and if such medical practitioner shall not shew to the said justices a good and sufficient cause for not having obeyed such order, to enforce the said penalty by distress and sale of the offender's goods, as they are empowered to proceed by any act of Parliament for any other penalty or forfeiture.

SCHEDULE TO WHICH THIS ACT REFERS.

(A.) *Form of Summons.*

Coroner's inquest at . . . , upon the
body of . . .

By virtue of this my order, as coroner for . . . , you are required to appear before me and the jury at . . . , on the day of . . . , one thousand eight hundred and . . . , at . . . of the clock, to give evidence touching the cause of death of . . . , (and then add, when the witness is required to make or assist at a post-mortem examination,) and make or assist in making a post-mortem examination of the body, with, or without, an analysis, (as the case may be), and report thereon at the said inquest.

(Signed) ———, Coroner.

To ———, Surgeon (or M.D. as the case may be.)

(B) *Table of Fees.*

1. To every legally-qualified medical practitioner, for attending to give evidence under the provisions of this act at any coroner's inquest, wheret no post-mortem examination has been made by such practitioner, the fee or remuneration shall be one guinea.

2. For the making of a post-mortem examination of the body of the deceased, either with or without an analysis of the contents of the stomach or intestines, and for attending to give evidence thereon, the fee or remuneration shall be two guineas.

(C.) *Coroner's Order for the Payment of Medical Witnesses.*

By virtue of an act of Parliament passed in . . . session of . . . , holden in the . . . , intituled . . . , I, the coroner of and for . . . , do order you, the overseers of the parish (or township, as the case may be), to pay to . . . the sum of (one guinea, or two guineas, as the case may be), being the fee (or fees) due to him for having attended as a medical witness at an inquest holden before me this day of . . . , upon the body of . . . , about the age of . . . , who was found dead at . . . (or other particulars or description), and at which said inquest the jury returned a verdict of . . .

(Signed) ———, Coroner
of . . .

Witnessed by me, ———.

To the Overseers, &c.

Special object of the medical witness at the court of the coroner.—The special object of your attendance as medical witnesses at the court of the coroner, is to assist that

court in determining on the propriety of further proceedings. It will mainly depend on the evidence given by you whether the case be dismissed at once as requiring no further judicial inquiry, or whether it be carried to a higher tribunal. If your evidence be inaccurate or incomplete, the guilty may escape, or, on the other hand, unjust suspicion may be fastened on an innocent man, who may be thrown into prison, and confined there several months before he can be brought to trial. At the trial in the high criminal court, as I have already stated, the evidence you give will be compared with that which you have already given in the court of the coroner, and there your evidence will be subjected to all the sifting of cross-examination; all the ingenuity which counsel can employ will be exerted to find in it something incorrect or incomplete; and if any such flaw can be detected, and more especially if your statements can be made to vary materially from the evidence you gave before the coroner, your reputation is lost.

Effect of evidence given before the coroner's court in case of the sickness or death of the witness.—There is one circumstance connected with evidence given before the coroner's court which it is highly important that you should bear in mind. If a witness be prevented by sickness from appearing at the trial in the high criminal court, or be overtaken by death before the trial comes on, the evidence of such witness is taken without any reserve or limitation, although it may not have been delivered in the presence of the accused, and although it be no longer possible to sift its truth and correctness by the process of cross examination. This should make you exceedingly cautious in the evidence you give before the coroner, and should render you watchful of the evidence given by others relative to all the subjects on which your profession renders you a skilled witness, or places you in a favourable situation for observing and collecting evidence. It has been already stated, that if a woman swear positively that a man has violated her, and die in the interval between her deposition and the trial, her deposition is taken as evidence against the prisoner without reserve. Whenever, therefore, you are engaged in any investigation of this kind, it is incumbent on you to avail yourself of every means in your power to sift the truth and correctness of her evidence, in order that you may prove a shield to the accused, if he be falsely accused.

The case which you are called upon by the coroner to investigate will frequently turn out to be a case of natural death,

occurring under circumstances which have given rise to a suspicion of violence, perhaps of poisoning. It may really be a case of poisoning. Then you must collect and state the evidence of the fact. On the other hand, it may be a case of natural death; however plausible may be the suspicion of poisoning, however clamorous and violent may be the rumour of it, at the close of your investigation you may be in possession of indubitable proof that the death in question has resulted from a natural cause. Whenever the facts ascertained by you clearly lead to this conclusion, you should state the result in the most decided and positive manner; for it is even more important to prevent suspicion from falling on the innocent, and to put to silence unfounded clamour, than to bring the guilty to justice. The following case, recorded by Dr. Christison, affords a good example of the completeness with which it may be sometimes in your power to accomplish these desirable ends.

A middle aged man, who had long enjoyed excellent health, one afternoon returned home tired. He had the misfortune to live on very bad terms with his wife; and after having been well beaten by her he went to bed. In about a quarter of an hour afterwards he was found by one of his workmen gasping, rolling his eyes, and quite insensible, and he died in a few minutes. From the evil treatment he received from his wife, it was suspected that he died of poison. Poisoning, however, in this instance was out of the question; for on inquiry into the circumstances of the case, it was proved that on the morning in question he had breakfasted about nine o'clock; that he had taken nothing whatever into his stomach from that hour to the moment of his death, and that he had continued perfectly well until his return home about two o'clock; consequently an interval had elapsed of five hours between his having taken any thing into his stomach and his death, during the whole of which period he had remained in his usual state of health.

This history was alone sufficient to put an end to all further inquiry as to the question of poisoning; it was alone sufficient to prove that death must have arisen from some natural cause. No inspection of the body, no analysis of the contents of the alimentary canal, were requisite to establish this point, because no poison but one of the most active narcotics, taken in a large dose, could have occasioned death with such rapidity; and the operation of such a poison, in such a dose, could not possibly have been suspended for the space of five hours. Of course, even in such a case as this, for your own satisfaction as well as for that of the jury, you

would examine the body; but then you would do it to discover the exact cause of death, to ascertain the true pathology of the case, and not to satisfy yourself that it must be referred to some natural cause. Of that you might be assured without any further investigation.

Without any knowledge of the species of violence inflicted, or the particular poison administered, it sometimes happens that a strong suspicion prevails that violence of some sort has been done, or that poison of some sort has been given; and you will be called upon by the coroner to decide whether there be a certainty, a probability, or a possibility, that the death in question has been occasioned by any species of violence or of poison.

The infliction of any kind of external violence capable of producing death, is so palpable, that you will in general have no difficulty in deciding a case of this class: to determine whether death has been produced by poison, when there is no indication of the individual poison that has been administered, requires much care. The means of arriving at a just conclusion I shall state hereafter; but commonly the chief object you will have to accomplish will be to establish the impossibility of poisoning, and, in the manner I have just explained, to remove plausible suspicion, and to silence vague rumour.

Special object of the medical witness at the High Criminal Court.—If, on the other hand, the evidence which you are constrained to give be of a criminative character, the case will be referred to a higher tribunal; and when you appear in the high criminal court, your position will be changed, and you will have a somewhat different object to accomplish.

Here, the indictment almost always charges the accused with the commission of some particular species of violence, or the administration of some one particular poison. If it be your conviction, from the investigation you have made, that the facts justify this indictment, then your main purpose must be to bring together and to state the whole medical evidence to this effect, and to secure it against the doubts which the ingenuity of counsel will be sure to throw over your conclusions, if the premises be any where false or defective. If your minds have been thoroughly imbued with the doctrine which has been delivered relative to the nature of evidence, and the means of rendering it correct and complete, you will, in every investigation of this kind, be constantly upon the search for infirmative facts; and consequently you will be always prepared to give full effect to every medical circumstance favourable to the accused. It will be impossible that you should ever allow your zeal for the

reputation of scientific accuracy or professional skill, to exceed your love of justice. To all instructed and well-regulated minds in the community, there is no sight more hateful than that of a medical witness at a trial assuming the character of a partizan. It is the part of a barrister to take a side; it is his office to bend every energy of his mind to make that side triumphant. Sophistry and falsehood, if they do but accomplish that end, are as good for him as reason and truth, and are used by him without scruple. But it is the part of the physician to search after Truth, and when he has found her, to reveal her so clearly that Justice can take no side but hers.

Sometimes the indictment charges the prisoner with administering a particular poison; and also some poison unknown to the prosecutor. There are cases in which the evidence of the particular poison is merely presumptive, and in which that presumption may not be strong. It may be impossible to prove what poison has been given, and yet possible to prove that some poison has been given. This is what is termed a charge of poisoning, in a general sense, and convictions have recently been obtained under such a charge; cases in which no satisfactory proof existed what poison had been given, but in which satisfactory proof was adduced that poison of some sort had been administered. These are cases of some delicacy and of great importance; and in a subsequent part of the course I shall direct your attention to the evidence upon which these cases may be sustained, and without which they must fail.

LECTURES
ON THE
ENTOZOA,
OR
INTERNAL PARASITES OF THE
HUMAN BODY,

*Being Part of a Course on Morbid Anatomy,
delivered at the London Hospital,*

By T. B. CURLING, Esq.

LECTURE III.

HAVING in the last lecture concluded the description of the common tape-worm, I come now to speak of the next in the list of the Entozoa, the

7. *Bothriocephalus latus*,

(from *βοθριον*, a small pit, and *κεφαλη*, the head.) This species of tape-worm may be readily distinguished from the *Tenia solium* by the form of the segments, which are broader than they are long, and by the

position of the genital pores, which occur in a series along the middle of one of the flattened surfaces of the body, and not at

B, Joints of the *Bothriocephalus latus*, shewing the central pores.

the margin of each segment, as in the *Tenia solium*. The head, from the formation of which the name of the worm is derived, was discovered by Bremser. It differs considerably from that of the *Tenia*, being of an elongated form, two-thirds of a line in length, and presenting, instead of the four round mouths characteristic of the true *Tenia*, two lateral longitudinal depressions or fossæ. The worm is thinner

a, Longitudinal fissures.

than the *Tenia solium*, and its length likewise is generally rather less; they are occasionally, however, met with of considerable size. Boerhaave states that he effected the expulsion of one, three hundred ells long, from a Russian. The *Bothriocephalus latus* is much less apt to part with single joints than the other spe-

cies of tape worm, which is perhaps owing to the circumstance that the longitudinal fibres entering into its composition are continued from one segment to the other, instead of being, as in the *Tænia*, distinct in each articulation. It inhabits the small intestines, in which as many as three or four are often found to co-exist. The people amongst whom they occur most frequently are the Russians, Poles, and Swiss. In the French they are as common as the *Tænia*, but they are rarely met with in England.

The symptoms which they occasion, and the treatment necessary for their removal, are similar to those of the *Tænia*.

8. *Polystoma pinguiola*,

(from *πολύς*, many, and *στομα*, stomach.) The body of this species of *Polystoma* is flat, truncated anteriorly, and pointed at the posterior extremity. On the under side of the head there are six orbicular pores disposed in a semilunar form. A large suctorious cavity exists on the ventral aspect, and a small orifice is situated at the apical extremity. This parasite has

only been found once in the human body. Treutler, a German, discovered it in a small tumor about the size of a hazel-nut, situated in the adipose tissue connected with the left ovary of a young woman who had died in child-bed. The tumor, which appeared to consist of indurated fat, was of a reddish colour, and hollow within.

Cruveilhier questions, and I think with good reason, whether the body found by Treutler was really a parasitic worm. In the first place, the ovary is not surrounded by fat; and it is somewhat surprising that this most curious animal should only have been seen by one individual. Besides, loose albuminous bodies are so often found floating free in ovarian and other

serous cysts, that it is not impossible that this body was nothing more than coagulated albumen, the orbicular pores being only small accidental openings in it.

A second species of *Polystoma*, the *Polystoma venarum*, is also mentioned by Treutler. It was found in the saphena vein of a man, which was accidentally ruptured while bathing, and is generally supposed to have been a non-parasitic worm belonging to a species of *Planaria*, and to have been introduced accidentally into this strange situation.

9. *Distoma hepaticum*, or Liver Fluke.

The form of the *Distoma hepaticum* is oval, flattened, and elongate. It measures generally from one to five lines in length, and from half a line to a line in width. The anterior pore, or mouth, is round and small; the posterior cavity, which is imperforate, and subservient only to adhesion and locomotion, is large, transversely oval, and situated on the ventral surface of the body in the anterior half. From the anterior pore proceeds a short wide tube, the œsophagus, which terminates in two nutrient canals, which run along the centre of the animal to the opposite end, sending off from their outer

- a, Mouth.—b, Genital pore.—c, Nutrient canals.

sides cæcal branches or processes, but have no anal outlet. Between the two pores already described there is a third orifice, exclusively destined, like the opening on each joint of the *Tænia*, to the generative system; and from which there is generally protruded, in the full-sized specimens, a small tubular process.

The *Distoma hepaticum* inhabits the gall-bladder and biliary ducts, and appears to derive its nutriment from the bile. In the liver of a sheep which I lately dissected, the biliary ducts containing these animals were much enlarged, some of them being capable of admitting the little finger; and the surrounding tissue was atrophied. Cruveilhier states that he has found the ducts cartilaginous, and even ossified, in animals affected with them. This worm very rarely infests the human species; in-

deed Bremser has never met it, and has only been able to collect five or six well-authenticated cases in which it has been found. It occurs, however, in many animals, and very commonly in sheep suffering from the disease called the rot. There is no account of the symptoms which the *Distoma* occasions in man. It would probably, as in animals, be attended with considerable emaciation. Chabert relates a case in which he effected the expulsion of a considerable number from a girl twelve years of age, by means of his empyreumatic oil.

Caecimintha.—We have in this, the fourth class, eight kinds of parasites infesting the human body.

10. *Filaria Medinensis* — *Medina, or Guinea Worm*—*D. acunculus*.

The length of this worm varies from six inches to two, eight, or twelve feet; and its thickness from half to two-thirds of a line. It is generally of a whitish colour, but sometimes of a dark-brown hue. The body is round, nearly of uniform size, but a little attenuated towards the anterior extremity. It is traversed by two longitudinal lines, corresponding to the intervals of the two well-marked fasciculi of longitudinal muscular fibres. At the anterior extremity there is a circular orifice, with swollen edges, which is the mouth. The caudal extremity of the male is obtuse, and emits a single spiculum: in the female it is acute, and suddenly inflected. This worm is so rarely obtained in a condition admitting of its organization being accurately examined, that a good account of its internal structure is still to be desired. No distinct tubes for digestion or generation have yet been discovered. In other kinds of the *Filaria* infesting animals, a simple ovary, oviduct, and uterus, have been observed. The generation of the *Filaria* is viviparous, and the progeny, which are extremely numerous, are not included in a special generative tube, but float freely along with a granular substance, in the common muscular integuments of the body. It is curious that the body of the young differs from the parent, one extremity being capillary, and terminating in the finest point.

The *Filaria Medinensis* is developed in the subcutaneous cellular tissue, generally of the lower extremities, especially the feet. It has been met with, however, in nearly all the superficial parts of the body, even beneath the conjunctiva of the eye; and several have been known to co-exist in the same patient. In 184 cases mentioned by Sir James Macgrigor, the dracunculus occurred 124 times in the feet, 35 times in the legs, 11 times in the thighs, 7 times

Filaria Medinensis.

in the hands, twice in the scrotum, and likewise twice in the groin and on the body. It occurs at all ages and in both sexes, and appears to be endemic in the tropical regions of Asia and Africa, where it appears generally in the hottest seasons. It is by no means confined to the natives: many facts tend to show that it may be

communicated from one individual to another; and Lind and other writers are of opinion that Europeans, on visiting the countries where it exists, become affected with it by contact with the negroes. In America it is said to make its appearance almost exclusively amongst the negroes, and chiefly in those who are newly arrived from Africa. We occasionally meet with it in this country, in individuals who have recently returned from the tropics. There is a specimen in the museum of the College of Surgeons, twenty-two inches in length, which was extracted from the leg of a boy who was a patient of the late Sir W. Blizard, at this hospital. We have also a worm in the museum, removed by Mr. Headington, who was formerly surgeon of this hospital, from the leg of a sailor, where it had been imbedded for two years; and there was another patient in the hospital at the same time, likewise affected in this way. From some observations by Sir James Macgrigor, it would appear that the disorder originating in these worms prevails at times in an epidemic form. Thus he mentions that some troops having embarked, after a residence of two months at Bombay, were attacked whilst at sea so generally, that out of three hundred and sixty as many as one hundred and sixty-one became affected with it. Clot Bey, a French surgeon, mentions that he has seen as many as a hundred patients, labouring under Guinea worm, in hospital at one time. Little seems to be known which can account for the development of this parasite, though authors have speculated abundantly on the subject. It has been noticed, however, that it occurs much less frequently amongst the officers than the common soldiers, and those who occasionally lie on the ground, or go about with their feet and arms naked.

The Guinea worm may remain imbedded beneath the skin for many months, without occasioning any inconvenience, but sooner or later it excites irritation and inflammation in the structures around, which vary in severity according to the constitution of the individual, and the situation and size of the worm. The symptoms commence in a formicating sensation or uneasiness under the skin, accompanied with a superficial cord-like elevation on the surface. A phlysaecous vesicle or pustule forms, which bursting, gives exit at a circular aperture, either immediately or after suppurating for a day or two, to the head of the worm. These local symptoms are preceded usually by slight derangement of the system generally. When situated about the fingers or toes, the worm is often productive of much suffering, and is with difficulty got rid of.

When deeply seated it sometimes causes considerable fever, great swelling, and tedious abscesses and sinuses, giving out a serous ill-conditioned discharge for many months without the worm making its appearance.

The treatment consists in the cautious and gradual extraction of the worm, special care being taken to avoid breaking it across, as this accident is liable to be followed by an aggravation of the inflammation, and the formation of sinuses in its course, together with great constitutional disturbance. These unfavourable effects are attributed, by Hunter, to the contact of dead animal matter, with a large extent of living surface, to which it now bears the relation of a foreign body; such violent symptoms being rarely seen so long as the dracunculus is alive and uninjured. When the worm protrudes, it should be laid hold of and gently drawn out from its resting place as far as possible. The part removed should then be secured at the aperture with a strip of plaster, or tied to a piece of stick, and the traction may be repeated once or twice in twenty-four hours until the entire worm is brought away—a process often requiring many days, or even a month, for its completion. Some surgeons recommend cutting down upon the middle of the animals, and by pulling simultaneously at both ends, shortening the period requisite for the removal of the dracunculus—a plan which is practised by the native Indians. When the worm is got rid of, the sinus usually closes readily. The use of internal remedies and external applications do not appear to be of any essential service. Sir James Macgrigor found that the extension of this affection amongst the troops was checked by requiring great attention in regard to cleanliness, and separating the soldiers troubled with these worms from those that were free from them.

11. *Filaria Oculi*.

The discovery of a species of *Filaria* in the interior of the human eye, we owe to Dr. Nordmann of Odessa. On examining an opaque crystalline lens, extracted by Baron von Gräfe, and partially covered by its capsule, he detected in the *liquor Morgagni* two very small and delicate rings, which, with the aid of a microscope, he recognised as convoluted *Filariae*. One of them had been wounded, probably by the instrument used for opening the capsule, and the intestinal canal was seen protruding at the rupture. The other was entire, about three quarters of a line long, and through the transparent integument could be seen a straight intestinal canal surrounded by convolutions of the oviducts. In a lens extracted by Dr. Jungken, Dr. Nordmann afterwards found a living *filaria*, five lines and a half long.

A larger species of the *Filaria* has been noticed in the eye of the horse.

12. *Filaria bronchialis*.

A third species of *filaria* infesting the human body, was detected by Treutler in the enlarged bronchial glands of a man. It was about an inch in length, slender, and emitting the male spiculum from an incurvated obtuse anal extremity. Treutler

Filaria bronchialis, magnified.

is the only pathologist who has met with the *Filaria* in this situation in man; but in many animals the bronchial tubes are often loaded with worms of this species.

13. *Tricocephalus Dispar*,

(from *τριξ*, *τριχος*, *hair*, and *κεφαλη*, *head*.) or *Trichuris*, as it was formerly called. This entozoon was only discovered towards the close of the last century. Like the *Filaria*, it is characterized by an orbicular mouth, but differs from it in the capillary form of the anterior part of the body, and in the form of the sheath or preputial covering of the male spiculum. The *Tricocephalus* measures from about an inch and a half to two inches, and its capillary portion, which makes about two-thirds of the entire length of the animal, is transversely striated, and contains a simple straight intestinal canal. The thick part of the body is spirally convoluted, and plainly exhibits the intestine which is here sacculated, and terminates in an obtuse anal extremity, from which projects the spiculum and its sheath, in form like an elongated cone, and attached by its apex. The corresponding extremity in the female possesses a simple foramen, which, like the outlet of a cloaca, serves the office both of anus and vulva. The head of the worm is acute, with a small simple mouth. It is necessary to observe that many writers, and amongst others

Tricocephalus Dispar.

* Natural size.

- a, Capillary anterior extremity.
- b, Intestinal canal.
- c, Preputial extremity.
- d, Spiculum.

Dr. Baillie and Dr. Mason Good, have fallen into the error of describing the long attenuated part of the animal as the tail.

The *Tricocephalus Dispar* inhabits the large intestines, and principally the cæcum; but it occurs occasionally in the small intestines. It is often found adhering by its small or anterior part to the mucous membrane, the remainder of the animal being lost in the canal. It is in consequence of this circumstance, and the minuteness of their size, that they are seldom observed in the stools. This species of worm, which infests many of the malarialia as well as man, exists sometimes in great numbers.

In the winter, at the commencement of the year 1761, the period at which this worm was first discovered in Germany, an epidemic broke out in a corps of the French army stationed at Göttingen. Röderer and Wagler, who have given us an account of this epidemic, under the name of *morbus mucosus*, having frequently found numbers of the *Tricocephalus* in the dead bodies of the soldiers who died of the disease, were induced to regard these animals as the cause of it. Now it is remarkable that M. Thibault, who has recently investigated the cholera morbus during its fearful ravages at Naples, in a communication lately made to the Royal Academy of Medicine, at Paris, states, that in the examination of more than 150 bodies of persons, all cut off within the fourth or fifth days of the disease, he found more or less capillary injection of the mucous membrane of the intestinal canal, hypertrophy of the follicles, a considerable quantity of a thick and viscid mucus, and large numbers of the *Tricocephalus*, together with the *Ascaris lumbricoides* and *Vermicularis* in the intestines. The unexpected discovery of this species of worm, in cases of cholera, which is due to Ramaglia, was thought at first to account for the disease; but M. Thibault and his *confrères*, acting with greater caution, and in a more philosophic spirit, than their German predecessors, Röderer and Wagler, extended their researches to persons dying of other diseases than the epidemic, when it appeared that in the inspection of the bodies of eighty individuals, dead of various affections, these worms, together with the viscid mucus, enlarged follicles, and preternatural injection, were found in all of them without exception, although they were present generally in less quantity than in the bodies of cholera patients. These worms have been detected in Germany, since they were first observed, in conjunction with most forms of disease, and in neither of the epidemics alluded to can their existence be fairly regarded in any

other light than as an accidental coincidence, though they may have tended to modify and complicate the diseases, for the cause of which they were mistaken.

No symptoms characteristic of the presence of the *Tricocephalus* have hitherto been noticed, and they appear to reside quietly in the cæcum without exciting much uneasiness.

MALIGNANT FEVER OF BRITISH GUIANA.

To the Editor of the Medical Gazette.

SIR,

THE newspapers have from time to time informed us that a fever of a very malignant character was raging in that rich and important colony, British Guiana. As I am not aware that any account of this fever has appeared in our medical publications, and as the mortality in the colony was at one time so great as to excite considerable alarm, I think the inclosed extract of a letter, lately received from my much-valued friend, Dr. William Fraser, health-officer of the colony, will be perused with considerable interest by many of your readers. The facts brought forward by Dr. Fraser are, perhaps, the strongest that were ever adduced in confirmation of a certain variety of the yellow-fever being highly contagious—at least they leave no doubt on my mind that the late epidemic in Demerara was not only contagious, and propagated only by contagion or infection, (I know not which is the best term), but that it certainly was introduced into the colony in consequence of the quarantine laws having been suspended at the urgent request of the merchants of George Town (the capital), because they led to some trifling expenses; and as alleged, “that their ships were *needlessly* and *uselessly* detained, merely because they came from places where contagious or infectious diseases were prevalent, though they had not a sick man on board.” Now I believe, sir, there is no doctrine more firmly established than this—that a man may convey contagion from one person to another without in any way suffering from the disease himself, and therefore maintain that we ought never in any instance to allow the crews of ships, coming from infected places, to have free intercourse with the inhabitants of the port at which

they arrive, until at least some precaution has been taken to render the danger of their causing infection less probable. Dr. Fraser is a physician of great experience, having practised in Demerara for more than twenty years. He, of course, had often treated every variety of the colonial fever, and bilious remittent, so prevalent in that land of mud; yet he confesses he had never seen the *yellow fever* until the late epidemic made its appearance. I can testify from my own experience, that the bilious remittent of Demerara is often characterised by that yellowness of the surface which is sufficient to entitle it to the name of yellow fever; but it seldom happens that any thing like black vomit is observed, unless when the constitution of the patient is very much impaired; and then, when such a symptom did occur, the case always terminated fatally. Dr. Fraser himself had the epidemic in a very aggravated form, but luckily recovered; and the letter from which I send the inclosed extract was written during his convalescence; it is dated the 5th of October, at which period the disease had been for some time on the decline.

I have the honour to be, sir,

Your obedient servant,

ANDREW HALLIDAY.

Hampton Court, Dec. 29, 1837.

Extract of a Letter from Dr. William Fraser to Sir A. Halliday, dated George Town, Demerara, October 5, 1837.

"Having made allusion, upon more than one occasion, to the epidemic which has caused so much sickness, alarm, and destruction of human life, throughout this colony, I cannot resist the temptation of making a few comments in regard to its introduction and appearance in this community.

"In the latter end of Feb. last, the small-pox having made its appearance in the colony, the quarantine laws, so far as regarded the West-India Islands, were again revived and put in force; as this loathsome and pestilential disease had spread itself far and wide throughout every island of the Archipelago, in some of which the disease had proved exceedingly fatal to the lives of the inhabitants. During the latter part of the year 1835, and the early part of 1836, the yellow fever, with its terrific offspring, the black

vomit, were raging and spreading dismay and death throughout Surinam. In February and March, 1836, I put vessels arriving from Surinam in quarantine, for which I was attacked and shamefully abused in the columns of the *Guiana Chronicle*. From Kerinane, during the summer months of the same year (1786), this dreadful pest found its way to the island of Barbados, where it was instrumental, in a few short months, in sending hundreds of the ill-fated inhabitants to the grave.

From having read a great deal, and seen *nothing*, of the yellow fever—one author pronouncing it contagious, another not—I was myself sceptical as to its real nature, or what claim it might have, or not have, to hold a place among diseases which are considered by all parties as contagious, or infectious. *Late experience* has, however, decided this question, and set at rest every doubt which *my mind* had formerly entertained on so important a subject to the pathological inquirer.

But to resume the history of the particulars connected with its introduction and spread in this colony.

From Barbados it found its way into this place, where it commenced its ravages among the ill-fated community in the early part of last spring. From a small beginning it went on progressively, until, in the months of May, June, and July, it had attained its *acme*, carrying death, sorrow, and lamentation, in its train, wherever it found an entrance. The centre of Water-street formed the focus in which it had, in the first instance, concentrated its pestiferous force; from whence, at a subsequent period, emanated the infection to every quarter and corner of the colony. Among the crews of the shipping the mortality was dreadful; some vessels losing half the number of their crew, others three, four, five, or six; no vessel escaping some loss in the number of its crew. Six, seven, or eight funerals, formed the daily average at this awful and calamitous period of the destroying angel's visitation. No shade or caste of colour, no peculiarity of country, made the least difference, provided there existed a susceptibility in the system to catch the infection. *New comers* were, at the first outset, the greatest sufferers, few of them escaping the deleterious effects produced by the fever in the course of

its progress to a final termination. Although the new comers suffered or sustained the greatest degree of mortality in the commencement, it at last carried off its victims from among every description of the human race inhabiting this province, who had communication with the infected. It is said, and I believe with some truth, that the African and his descendant suffered less by death than any other race domiciliated among us since the appearance of the fever. I have heard it stated that the *black vomit* is unknown among the sable race; but whether this is true or not I cannot, from my own experience, attest or contradict. I have had two or three cases of blacks under my care affected with the fever, but they soon recovered and returned to their usual occupation. Since the appearance of yellow fever amongst us, there have prevailed three different kinds or types of fever. First, the colony intermittent, arising from marsh miasma; secondly, the common bilious remittent, or seasoning fever, both of which are endemic, and neither of which are infectious; and, thirdly, *the intruder* lately imported amongst us from Barbados, which is, as I have already stated, *highly infectious*, as I think I shall prove to your entire satisfaction before I have brought the subject to a conclusion.

People, you are well aware, are, in respect to the nature or existence of infection, as much divided in opinion as they are in other matters, wherein the mind is allowed to wander from what truth and experience ought to teach, to the more intricate and out-of-the-path road of speculation and abstruse theory. There is no truth, however clear and self-evident its existence to the unbiassed and unprejudiced mind, but there are to be found theorists fool-hardy enough to deny and cast under foot. Both theology and the philosophy of the schools furnish ample and sufficient illustration of this assertion. It may appear a matter of wonder and astonishment to the mind accustomed to contemplate the works of creation and Providence, and bow down in humiliation and prayer to the Sovereign Lord of all, that men, rational thinking men, should be found who prided themselves in denying the God of heaven, and avowing openly, and with the most audacious effrontery, their atheistical

doctrines; yet such are to be found even in the heart of these countries where the gospel of Christ has spread its benign and celestial influence. It is not to be at all wondered at, then, that when men are to be found who act the part of a Voltaire, a Jean Jacques Rousseau, a Hume, or a Tom Paine, in denying the very essence of the groundwork of religion, that other men should be found equally strenuous in denying that contagion or infection does exist, and that it proves the fertile source through whose agency disease is engendered and communicated from the infected to those wholly free from infection.

The most bigotted non-contagionist, be he a Bancroft, a Jackson, a McLean, or a Burnett, must allow the fact, and of course the pathological axiom from thence arising, that, "*all diseases communicated from persons labouring under them, to those free from them, are infections.*" If this truth is admitted, then I maintain, and will prove from circumstances which came under my observation during the prevalence of the epidemic, (now, thank God, happily on the wane,) that *infection alone* formed the source and entire medium of its existence and propagation.

Two missionary parsons residing in Berbice, came down here on some business connected with their mission, in May or June last; having completed their business they returned to Berbice, the one feeling himself rather sick or indisposed, the other apparently well, or in his usual state of health. On their arrival at their respective homes, the one who left Demerara indisposed, got worse and died; the other got the fever, and black vomit also, and died likewise. The wife of the first deceased, who also happened to be the sister of the last, was in like manner attacked, taken sick, and consigned to her grave. From *these three* individuals the infection extended itself throughout the town and district of Berbice, causing great mortality in its progress from one part of the district to the other.

M. Schomburg, the traveller sent out by the Royal Geographical Society of London, returned to us here in June last, from his excursion up the Corantyne River, bringing with him, as his attendant, an Indian, indigenous to that part of the colony. Mr. S., be it remembered, had had repeated attacks of

the colony fever and ague, and the colony bilious remittent fever, not only while engaged in his exploring duties in the interior, but while residing in Georgetown, after his return from his former expeditions. On his late return, however, from the Corantyne River, he took up his quarters in the house of a druggist up town, who accommodated him with a bed and bed-chamber in which, two or three weeks before, a young man belonging to the establishment had died of yellow fever, and its terrific derivative, black vomit. Poor Schomburg and his Indian attendant had no sooner come within the pernicious influence of the fomites of the bedding, &c. of the room, than first he was seized, and soon after his attendant, with the yellow fever, from which they both made a very narrow escape. Many of the Arrowack and other Indians, who had come to town with their little commodities to traffic, caught the infection, returned to their sylvan villages, and not only fell victims to the disease which they had thus casually caught, but communicated the infection to others of their tribe who had not on that occasion left their homes, and of which some also died.

A lady, sister to a gentleman who conducts a large mercantile establishment in town here, went and paid a friendly visit to another lady, the wife of a neighbour of hers, whose husband lay very dangerously ill of the disease. I warned her of the very great danger and risk she was running of catching the infection. She, however, contrary to my advice, paid her visit. The consequence was what I foretold, that she was taken sick, and communicated the infection to the maid-servant who waited and slept in the same room with her. From mistress and maid the infection extended itself to the book-keeper, brother clerks, and every single individual about the store, which was in consequence for at least a couple of weeks shut up. I was their annual medical attendant; and I am happy, and truly proud to say, that I was fortunate enough not to lose one out of so many sick of the infection.

A ship arrives in the river; the captain tries by every possible means to avoid having communication with either the shipping or shore. This precautionary sort of measure does very well for about a week or a fortnight; but at the expi-

ration of that period the rigorous restrictions he has placed himself and crew under become relaxed, and they steal a visit to see some of their old messmates, who may perhaps be at the time very ill with the fever. The visitor sits and has a long yarn with the visited; he returns to his ship, his system having imbibed a sufficient dose of the infection, which, perhaps after a few days' illness of fever, may terminate in black vomit and death. The rest of the crew become smitten with the infection, and one, two, three, or more of them, may be consigned to the grave in the same way. An overseer of an estate comes to town with produce to be shipped; he visits some friend's house where the fever is raging; he returns to the estate, sickens, and dies; and his fellow overseers go through a similar ordeal, from having caught the infection from him. From this point the fever spreads itself to every family in the district. Every member of the medical profession, who from their avocations were necessarily exposed to the infection, have been attacked, and undergone a most severe fit of sickness; none of them, however, have died. The mortality has been great among the clergy, considering their very limited number; not less than seven or eight of them have gone to their long account.

If the facts I have adduced in regard to the manner in which yellow fever extends and spreads itself throughout a district of country, or a province, prove not its eminently infectious nature, I know not what will establish or prove it, either in respect to the yellow fever, or any other disease which is on all hands agreed to be propagated and spread by specific contagion or infection. The facts and illustrations I have given above correspond exactly with the manner in which *I have seen*, and it is well known, the small-pox, scarlet fever, measles, and typhus fever, are communicated from those labouring under either the one or the other of these diseases, to those who, *previous* to having had communication, had been free from sickness or disease, and were likely to have continued so had they taken the necessary precaution to have kept beyond the sphere of contamination or infection. In seven months, that is to say, from the month of January last till the end of August, the number of deaths in Georgetown *alone*, the Colonial sex-

ton reports to have been, within two or three of six hundred. This number of course includes the white inhabitants of the town, the seamen, the free coloured, and the apprenticed labourers.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

BY WILLIAM GRIFFIN, M.D.

Limerick.

The Cholera at Limerick.

No. III.

THE many harrowing scenes and incidents to which I was witness during the prevalence of this epidemic, have left impressions on my mind which I shall never forget. One may see much of the vicissitude of fortune, and even instances of appalling misery, in ordinary life, but it is in such wasting pestilences that the influence of the more powerful passions are thoroughly displayed, and human nature laid nakedly open to us in its strength or its weakness. Nothing struck me so forcibly on all occasions as the extraordinary resignation and deep religious feeling evinced by the very poor, in the most desolate situations. The temper in which they generally met the most frightful visitations, and beheld themselves suddenly stripped of every earthly comfort, might very well put to shame the bearing of those in far lighter trials, who descant superciliously about their ignorance and superstition. I remember one instance of this among many, which I cannot refrain from mentioning. As I was walking round the ward one night, administering medicines from bed to bed, my attention was attracted to the door, when I saw a poor widow, whom I had formerly known, tottering in with her only son, a fine boy of fourteen years of age, on her back. She laid him down, cold, blue, and shrunken, on some straw, and flinging herself at my feet, clasped her arms convulsively round my knees:—"My only boy, Doctor!" she exclaimed with broken sobs; "I have brought my only boy, my hope, my support; I trust him to you, and if he was ten thousand times dearer to me I'd trust him to you; save him for me; oh! save him for me, won't you? God will bless your efforts

if you try to save him, for I have only him in the world belonging to me." Having quieted the poor woman as well as I could, I hastened to get something done for her child, who was in a bad collapse. The most unrelenting attention was paid to him; but, unhappily, time after time as I moved round the ward, I found him getting worse. The wretched mother, sitting beside the straw on which he lay, watched me anxiously when I approached, ever repeating with beseeching look the only question of interest to her in the world, "Is there any hope, Doctor?" At length I came round again, and, though despairing of his recovery, was astonished to find him dead, for there was no new complaint of the mother—no fresh gush of sorrow when her last tie to earth was divided, that could have apprized me of the event. She was still sitting quietly beside his remains, waving her body backwards and forwards with a see-saw motion, and clasping and unclasping her hands softly, as if she feared to disturb him. When I stood beside the bed, she looked up at me and whispered faintly, "The Lord's will be done, Doctor! I wasn't to have him."

To me, who have never witnessed the progress of a pestilence which dispatches its victims so summarily, the various modes in which the patients die in cholera is a subject of considerable interest. Some were struck down by their own firesides without previous complaint, breathing their last, blue and cadaverized, within two or three hours; some who were under treatment, and did not appear to be in very imminent danger, when resting on the elbow to take a drink, dropped back suddenly, and died without moan or struggle; others seemed to wear out, and lose life so slowly and insensibly, that it was often difficult to tell in passing the bed whether they were living or dead. It was beyond description pitiable to see little infants, of a year or a year and a half old, in this condition. They did not cry or become peevish, as in ordinary illness, nor look as in health for the mother's attendance; but as if their little faculties were matured by the greatness of the calamity, seemed impressed with some sense of its awful nature, and exerted their feeble energies uncomplainingly to resist it. I remember one little fellow who, when lying

apparently insensible at the foot of his mother's bed, used to start up suddenly whenever he heard any one near him, call for water, drink greedily, and without taking the least notice of those about him, drop off into the same state again. With older persons, however, the appearances of death were more imposing than in infants. I have on several occasions, after a patient had as I supposed expired, been much startled to see the seeming corpse turn in the bed, and call in low whispers for "cold water." Even where they went far beyond this, and with every other sign of mortality were speechless and motionless, it seemed sometimes possible to call them, as it were, back again to the world by the application of some powerful stimulant. I saw one young girl in this state, who was several times brought back suddenly to life, by the application of flannels wrung out of scalding water to the chest. It is, indeed, a very remarkable feature in this extraordinary disease, that both the mind and sentient powers remain perfect as long as the most feeble spark of life remains.

The manner in which drunkards died struck me as peculiar and extraordinary, presenting as it did some of the phenomena observed to follow poisoning by prussic acid. The expression of the features usually remained very much the same as it was before death; the eyes continued open and glistening, and the body maintained the position it had been lying in, however different from that usually assumed in the last moments of existence. A woman, aged about 40 years of age, was brought into the hospital to me, one morning, by her own son. She had a wild staring look, appeared stupid, which is unusual in the disease, and was pale and pulseless. She had been, by her son's account, in a state of intoxication for three days, and was, I believe, then brought direct from the public-house in which he had found her. "She has been drinking, sir, continually," he exclaimed, "in defiance of all I could say; and if Hell was opening for her, she would still drink on!" I had her immediately removed to bed and attended to. In about an hour afterwards, when I went round the ward with the apothecary, she was lying on her side, her head resting in a very natural position on the pillow, and her eyes staring at me with a glistening

wild kind of expression. I sat down, asked her how she felt herself, and commenced filling out some medicine; but there was neither movement or reply, and she still eyed me with the same fixed, life-like glare. On shaking her by the shoulder, I found she was stone-dead.

The deaths of such patients as went into consecutive fever were as singular and various as of those who did not outlive the stage of collapse. It is hard to conceive how human life could come to its close in a more quiet way than it did with some who lay down and died, as if, a little wearied, they were only enjoying a refreshing slumber. This treacherous end was slow of approach and had its forewarnings. A beautiful blush first appeared on the cheek which the day before was of a corpse-like paleness—there was a constant drowsiness or disposition to sleep, and when addressed, the patient usually answered, perhaps with a smile, but always with a happy expression of countenance, "I'm finely, sir." On the succeeding day he was usually found in a still sounder sleep; but when roused up and questioned, returned the same reply. On the third day he was snoring—it was harder to awaken him, and though yet muttering "finely, sir!" to all inquiries, there was an appearance of stupor and wandering about him. On the fourth morning he was generally found insensible. How opposite and how shocking were the deaths of others, happily but a few! After outliving a long and deep collapse, they seemed to struggle into a kind of congestive, half insensible state, with the eyes upturned and reddish, the lips dark and frothy, and putrid blood ejecting from the bowels. Unable to swallow, or speak, or look up, their moans in this state were horrible beyond imagining; and when placed apart from less hopeless cases, they often writhed themselves off their straw, half across the room, as if in the agony of their last hour. I have known them continue in this state to the second or third morning, the horrible moan never leaving their lips night or day.

To get a perfect idea of a plague, we should, after all, visit the dead-house, especially on the first or second morning after the incursion of the disease, when, probably, the mortality and confusion have been greatest. It is like visiting the battle-field on the morning

after contest. On entering, one may behold naked bodies stretched in various positions, such as they chanced to fall into when heedlessly dung down by the hardened cot-men. None of the faces have the calmness observable in a short time after death by ordinary disease, but each exhibits some peculiar expression of the pestilence, or of the agony with which it closed. One, with pale and dragged features, looks as if he died after a violent struggle in some bloody combat; another has a quieter, yet painful expression, as if the hand of the assassin had laid him suddenly low; a third seems to have sunk under some painful and protracted illness;—a fourth resting against the wall in a corner, stares at you with glistening eyes, as if an insane consciousness lit up life again, and he was angered at your scrutiny. Then the revolting recklessness with which here and there they are heaped over one another—the mockery of all our strongest feelings and instincts—the familiarity with death which it betrays, and the recollection that all this was but the work of a few hours!

That startling phenomenon, automatic motion after death, which has been noticed both in India and on the continent of Europe, occurred but twice in the course of my attendance on cholera cases, and in both instances in St. John's Hospital. The apothecary, however, who was resident in the house, seemed to be more familiar with it, although he had not before reported the circumstance. In one of these cases the man had died in collapse, and the blanket was as usual thrown over his face until he should be removed to the dead-house. Some time elapsed before this was thought necessary, when the surgeon whose watch it happened to be observed the blanket stirring! His attention, and that of the nurses, was immediately excited, and to their horror and astonishment they saw the blanket gradually lifted, and the hand of the man moving with a tremulous motion, until it rested above the head. Soon after the leg at the same side was lifted up with the same quivering movement, and slowly crossed over the other, and subsequently it was brought back again.—The surgeon after this took the hand that was laid above the head and placed it on the breast, where it was before, but it was once more lifted up and deposited above

the head. There was little or no movement afterwards. The body showed no other sign of vitality all this time, and was in fact perfectly dead!

In the other instance, the medical attendants, while walking in the ward, were alarmed by piercing cries from the dead-house, and on running down, found the nurses aghast at the door, exclaiming in terrified accents that one of the patients who died was moving within. On entering to ascertain the truth of this story, they perceived a corpse, which was resting against the wall opposite the door, elevating and depressing its arms alternately. These motions continued for a few minutes; and on examining the body there was not the least sign besides that could be considered indicative of life. My brother, Dr. Griffin, of Pallas-Keury, was witness to an incident of the same kind, but differing in the nature of the motions. There was a crowd of people *wakeing* the body of a cooper, who had died some hours before of cholera, when the sheet was suddenly observed to move. One of the relatives immediately raised it, to ascertain the occasion of the movement, and to his utter horror saw the fingers of the corpse stirring. There was an instant scream throughout the room, and the company betook themselves to flight. When my brother, who was sent for, arrived, and examined the body, he found the man was perfectly dead; yet, on looking down at the hands, the motions were still going on—the fingers slowly contracting towards the palm of the hand, one after another, and again expanding. He then looked to the feet, and found the toes were contracting and extending in a similar manner: the motions soon after ceased.

ON SOME OF THE EFFECTS OF ENDOCARDITIS;

And particularly on the Scutiform Thickening of the Aortic Valves.

BY JOHN THURNAM.

As the peculiar morbid condition of the sigmoid valves of the heart, which has been lately described by Dr. Watson, in the pages of the *MEDICAL GAZETTE**, has, during the last fifteen months,

* *MEDICAL GAZETTE*, vol. xxi. p. 450.

frequently fallen under my notice, and as the conclusions which I have for some time come to, regarding it, differ somewhat from those of that gentleman, I am desirous of offering a few remarks upon the subject.

With respect to the normal structure of the valves in question, although I am disposed to believe that the bases are thicker and stronger than the upper free portions of the valves, yet I think it will be found that there is no portion of the valves into the structure of which the fibrous tissue does not enter. It would, however, appear that the fibres constituting this tissue are frequently separated from each other by rather considerable intervals, which are, of course, closed only by the investing fold of endocardium; and that such portions of the valves are, from this cause, much more liable to become ruptured than those which are adequately supported by fibrous tissue. This defective supply of fibres occurs, I believe, more often near the angles of attachment of the valves than elsewhere, in consequence of the fibres being gathered into bundles at these points; a circumstance which would account for perforations of the valves being more frequently met with in this situation.

The cribriform condition of the valves here alluded to, it may be observed incidentally, was known to, and depicted by, Senac*; but it appears to have been first *particularly* described, about the same period, by two independent observers—Dr. C. J. B. Williams and Dr. Kingston†; and, as Dr. Watson remarks, is not very uncommon. I can scarcely conceive that, in the extreme case of this lesion, which is given on the authority of Dr. Budd, the edges of the valves could possibly have remained uninjured, in the form of strings, unless we admit that the delicate endocardium forming them was supported by a bundle of tendinous fibres, which formed the free borders of the valves. I believe it will also be found, that in the healthy condition of the valves they are transparent throughout. The view which I have taken of the structure of the semilunar valves of the heart in man appears to be strongly supported by an examination of those of some of the larger ruminant quadrupeds. In

the bullock they are distinctly seen to be formed of bundles of tendinous fibres, more or less completely interlacing each other, but presenting the largest interspaces near the angles of attachment of the valves, from which the bundles of fibres diverge*.

There appears to me to be so much analogy between the endocardium and the proper serous membranes, that I cannot but conclude, with M. Bouillaud, that the phenomena which are manifested by it when the seat of inflammation, have a corresponding analogy to those which, under similar circumstances, are presented by the pleura, the pericardium, and the peritoneum. That the lymph, and other more fluid products of inflammation, are neither so frequently nor in such large quantities met with on the surface of the endocardium as on that of the other serous membranes, cannot be matter of surprise; and it is even remarkable that the current of the blood should, so often as there is reason to believe it does, leave any such traces of inflammation undetached. From three or four marked cases of acute recent endocarditis, which I have now had an opportunity of seeing, I have little hesitation in stating that the true anatomical character of this disease consists in a beautifully delicate stratum of semi-transparent, granular, red lymph, of greater or less extent and depth of colour, closely adherent to, but capable of being separated from, the subjacent endocardium.

In two of these cases rheumatic pericarditis had also existed, and a recent false membrane, having the above characters, was met with in considerable patches in the left auricle, stretching on to the surface of the mitral valve. In both of these cases, the scutiform thickening of the aortic valves, closely resembling Dr. Watson's second figure, was also met with. In the third case the endocarditis had its seat in the inferior or ventricular surface of the anterior large portion of the mitral valve, and extended also, in a diminished form, to the ventricular surface of the aortic valves. This was in a case of aneurism

* *Traité du Cœur*, 1783, tom. i. pl. 19.

† *MED. GAZETTE*, vol. xvii. p. 887 and 955; and *Med. Chir. Transactions*, vol. xx. p. 90.

* Since writing the above, I have satisfied myself, by repeated examination of both the right and left sigmoid valves in the human subject, that their structure is such as I have described; but I may observe that this is most easily verified by an inspection of their internal or arterial surface, and especially by viewing this with the assistance of transmitted light.

of the aorta, of singular interest; and which, I believe, will be shortly communicated to the profession by Dr. Roe.

It appears to me to be the more necessary to allude particularly, on the present occasion, to those cases of endocarditis which have presented a pseudo-membranous exudation, (which Laennec states, and I think correctly, to be the most unequivocal, and, with the exception of ulceration, the only certain sign of inflammation of the lining membrane of the heart), in consequence of M. Bouillaud, who of all authors has contended the most strenuously for the existence, and indeed for the frequent occurrence of this disease, having adduced scarcely a single case which displayed the unorganized or recent form of such an exudation. The "first category of cases of endocarditis" of this author*, contains thirteen cases which proved fatal during the first stage of the disease, or during that which, according to M. Bouillaud, is characterized anatomically by sanguineous congestion, by thickening, softening, and ulceration of the membrane, and by a *pseudo-membranous secretion*.

Upon looking these cases carefully over, I do not find more than one (42.) which makes any pretensions to the last-named incontestible character of recent endocarditis; and even in that, I am strongly inclined to believe that the "*caillots albumineux*" were in reality a deposit from the blood. I cannot agree with M. Bouillaud that it is an error of trifling importance to mistake a discoloured and adherent sanguineous concretion for a pseudo-membranous production, inasmuch as the former, there can be little doubt, are frequently found in cases where there has never existed the least trace of inflammation of the endocardium. With the exception of one case (50.) in which ulceration is reported to have existed, the remainder of the cases placed in this class are chiefly characterised by redness of more or less intensity, in addition, however, to certain *chronic* changes, such as thickening and fibrous excrescences of the valves. Redness, taken alone, appears to be open to so many fallacies, that I cannot help concluding that several of the cases in question ought to have been referred to the

"second class of cases of endocarditis," which is characterised by the organization of the secreted products, or of the fibrinous concretions—by vegetations or excrescences—adhesions of the valves—organized patches of false membrane, in the form of white spots, on the internal surface of the heart—and by the hypertrophy of the endocardium and its subserous cellular tissue.

I have not unfrequently met with hearts exhibiting imperfectly organized false membranes, of the kind just alluded to, on the internal surface of the left ventricle in particular, which were capable of being raised from the endocardium beneath them, and which had doubtless originated in the transformation of patches of delicate pseudo-membranous exudation, such as I have described as having met with in the three or four cases already alluded to.

CASE.—I have a drawing by me at the present time, of the interior of the left ventricle, from a female aged 26, subject to rheumatism, who died rather suddenly after an illness of about four months, in which the chief symptoms had been pain, palpitation, extreme breathlessness, and a double sawing sound and purring tremor over the aortic valves, at the last only accompanied by very little œdema of the ankles: pulse varying from 90 to 120, very thrilling. In this case the aortic valves were remarkably altered, by the presence on their ventricular surfaces of a thick layer of semi-organised lymph, which was here and there accumulated in the form of irregular masses, by which the valves were soldered together to a considerable extent. The valve which was the most extensively affected in this way was likewise perforated by a round hole, about a line in diameter; but independently of this, the changes were of such a description as not only to have acted as an obstruction to the course of the blood, but also to have permitted its regurgitation. Immediately beneath the valves there was a large white patch, underneath which a bristle was introduced; and this being pushed forwards with the slightest force, came out at the free margin of one of the valves, having insinuated itself between the valves and the superimposed mass of false membrane. There was likewise contraction of the mitral orifice; and in the left auricle, near the border

* *Traité Clinique des Maladies du Cœur*, par J. Bouillaud. Paris, 1835; t. ii. pp. 9 and 171.

of the valve, there were two or three small recent patches of granular lymph, being the fourth case in which I have observed its presence. The heart was considerably hypertrophied and dilated, especially the left ventricle; and there was a thick white spot on the pericardium, covering the point of the heart.

From the cases I have above alluded to, as well as from the examination of numerous others, in which the products of the inflammation had undergone various changes, I have no doubt that in endocarditis lymph and serum are, as in the case of the other serous structures, deposited on the free surface of the membrane.

In some particular cases, and I believe especially in those in which, from some cause or other, there exists an obstruction to the circulation of the blood, I think that the effused patch of lymph may serve as a nucleus for the deposition of the fibrin of the blood, and that in this way may be explained the formation of some of the *larger forms* of excrescences and vegetations*. This, however, I should regard as an accidental complication of endocarditis, and not at all as an essential result.

It may be observed, that whilst the morbid products which result from these inflammatory actions have their seat on the free surface of the endocardium, there are other different adventitious productions, such as steatomatous, atheromatous, cartilaginous, and osseous matter, which are deposited *beneath*, or, in other words, on the attached surface of this membrane: just as it is observed that cartilaginous and osseous plates are often developed on the attached surface of the pleura, and other serous membranes.

If we admit the view which, I hope not on insufficient data, I have ventured to offer of the phenomena of endocarditis, and in which I have chiefly followed M. Bouillaud, there appears to me no difficulty in explaining the peculiar morbid condition of the aortic valves, which has been so well described by Dr. Watson, and depicted in Mr. De Morgan's Sketches.

Every time the heart acts, during its diastole, and when the sigmoid valves are engaged in closing the arterial orifices, certain portions of these valves are

necessarily brought into apposition with each other; and I believe it will require very little consideration to perceive that these are precisely the "thin crescentic portions" spoken of by Dr. Watson, and that the festooned line, to which he has drawn attention, forms the exact boundary between that portion of each valve which is presented towards the ventricle, and which is actually engaged in closing the mouth of the artery, and that other portion which is in coaptation with the corresponding part of the adjoining valves. The festooned line in question is doubtless the result of hydrostatic and mechanical laws, and where not obviously present, might in any given case be indicated with mathematical accuracy, could we appreciate the precise force of the ventricle, and other co-operating influences.

In case of these valves becoming the seat of acute or subacute inflammation, and having, as the result of this, a stratum of lymph effused on their ventricular surface, it is easy to conceive, or rather it is what would *a priori* be expected, that this lymph would be rubbed off those "crescentic segments" of the valves which during the diastole are brought into mutual apposition, and that it would become accumulated in the form of a ridge on those festooned lines which form the lower boundaries of these segments.

Pericarditis is a disease which strikingly exemplifies the modifying effects of motion and attrition on the appearances presented by the inflammatory products, and which may be here adduced analogically. Upon this principle we must doubtless explain the peculiar appearance of the surface of the heart, which varies so much in different cases of this disease, and which has sometimes been compared to the second or honeycomb stomach of ruminant animals, to tripe, or even, as by the older authors, to hair and wool—(*cor hirsutum, tomentosum, &c.*)

I find from my note-book that, during the last fifteen months, I have met with this *scutiform* thickening* of the aortic

* The "Globular Excrescences" of Laennec and "Fibrinous vegetations" of Bouillaud.

* The term "scutiform," which I here apply to this morbid condition of the valves, appears to be justified by the degree of resemblance which there is between the form of the thickened portion of the valves and that of some forms of heraldic shields. I was very desirous of retaining the term "festoon," introduced by Dr. Watson; but this cannot be done without much circumlocution. The term "festooned thickening"

valves, in a more or less advanced stage, in thirty-seven out of seventy-seven hearts taken indifferently from nearly all the cases which I have had an opportunity of examining during that period. In only one or two of these cases, do I find that the pulmonic valves were also affected, and then only in a much less degree. In a considerable proportion, and in all in which I attempted the proof, I found that this peculiar form of thickening was dependent upon the presence of a scutiform pellicle of false membrane which adhered closely to the ventricular surface of the valves, from off which, however, it was capable of being peeled more or less completely, either with the finger-nail, or the edge of the scalpel. When the false membrane had been in this way separated from the valves, their surface was left comparatively healthy, and all trace of the festooned line was destroyed.

In several of the cases the false membrane covering the valves extended beyond their bases to the surface of the muscular substance of the heart beneath them. Whilst in a large proportion the thickening was slight, and had not proceeded farther than that represented in Dr. Watson's first figure, in others it equalled, or even exceeded in extent, that represented by his second, and the festooned line, as there represented, was studded with minute granules of lymph. As a further confirmation of the view which I have taken of this pathological condition, I may remark that, in a few of the cases, and especially in one which it has occurred to me to observe since the publication of Dr. Watson's paper, the valves had gained an adhesion to each other for the extent of a line or two from their attachment, the medium of which adhesion was evidently to be found in the layers of false membrane covering the valves. I may also state, that I have never observed it on the upper or arterial surface of the valves, *only on the ventricular surface*.

The cases in which I have found this condition the most marked, were generally those in which some other more or less important disease ex-

isted, such as white spots on the pericardium; thickening and contraction of the mitral valve; a peculiar form of hypertrophy of the lining membrane of the left auricle; and different degrees of hypertrophy and dilatation of the cavities of the heart. I have, however, met with it in cases in which no other lesion was detected, and I believe that, after very slight alterations of the thickness and capacity of the heart's cavities, it must be regarded as the most frequent pathological alteration of this organ.

That I might leave no means unresorted to for determining accurately the nature of this lesion, I performed the following experiment, which had for long suggested itself to me, and to which I was naturally led by the view which I had taken of the subject, and which has been above explained. I took the commencement of the aorta of a bullock, with its valvular apparatus complete, and after having equally distended it with glazier's putty, so as, with the valves, to close the mouth of the aorta, I painted their inferior surfaces, remaining *in situ*, with a strong solution of gelatin, coloured with vermilion. Upon laying open the aorta after this had dried, I found that I had in this way produced an artificial specimen of the festooned thickening, closely resembling, as the accompanying sketch [see next page], by my friend Mr. Wm. Gerrard, will shew, that which occurs naturally as a pathological change.

It may be observed, that the mechanism of the production of this peculiar form of thickening of the aortic valves, which I have advocated, is equally applicable, whether the matter producing it be traced to an exudation of coagulable lymph, as I have contended, or to a deposit of the fibrin of the blood.

It is remarkable that a condition of the aortic valves, which is so very far from uncommon, appears to have escaped the notice of two such accurate observers as M. Bouillaud and M. Bizot. Since the foregoing observations were written, I have had the pleasure of perusing the admirable "Recherches on the Heart and Arterial System," by M. Bizot*. It is gratifying to me to find that many of the views which I have now taken are supported by the investigations of

would be incorrect, for the portions of the valves included by the festooned lines are those which are not implicated in the thickening. The term "scutiform" may perhaps be received with the less hesitation, as it has already found a place in anatomical nomenclature, as well as in that of another department of natural history.

* Mém. de la Soc. Méd. d'Obs. 1836, t. i. p. 262.

an observer of such great merit as M. Bizot, who has examined with excessive minuteness the hearts of 156 subjects, upon which his memoir, which is richly stored with facts connected with the pathology of the heart, is founded.

Although he does not allude to the festooned arrangement which has now chiefly claimed our attention, yet I feel little doubt that he has been describing this lesion under the head of "Alterations of the tubercles of Arantius," in speaking of which he alludes to "minute albuminous bodies" in the immediate neighbourhood of these tubercles, which are "round, reddish, polished, and half-transparent, and evidently of recent production." In a more advanced stage they pass into "an opaque and more solid or even cartilaginous state." M. Bizot met with the cartilaginous form of this alteration 37 times in 121 cases*. Dr. C. J. B. Williams has likewise alluded to this condition of the sigmoid valves, under the term of "the thickening or hem of the tubercle of the Arantius†."

I may just observe, that I should not suppose that this condition of the valves, even when in a very extreme form, could of itself give origin to symptoms of disease; but I have no doubt that it has been and still is very frequently passed over in dissection, in cases where

there is chronic disease of the heart, and in which these valves are reported healthy.

Westminster Hospital,
Jan. 11th, 1838.

ON THE SO-CALLED CHOROID GLAND OR CHOROID MUSCLE OF THE FISH'S EYE.

To the Editor of the Medical Gazette.

SIR,

ABOUT five years ago I examined the structure of the body in the eyes of the fish known by the name of the "choroid gland," or "choroid muscle," and obtained the following results:—

When the sclerotica is removed from the back part of the eye of a fish, of a cod (*gadus morrhua*) for example, a silvery-like membrane is seen covering the posterior surface of the choroid coat. Tear this off, and a dark red swollen body, somewhat of the shape of a horse-shoe, and encircling irregularly the entrance of the optic nerve, will be exposed. This body, the relief of which can be seen before the removal of the silvery-looking membrane, is the so-called *choroid gland* or *choroid muscle*. Its extremities meet, but are not incorporated together, at the line or fissure which runs from behind, forwards,

* Op. cit. 362.

† Med. Gaz. vol. xvii. p. 890.

along the lower half of the eye. A fine aponeurotic-looking expansion covers the body.

A great number of large vessels are connected with the outer edge of the so-called gland or muscle, and a little careful examination will show that vessels enter by its inner edge also.—How do these vessels comport themselves? Examined with a magnifying glass, it will be discovered that at either edge the vessels, after subdividing to a considerable degree of minuteness, anastomose with each other, and form a network. If now we subject the central substance of the body to microscopical examination, we shall find it is composed of an aggregation of minute straight vessels running across and connected by their extremities with the plexus on either edge of the body.

Close by the optic nerve two blood-vessels are connected with the eye; one of these, thicker in its coats and a little larger than the other, an artery, after having entered the eye divides into two branches which run along the inner edge of the body, giving off twigs which by their subdivision and anastomosis form the net-work already mentioned at the inner edge. From the minute plexus at the outer edge vessels emerge, which run together to form larger twigs. The latter enter pretty considerable trunks, which at first skirt the outer edge of the body, but afterwards turning away from it, proceed forwards and ramify in the choroid coat.

The vessels which emerge from the outer edge of the body have very thick fleshy-looking coats. The minute vessels forming the central substance of the body, have also thick coats; on account of which circumstance, and on account of their straight parallel course betwixt the two net-works, the body, when torn, presents a fibrous structure. And this structure, on account of the red colour, (which is derived, in a great degree, though not entirely, from the blood globules the vessels contain), simulates very much the appearance of muscular fibre. It is easy to inject with mercury the artery entering the eye as far as the network, on the inner edge of the body; but I have not found the mercury go across to the network at the outer edge. Sometimes, however, a minute globule may be pressed across.

After this description there can be little doubt but that the so-called cho-

roid gland or muscle of the fish's eye is a tissue of vessels—that it is in fact a *rete mirabile*. But this is not the only *rete mirabile* in the eye of the fish, for the arteries as they proceed forward in the choroid, many of them subdivide into small branches, which again unite into one, thus forming secondary and more simple *retia mirabilia*. Lastly, the arteries of the choroid terminate in a starlike manner, and the radiating twigs of these stars inosculate together.

Fig. 1 represents the so-called choroid gland or muscle, or, as I would now call it, the great *rete mirabile* of the eye of the cod. Its posterior prominent surface is sliced away to a level with the entrance and exit of the vessels, in order to show the network at its edges, and the straight vessels between these networks, forming the central substance of the *rete mirabile*. It is to be remarked that the whole body is delineated of the natural size, but the lines representing the straight vessels are drawn in a gross diagrammatic manner: *a* is the artery at its entrance into the eye, subdividing into branches.

Fig. 2 is a magnified representation of one of the secondary *retia mirabilia*.

Fig. 3 is the star-like terminations of the vessels in the inner layer of the choroid, also magnified.

At the time I made the above observations, I thought of communicating them to the public, but I observed in

Carus's Comparative Anatomy a reference to a communication made about thirty years ago to the Royal Society of Göttingen, by Dr. Albus of Bremen, in which he also had compared the so-called choroid gland to a *rete mirabile*. I was anxious, before publishing any thing on the subject, to learn how Dr. A. described the structure of the body, but I could not procure the volume of the Göttingen "Gelehrte Anzeige," in which Dr. Albus's communication is noticed. I therefore thought no more of the matter. I now only write this at the suggestion of my friend Dr. Mackenzie of Glasgow, in order to confirm Dr. Albus's views of a structure which is still very much misconceived;—witness the most recent account we have of the Anatomy of the Eye, by Dr. Jacob, in Part xi. p. 205, of the Cyclopædia of Anatomy and Physiology. To call it, with De Blainville, a *vascular ganglion*, does not help us much.

I have since seen the report of Dr. A.'s communication in the 2nd volume of the "Gelehrte Anzeige" for 1806: no details of structure, however, are given: it is merely said, "The middle of the three membranes which, in the fish's eye, take the place of the choroid, consists in this species (the cod) of a most beautiful net-like plexus of vessels, the roots of which have their origin in a prominence of a horse-shoe shape, altogether peculiar to the fish's eye, and which was formerly so obscure. It has been considered by many zootomists a gland, by others a muscle; but according to the accurate researches of Dr. Albus, it is only a convolution of considerable blood-vessels, and is consequently to be looked upon as a kind of reservoir of blood (just as a *rete mirabile*)."

In conclusion I would observe that the demonstration of the above structure, and some peculiarities in the distribution of the veins outside the eye, which I have not now time to notice, remove from Mr. Alexander Shaw's reasonings * regarding the relations between the respiratory function, the eyelids, and vasa vorticosæ, the negative support which he seeks to draw from the eye of the fish.—I am, sir,

Your obedient servant,

T. WHARTON JONES.

TRANSPORT OF THE WOUNDED.

To the Editor of the Medical Gazette.

SIR,

THE transport of wounded from the scene of action is an affair of no small importance and difficulty in the operations of all armies, not only involving the lives and welfare of the maimed, but sometimes affecting directly, at others indirectly, the whole corps-d'armée. It is a subject, therefore, to which I have given much consideration during several campaigns in Portugal and Spain, with a view to determine, in my own mind, the best and most efficient plan, and put it to the proof of experience.

Twelve of Cherry's carts were sent out with the British Auxiliary Legion, at Mr. Guthrie's recommendation. They were employed on several occasions in the neighbourhood of Vitoria, and in all the actions in which the legion was engaged in Guipuscoa.

Upon the whole I found them serviceable, and much may be said with justice in their favour; but they are also liable to objections of some importance.

Small as they are in size, calculated only for four wounded capable of sitting upright, in heavy roads they become too much for one horse or mule, unless a very powerful one. It is rare also that a single draft mule will draw well; it was almost invariably necessary to employ two whenever we turned off the main road.

The shafts and the wheels seemed scarcely proportionate in strength to the work of the cart: in heavy roads they broke down in several instances, and at each time either in the shaft or the wheel. It is precisely in such situations, in narrow, deep, and hilly roads, where there is no possibility of flinging a broken-down vehicle out of the direct line of march, that such an accident is sure to cause great delay and confusion, by rendering it impossible for anything in the rear to pass or advance a step. Any other accident would only be to the detriment of the four wounded, but one of the nature pointed out may affect the march of a whole column, if more than one move by the same line, and at all events interfere with the closing up of the rear for hours, and of course, if

an active enemy be hanging on the skirts, is likely to compromise all that may thus be unavoidably detached from the column.

There seems to me another objection relative to the wheels, but upon which I speak less confidently. Speed can never be an object in these carts, but rather a capability of progression, however slow, under the worst circumstances of time, roads, and weather; this is of the last importance. I fancy, therefore, that if, at the same time that the wheels were made stronger, they were also somewhat increased in width of rim, they would cut less deeply into heavy roads, and be less liable to stick fast, and create a stoppage, which—however short it may be, as all military men know—is among the worst evils which can befall a column *en route*.

As to the remedy proposed, however, it will be for abler mechanics than myself to determine how far it is calculated to answer the end proposed.

The mechanism and construction of the carts in many other points—the slinging of the cot, the covering, and the mode by which the cart may be used, either with springs or without—I think excellent. As to the general question of how far they are adapted to supply the transport for wounded, required by an army on active service, I have formed an opinion unfavourable to their general—perhaps I should rather say—exclusive use.

A general action, even when but a few thousand men are engaged on each side, if at all well sustained, will often produce from 500 to 1000 wounded. To remove this number from the field, supposing one-half to be slight—and this is a very favourable proportion—the number of carts would be enormous,—sufficient to fill a town of themselves, and extend and encumber a line of march for miles.

A single campaign, however, is sufficient to prove to any one the importance of having means readily available for the transport of wounded from the immediate scene of action, without allowing a legitimate excuse for any part of the effective force being so employed. In all armies, I fancy there are a sufficient number of men who, although they may have passed their previous lives without manifesting any sympathy for the misfortunes of their neighbours, suddenly, on a field of

battle, become wonderfully compassionate to a wounded comrade; and never is this sympathy so strongly displayed, perhaps, as when there is a check or the probability of a reverse,—precisely the moment when their presence on the scene, and not their sympathy for their comrades going to the rear, is required. As battles are not generally fought upon plains, but upon some vantage ground, often steep or wooded hills, I believe the most rapid and effective mode of withdrawing the wounded from the scene of action to any point in the rear previously fixed upon, is the following, which I had opportunity of putting to the proof more than once, our deficiency of mules alone rendering it generally impossible.

A brigade of mules, say twelve to each column of 2000 rank and file, and four of Cherry's carts placed on the main road, or by the side if possible, at the point nearest to the centre of the column engaged, each mule having a bat-man, a chair or seat on each side (commonly used throughout the Peninsula, and forming a part of the pack-saddle), will in most cases be found capable of picking up the wounded within a few yards of their post, and without delay. The carts, from the smallness of their size, may often approach close to the rear of the force engaged, and pass along its line, although there be only a cross-road, or even none at all; and they would thus take up at once officers or men with fractured limbs, or who may be otherwise too seriously wounded to be able to ride or sit. These are the means of transport from the *immediate scene of action*, for at or near the point from whence they started should be a relay of spring waggons, capable of containing from twelve to fourteen wounded, and conveying them to the first ambulance or hospital station.

In this manner I think Cherry's carts might be employed with great advantage, as peculiarly fitted; and in proportion as the means of the corps-d'armée to which I was attached enabled me to make the arrangements described complete, I have always had the satisfaction of seeing the wounded more speedily transferred to the hospital station, and the number of sympathising and aiding comrades greatly diminished. I once observed, in less than an hour, a whole Spanish battalion tail off after some fifty

wounded! one carrying his comrade's musket, and another his little finger.

A better contrivance than the "jolters," or spring waggons, hitherto used in the British army, might, I think, be easily found; but I am firmly convinced, that whatever their construction, they should be adapted for carrying at least twelve wounded men. And upon the same grounds I think the proper use of Cherry's carts is to circulate as close as possible along the rear of the scene of action, for the purpose of removing men so dangerously wounded as to require a stretcher, and eight, twelve, or sixteen men from the effective force; and such a number may now and then be seen accompanying a wounded officer far into the rear.

The British Legion, which in the first instance was organized in all its departments closely upon the regulations and system of the British service, offered many difficulties to the medical officers upon whom devolved the duty of organizing general hospitals, and directing the service on the field.

A series of changes were effected in this branch of the service, under the sanction of the Inspector General, Mr. Callander, and authorized by the Lieutenant-General commanding; the results of which were beneficial in the extreme, —I believe in every way, I may confidently state, and acting not less directly upon the inmates of the hospitals than upon the effective force in the field.

There might be objections to some of these innovations in the British service, for many were adopted with reference to the peculiar and temporary nature of the force and other circumstances which, affecting the legion, would not have exercised any influence upon a portion of the British army. Nevertheless, I am strongly impressed with the conviction that the principle of some of these changes might be acted upon with manifest advantage in a more permanent service; and at all events the facts resulting from their adoption on service may claim some attention.

The first, perhaps the greatest difficulty experienced, was the impossibility of obtaining fitting men for the various and responsible duties of ward-masters, clerks, orderlies, &c. from the different corps composing the force. No commanding officer willingly sends for hospital service his best men, were there

not even a prevailing and very erroneous idea among military men, that any class of subjects will do for an hospital. Thus, if there be an incorrigible thief, a drunkard, or a skulker, the first requisition that arrives for an orderly, he is dispatched. And if a good man by any chance finds his way into the hospital establishment, no pains is spared by a zealous Colonel to get him back again, even although he may have learnt all his duties, and become familiar with the routine, in spite of his being declared indispensable in his situation. It matters not—he is a good man—*ergo*, the regiment wants him; and nine times out of ten the regiment gets him, and the hospital in exchange receives a stupid or a drunken fellow, or both, totally ignorant of all the duties, and as unwilling to learn as he is incapable of doing so.

Wearied at last by the perpetual recurrence of these annoyances, and convinced of the impossibility of establishing a regular and efficient system in the general hospitals while labouring under these disadvantages, I obtained permission to form two small corps, or companies, for the service of the hospitals and the transport of the wounded in the field. The first consisted of fifty rank and file, the skeleton of which the Inspector General had formed in England as conductors for the carts; these were generally able-bodied men, and received artillery pay. The second, or "hospital corps," was selected principally from the weakly men of all the regiments, and from the wounded who remained partially disabled. These men had infantry pay, and neither corps had any extra allowance. The two companies were commanded by a Lieutenant, under the orders of the Head of the Department; and a Deputy Purveyor of Hospitals, with 2s. 6d. additional pay per diem, was appointed Paymaster, and was enabled to perform the duties of that office as well as those of Deputy Purveyor.

The men were selected with reference in some degree to their trades; so that if the carts required repair, or any minor work in the hospitals, they were always at hand, and were the means of saving the government much expense, and the hospital administration delays—inevitable in Spain. From this last company the hospital staff were

allowed each a servant. The whole of the two companies were instructed in their duties, the wardmasters and clerks being selected from the "Ambulance Transport Corps," and the orderlies and inferior servants from the "Hospital Corps," with the prospective advantage, if their intelligence and conduct merited it, of promotion to the Ambulance Transport Corps. The conductors, and a small guard in charge of the carts, medical stores, &c., when sent to the lines, or on the field, were furnished from these last.

A month had not elapsed after these arrangements were made before the general hospitals assumed an improved appearance. The utmost order, regularity, and cleanliness, was maintained in every division: every man soon knew his duty thoroughly; and being under the entire control of the medical department, equally quickly learnt the necessity and advantage of strictly conforming to his instructions. The hospitals became a source of pride to all connected with them, and the General commanding often took occasion to express his satisfaction when visiting the wounded.

How far it might be possible or advisable, on service, in a British army, to form a corps of this kind, by selecting from time to time those who become weakly by climate and chronic complaints, or in consequence of flesh wounds, which often prevent the perfect use of an arm or a leg for months after they are healed, is a question upon which I do not presume to decide. But I feel assured, and the French have proved by long experience the fact, that a corps peculiarly and solely destined for the transport of wounded and the service of hospitals, is not only highly advantageous to the sick and wounded, but it appears to me a politic measure in every point of view. When properly formed and directed, such a corps must greatly tend to produce three important results: 1st, To prevent great straggling to the rear, of effective men accompanying the disabled, which not only weakens materially the actual strength of a battalion under fire, but tends also to produce a disorganizing effect, more or less strong in proportion to the character and discipline of the troops, and the nature of existing circumstances. 2d, To insure the more prompt and efficient transport of the wounded. 3d, A more efficient system of hospital treatment and admini-

stration; for as a surgeon, however zealous, cannot do every thing with his own hands, the result of his treatment depends, in no unimportant degree, upon others. Thus there would be a saving of human suffering, and the more prompt and certain cure of the patients. Not only this, but such a measure will remove many sources of irregularity and injury to the service, arising from the incessant struggle between the opposing wishes and interests of commanding officers, who are naturally intent upon the strength and efficiency of their corps, and medical officers not less anxiously bent upon the efficiency of their establishments.

To prove that these evils existed, not in the British Legion alone, but have always been experienced, and often commented upon, in the British army, I confidently refer to the testimony of the British officers who served in the Peninsular war; for from the lips of not one, but a hundred, I have heard them detailed. Why should not this be remedied? The Canadian war offers an excellent opportunity of trying, on a moderate scale, some new and better system.

Your obedient servant.

J. RUTHERFORD ALCOCK.

Bury Street, St. James's,
Jan. 10, 1835.

THE IRISH APOTHECARIES' HALL.

To the Editor of the Medical Gazette.

SIR,

A LETTER has been lately published in the Dublin Evening Mail, headed "Queries for Apothecaries," and subscribed "A Graduate in Medicine, Surgery, and Midwifery, of Dublin, Edinburgh, and London."

The main design of the writer of this letter appears to have been twofold. 1. To throw odium upon the apothecary branch of the medical profession, and 2d, to promote thereby the attainment of an object at present desired by a party in the Irish College of Surgeons, by degrading it and its members from the station they have hitherto held. With this design I feel myself no further concerned than other members of the medical and surgical professions at large; nor should I have thought it necessary to notice the letter, had its author been content to confine

himself to the discussion of the question at issue between him and the apothecaries. I am not in their counsels, nor am I their advocate; the task of justifying their proceedings I leave to themselves; and I only hope that, for the sake of the common profession, of which they constitute so useful and so respectable a portion, they will continue, as they have commenced, to defend themselves, without forgetting that something is due to the station which they claim to hold in the opinion of society.

In the course of his letter, however, the "Graduate" has thought fit to arraign the conduct of those persons who have become professors in the school of the Apothecaries' Hall, and to charge them with perjury. Such an accusation is, you will allow, too grave to be lightly regarded, or to be submitted to in silence by those who would claim credit for honourable feelings and action. The place which he holds in the opinion of others is to every man too valuable an object to be forfeited without just cause, and above all, in a profession the only distinction of which is public esteem. You will therefore, I doubt not, admit the validity of the motives which induce me to undertake the exculpation of the professors of the Hall School from an imputation which I hope to prove to be as devoid of foundation, as, if well founded, it ought to ensure the united condemnation of the profession and the public.

The charge against which I am about to protest, is contained in the following extract from the letter of the "Graduate":—"Your attempt at the Hall to establish a school, where *renegades from the sworn interests and honour of our surgical and medical professions, and colleges are to give lectures.*" Before proceeding further, I must pause for a moment to guard against a complaint of misrepresentation, and ask, what is to be understood by "sworn interests and honour?" Does he mean that the interests and honour have been put upon oath, or that they have been proved upon oath? These, the legitimate interpretations of the words as used, cannot have been intended, and I am forced to supply what must have been the writer's meaning, else the passage is pointless—viz. interests and honour to which the renegades have been sworn. At the same time I would suggest to the "Graduate," that in future, when he may

please to appear before the public as a censor, it would be well that he wrote with more accuracy both of style and meaning; a total disregard of which is displayed in many other parts of his letter besides that just adverted to; or, failing in the ability to do so, that he submitted his lucubrations to some one competent to correct them, in order that his readers may be spared the labour of unravelling his mysteries.

Now, sir, I ask, how have those who have been elected professors in the school of the Apothecaries' Hall, become thereby renegades to the honour or interests, whether sworn or otherwise, of our medical and surgical professions and colleges? In plainer words, how have those professions and colleges been dishonoured, or their interests deteriorated, by their members becoming professors to the Apothecaries' Hall? What is there in their honour and interests which causes them to be impaired by that which advances those of others? Is it not to the honour of every institution, that its members should be selected by others, as the fittest and best qualified individuals to discharge important offices; offices whose title to respect is independent of extrinsic circumstances, and which of themselves reflect honour upon those to whom they may be entrusted? Is it not to the advantage of every institution, that opportunities for utility and advancement should be opened to, and conferred upon, its members? And if so, how can their members dishonour or injure them thereby? There must surely be something peculiar in medical institutions which thus converts to poison what should be healthful and beneficial. Let us, then, inquire what obligations exist which have been violated; what interests are at stake, which are likely to be affected?

That we may the better understand the question, I will state the case as it is. The apothecary is compelled, as well by the wants of society as by the position in which he is placed by others rather than by himself, to act in the double capacity of the prescriber and the dispenser of medicine; and the Hall have, accordingly, long required the candidates for its license to attend certain courses of medical lectures. The number of these courses has been from time to time increased, until, at present, a certain certificate of attendance upon

each of the branches of medical science included in the ordinary medical and surgical curricula, is required. In conjunction with the extension of their course of education, they have established a school, and elected a body of professors to teach the several branches which candidates are expected to study; and because certain members of the Colleges of Physicians and Surgeons have sought and obtained chairs in this school, they are stigmatised by the "Graduate" as perjured renegades. I ask again, by what obligations are we bound, which we violate or disregard, whether as physicians or surgeons, by becoming professors in that school, and by lecturing therein upon our several departments? I know of none whatever, save only those which we took upon ourselves when we became fellows, members, or licentiates, of the colleges to which we belong. And what are they? They are comprised in the forms of oath and declaration prescribed by their charters for the fellows, members, and licentiates of the Colleges of Physicians and Surgeons; and are so similar for both, that those of either College will suffice for our purpose. I take those of the College of Surgeons, as more express and stringent. That for fellows, or members, is as follows:—"Well, truly, and faithfully to attend and execute his and their several and respective office or offices, place or places, duty or duties." What obligation, I ask, does this impose, which can be interpreted to forbid a member of either College from undertaking a professorship in the school of the Apothecaries' Hall, or any other honest occupation (no matter what) which is not incompatible with the discharge of such offices, or duties, as the College may intrust to him? Provided he "well, truly, and faithfully executes his duties," may he not do what else he pleases, and honestly can? I leave the answer to the "Graduate," only adding for myself, that I neither have neglected, nor will I so long as I continue a member neglect, the faithful execution, according to my judgment, of any office which the body may commit to me; and I say the same for my colleagues. The oath imposed upon licentiates is as follows:—"I do solemnly swear that I will observe, and be obedient to, the statutes, by-laws, and ordinances of the Royal College of Surgeons, and

that I will, to the utmost of my power, endeavour to promote the reputation, honour, and dignity of the said College; and that I will not, at any time hereafter, practise, follow, or pursue the business or profession of an apothecary, or druggist, or sell drugs or medicines, within the City of Dublin, or at any place within ten miles thereof. So help me God."

It cannot be necessary to insist that we do not pursue the business of an apothecary by lecturing in a school established by the Apothecaries' Hall. And there does not exist statute, by-law, or ordinance, whether of the College of Surgeons or Physicians, which forbids a member or licentiate from becoming professor in any school which may be open to him. On both these counts, therefore, we stand acquitted. But it may be said, that by so doing he does not promote the honour and dignity of his college. In what, I ask, does he detract from them? Does he do so by winning the preference over members of other bodies, by his talents, his industry, or his acquisitions? May he lecture in the pettiest, the meanest school, which private resources can establish, and not detract from those attributes of his College?—and may he not, consistently with a due regard to them, become a professor in one established by so respectable, so influential a body, as the Corporation of Apothecaries? It were but trifling to entertain seriously such a question. He not only does not detract from, but he advances the character of his College, by his election to the office. How, I would ask, is a member of any public body to promote its honour? Is it by being idle, and not exerting the talents with which he may have been endowed? Such a course might serve the purposes of others—perhaps of the "Graduate;" but it would reflect little credit whether upon himself or his College. Is it by allowing the members of other institutions to be preferred, or to appear to the public as preferred, for places of public service, in which scientific qualifications are considered the legitimate title to success? Such, again, is well calculated to promote the reputation of those Colleges, but not of his own. No, sir, such are not the modes by which the members of a public body can best advance its character: but the more useful, the more eminent, each man renders

himself, by the honest and legitimate exercise of his professional acquirements, the more does he promote the reputation of the institution with which he is known to be connected; the more does he raise it in public esteem; and in the selection of its members by another body, as the best qualified for the discharge of an important public duty, a compliment is paid to it through him.

Away, then, with the calumny—it does not deserve a milder name—the unfounded, the disingenuous calumny. It is plain that the honour of the Colleges is in nowise compromised by the conduct of their members, who have been elected as the most competent individuals whom the Apothecaries' Hall could procure as teachers for its school; but that, on the contrary, their honour and character have been maintained and advanced thereby.

But, say some, (and I cannot refrain from meeting the objection) “it is derogatory to a physician or surgeon, and to his College, that he should be connected with an Apothecaries' Hall, or that he should lecture to apothecaries. So far as we are personally concerned, I am entitled to reply, while I thank them for their disinterested solicitude,—Surely that is a matter for our consideration, not their's; they are not the worse; they ought, by contrast, to be the higher. If we take a different view of the subject, are we not at liberty to judge for ourselves? But what is there in an apothecary, or in his calling, to render a connexion with him or with his corporation degrading to the physician or the surgeon, or their respective colleges? Is it degrading to a barrister, or to the profession of which he is a member, that he should be counsel or law-officer to an Apothecaries' Hall? I trow not. And if not, why should it degrade either of the others to be a scientific professor to the same corporation? Let the Graduate answer. Again, I ask what is there in the apothecary which renders it derogatory to the other branches of the medical profession to hold a scientific connexion with his Hall? What difference is there between them? The apothecary is not so highly educated; and he compounds, dispenses, and sells medicine. Well, those differences seem likely soon to be at an end, at least between the apothecary and the surgeon. The former has determined to be well educated, and who

shall prevent him if he choose to be so? The latter seeks to make himself an apothecary, if he can. How appropriately, then, comes the objection, from men, who are now endeavouring to render the College of Surgeons more respectable, more exalted, and more dignified, by converting it into a corporation of drug-venders. Forsooth, its member may, with all due regard for his own and its honour and dignity, compound and sell a sixpenny draught to the pauper, who cannot give him a fee, and therein find remuneration for his professional service; but he is degraded by lecturing on a science to the men from whom those honourable gentlemen would wrest their means of livelihood if they could. Out upon them, out upon them—grovelling guardians of the science and honour of surgery! The objection comes well from others also. The time has not yet passed; and it seems to be now ordained that it never shall pass, at least in Ireland, when the physicians regard the surgeons, as a body, as much beneath themselves, as do the surgeons the apothecaries; yet it is surprising with what avidity licentiates and fellows of the College of Physicians have sought professorships in the school of the College of Surgeons when open to them, and yet they talk of the degradation of holding a professorship in the school of the Apothecaries' Hall! But, they say, the School of the College is a chartered school. A chartered school indeed! Chartered, in an Irish sense of the word, *i. e.* a school without a charter. Where is its charter? It has not one. The School of Physic has a charter, but it has not. Albeit, it has been set forth in medical almanacks, as one of two chartered medical schools, with which Dublin is provided, and as “established by Act of Parliament.” It was established by a body having a charter; and so has been the School of the Apothecaries' Hall; but no more: that charter was originally granted, as I will show in a future communication, for another purpose, and contained no mention whatever of a school, from one end or to the other.

Again, forsooth, it is debasing to teach Apothecaries! Is it not a little surprising that this was not sooner discovered? The Hall have, for some time past, required of the candidates for its license attendance on anatomy;

and where did they attend before the foundation of its own professorship? Through all the schools of Dublin, and probably not least in that of the College of Surgeons. Yet no complaint was made. No man felt his dignity in the least diminished by lecturing to apothecaries. And why? The "Graduate" can doubtless explain. Can it be that, while the Hall was content to impose lectures, and thus swell the classes of existing schools, it was well; but soon as it dared to imitate the example which had been set by others, and to establish a school which might intrude as a competitor into the field, that then was discovered the enormity, the degradation, of teaching a pupil, who intended to be an apothecary. The "Graduate" will do me a favour if he will also explain how it came to pass that at the opening of the same session which saw the professorship of anatomy in the Hall school first entered on, the profession and the public were edified with an introductory lecture from the anatomical chair in the school of the College of Surgeons, the object and end of which were, the high crimes and misdemeanors of apothecaries, and the necessity, which had been discovered to exist, for converting the college into a corporation of apothecary-surgeons. It was not said that the classes of the College school had declined, and that unless recruited they were likely to decline more. It was not said that the school of the Hall threatened to cope with that of the College, and that, now the lecturer's own province had been invaded, a *coup d'état* must be accomplished, which would at once annihilate not only its prospect of success, but also that of his more formidable rival of the University and the School of Physic. It was not said, that if the College of Surgeons could obtain the power of licensing apothecary-surgeons, the classes of the school, which is supported by its money, its influence, and its sanction, would be filled anew, while the benches of the School of Physic, and of the Hall School, neither of which is admitted by the College, must be abandoned and empty. None of these things were even hinted at, and, of course, they did not enter the calculation of the lecturer, whose only motive was the honour and

dignity of the College, and the welfare of the profession and the public.

Alas! how weak and fallible an attribute is reason, when blinded by intemperate zeal or by overweening self-bussness. A member of the Colleges of Physicians or Surgeons cannot, according to the "Graduate" and his abettors, advance himself by the honest and independent exercise of his talents, in a school established by a public body, and in an honourable position, perfectly compatible with his relation to his College, without being renegade to its honour; and yet our censor subscribes himself a "Graduate of three Colleges," while at the same time he stands forth the intemperate partizan of one, and the vilifier of another of the three. How, let me ask, is such conduct to be reconciled with a due regard to the interests and honour of those corporations? Perhaps he may say, my signature is only assumed and fictitious. I answer, it matters not: light objects indicate the current of the air; and this circumstance, trifling as it may be, proves either how little principle is concerned in the matter, or how dead to its obligations is he who voluntarily places himself in such a position.

Having, as I trust, satisfactorily shewn that the honour of their professions and colleges has been in no wise affected by the conduct of those physicians and surgeons who have become professors in the school of the Apothecaries' Hall, I postpone till my next the consideration of the obligations imposed upon them by the interests of these institutions, upon the true nature and present condition of which I hope to be able, at the same time, to throw some light.

Meantime I have the honour to remain, with all due personal respect, of course, for the "Graduate of three Colleges,"

Your obliged and obedient servant.

A PROFESSOR IN THE SCHOOL
OF THE APOTHECARIES' HALL
OF IRELAND.

Dublin, Jan. 9, 1835.

[The writer of the above has given his name, and any one who may choose to answer him must do the like. — Ed. Gaz.]

ON THE FORMATION OF PUS.

To the Editor of the Medical Gazette.

SIR,
I hail with pleasure the appearance of the papers of M. Bonnet, of Lyons, on pus, which you have so recently published, because it encourages me to hope that more correct opinions will, ere long, be entertained on this subject than those which now prevail. I see that M. Bonnet has proved by an interesting series of experiments that the composition of pus is "the same as that of the blood, minus its colouring matter."

If there is any credit due to this discovery, I must beg to be allowed to put in my claim for at least a share of it, upon the ground of having published the same opinion nearly three years ago. If you will have the goodness to refer to your No. for May 2, 1835, page 142, you will find it there stated as the result of an inquiry into the mode in which pus is formed, that "pus is not a secretion, but a simple effusion or exudation, and yet not so much a straining of the juices from the blood as the blood itself, *minus its colouring matter*." I have even gone farther than M. Bonnet; for in the succeeding paper (in the number for May 9), I have not only shewn the order in which the constituent parts of the blood are effused, but also the manner in which the globules of the blood become deprived of their colouring matter. Those papers were written nearly two years before they were published, so that my claim to originality is clear enough; but if I were to re-write them, I could press the last point very much more strongly; so much so, indeed, as to leave no rational doubt remaining about it.

As the papers I have alluded to contain the only *complete* revision of the whole subject of inflammation (not an unimportant subject, surely) which has been made within the last half century, nearly with the view of ascertaining how far Mr. Hunter's doctrines are affected by the various physiological and pathological facts which have been gradually accumulating during that time, I had expected that they would have excited some little attention. Probably, if I had proclaimed the discovery of some hydro-pyro-fuliginous extract of

calcined cockatrices, as wonderfully efficacious in the cure of cancer, &c., there would have been anxiety enough to know the proper dose; but it seems that an honest endeavour to improve the scientific part of our profession, from which general rules may be obtained, applicable, when properly modified under particular circumstances, to all cases, is received with indifference, and treated with neglect.

I have the honour to be, sir,

Your obedient servant,

JAS. WM. EARLE.

Loretto, Cheitenham, Jan. 11, 1838.

CASE OF HYDROPHOBIA*.

To the Editor of the Medical Gazette.

SIR,

As you have expressed a wish to have further particulars of the case I lately communicated for insertion in the MEDICAL GAZETTE, I submit the following:—

Salivation was induced by rubbing ʒj. of the ungt. hydrarg. fort. manè noct. on the inner side of each ankle. I have stated that the dread of fluids decidedly came on before there was any "dérailonnement." With regard to the medical treatment in this case, if we consider the loss of blood from leeches and phlebotomy, the total abstinence from food, solid and liquid, since the Saturday, it may be supposed that the draughts had a powerful effect. I have said that he took the first at 10,—then the pulse was perceptible; but at 12 it could not be felt, and he then appeared insensible. At half-past 12 the pulse was again perceptible, and he took the second draught: during the night he took altogether five. In the morning he was pulseless and insensible, and much altered from what he was on the previous day: then his mental faculties were greatly increased,—he was watchful and irritable: now he appeared insensible to what passed around him. It was then, and not till then, that he became incoherent.

I must say something to account for

* For the history of this case, see MEDICAL GAZETTE for December 30, 1837, p. 533.

the difference of opinion between the other medical attendants and myself. The fact was, they staid with the patient only a few minutes, merely to feel his pulse, view his tongue, and to ask a few questions; though I repeatedly stated to them that it was impossible to determine the nature of the case unless it was narrowly watched, and seen often. When I say the medical attendants, I must except one (Dr. Scholefield), who, indeed, staid one whole hour, in order to see the patient in a paroxysm of convulsions, but without success; and he refused to attend the case further, because a junior medical man had felt the patient's pulse before him, the senior medical man.—By some inadvertence the printer has misspelt my name.—I am, sir,

Your humble servant,

WILLIAM DU HEAUME,

M R C.S.L.

Jersey, Jan. 12, 1833.

PERNICIOUS EFFECTS OF ENAMEL CARDS.

To the Editor of the Medical Gazette.

SIR,

As you devoted several pages of your last number but one to the subject of arsenical candles, which are not demonstrated to have proved destructive to human life in a single instance, although it may be highly probable that they would be injurious, under certain circumstances, if brought into general use, I venture to consider you as not unwilling again to undertake the office of guardian of the public health in a much more flagrant case; and it is the more necessary that our respectable medical journalists should take upon themselves such duties, as we unfortunately have no responsible board or council to whom these are officially confided. I wish, then, to bring to your notice an evil which, if generally known, will, I am persuaded, make a strong impression on the public, and lead to the application of a remedy which at their hands alone can be obtained.

It will doubtless have fallen under your observation, that enamelled visiting and shop cards are now so much in vogue, that persons of fashion, and the

superior classes of tradesmen, scarcely use any other. The only advantages which, as far as I am aware, they possess over other cards, are, that they please the eye, and that they take a finer impression from a copper-plate, a thing of hardly any importance under the circumstances in which alone they are employed. The disadvantages attending their use are, 1st, that they blacken on exposure to mephitic air, which is often disengaged from common coal, as well as from the sinks and drains in private dwellings, and still more often from the gas in shops, which moreover, being always on ground floors, are particularly exposed to the noxious vapours arising from imperfect drainage. This defect in enamelled cards wholly precludes their employment for receiving the impressions of more permanent engravings. 2dly, That it is difficult to write legibly on them, whether in pencil, which will not mark, or in ink, which runs; so that one person cannot conveniently add his name to the engraved card of another; nor can visiting cards be used, as formerly, in writing addresses for boxes, parcels, or game. 3dly, That when slightly bent they crack and look unsightly; and that they cannot be applied, as old and otherwise useless cards often were, to the lighting of fires or candles, for they burn with great difficulty.

The advantages and disadvantages are thus, it seems, pretty fairly balanced; but why do I enumerate them, or wish to disturb the exercise of the general taste, in a matter apparently so unimportant? For a very cogent reason, to which it is the sole object of this letter to direct your attention, namely, that of the many deleterious employments carried on in this metropolis, the manufacture of these enamelled cards is the most deleterious. It is my belief, founded on inquiry, that the lives of many workmen are annually sacrificed to the production of this useless luxury; and that a far greater number are, from the same cause, more or less injured in their health, and unfitted, some temporarily, some permanently, for providing for themselves and their families. I would avoid the imputation of an overstrained sensibility, and I fully admit that the state of civilization in which we live renders necessary much risk of health in the exercise of the various arts that contribute to the supply of our

wants and comforts; but I do maintain, that, where the advantage to be gained is so paltry, common humanity should prompt us, one and all, to refrain from indulging in a luxury which can only be obtained at so heavy a sacrifice. It has been stated to me that the card-makers are only occasionally employed in making enamel, and that none of them would be thrown out of work if not another card of this kind were ever used.—I am, sir,

Your obedient servant,
M.D.

MEDICAL GAZETTE.

Saturday, January 20, 1838.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”

CICERO.

CASE OF SUPPOSED IDIOCY.

IN our last article we gave a sketch of the case of David Yoolow, a man who, on very slight pretences, was alleged to be an idiot, but who easily succeeded in disproving the flimsy evidence brought against him. We concluded with some quotations from the evidence of Dr. Christison, the chief witness for the plaintiff, who not only failed to show that Yoolow was, in the words of the brievé, *incompos mentis, fatuus, et naturaliter idiota*, but entirely broke down in the attempt to prove that he was deficient in good sense.

The next witness for the plaintiff was Dr. William Malcolm, who deposed that he asked Yoolow “if he had heard of the Reform Bill, and that farmers, of his extent of land, were entitled to vote? But this seemed to be all a blank to him*.” On cross-examination, it turned out that the witness believed Yoolow to have been the tenant of the farms and the two mills, since his father's death; and that he thought Yoolow was in

possession of the farm as tenant, when he (witness) said that he was entitled to vote under the Reform Bill. “If you had been aware that the farm is held by trustees, would you have considered Yoolow as entitled to vote? *I am not a lawyer, and am not able to answer that question*.*”

In his examination in chief this witness stated, that he had asked Yoolow how much the weight of a boll of meal was, and that he answered, “Sixteen pounds;” but on cross-examination it appeared that the question was really put in these words, “How much is a boll of meal?”

One of the strongest points in this witness's evidence against Yoolow was, that he could not tell how much 48 and 52 made, nor even 50 and 50. But, independently of the injustice of making arithmetical questions a sort of Procrustean bed on which to stretch every one's intellect, it appears, from the testimony of numerous witnesses, both for the plaintiff and the defendant, that Yoolow was in the habit of correctly answering arithmetical questions of a far more difficult kind, and this, although he had never been taught accounts.

It was also the opinion of Dr. Malcolm that there was no chance of Yoolow's recovering or improving. If by “improving” is meant increasing in knowledge, or being able to answer questions that previously had been too hard for him, we have abundant proof that Yoolow was capable of this, not only in the evidence of other witnesses, but in that of Dr. Malcolm himself, for he says, “At one of the interviews after the first, I resumed the subject of the Reform Bill, and he said he knew that the Reform Bill had passed. He also knew the price of meal. He appeared to have been told that†.”

* Report, p. 17.

† Ibid. p. 17.

A number of minor witnesses were then called, among whom was James Bruce, messenger-at-arms. We will give the whole of his examination and cross-examination, as they are not very long:—

“I was at school with David Yoolow, and considered him then a silly boy,—that was before he had his paralytic stroke.”

“Cross-examined by Mr. D. McNeill.—I will not swear that David Yoolow was not as clever as I was when we were at school together*.”

Next to the messenger-at-arms came a medical witness, who broke down most sadly in his attempts to convict the defendant of fatuity, as the following extract from his cross-examination may help to shew:—

“Did you put questions to him to try whether he knew the value of money? I did. What questions did you put? I put the questions to him, how many shillings were in five shillings, and how many shillings were in ten shillings; but he had difficulty in answering how many shillings were in ten shillings, though he said that ten shillings was half a pound. How did you put the question to him as to how many shillings were in ten shillings, or in five shillings? what words did you use? I used the words, ‘How many shillings are in ten shillings?’ and ‘How many shillings are in five shillings?’ And did he not know how many? He did not. Then he knew that ten shillings was half a pound, but he did not know that ten shillings was ten shillings: was it so? Yes†.”

Re-examination, and a second cross-examination, made the matter still more perplexed, so that on being asked what was the question he had put to David Yoolow relative to the five shillings, the witness was driven to say, “I am embarrassed, and cannot tell.” We are not at all surprised that a witness, though sensible and well informed, after falling into a mistake, should be so per-

plexed by examinations and cross-examinations, as to be unable to recover himself, and at last come to a deadlock; but we are surprised when we find that, in the examination of persons supposed to be of unsound mind, the slightest hitch or slip is immediately laid hold of, and triumphantly exhibited as a proof of their fatuity. The fact is, that the number of persons is very small, who have all their knowledge ticketed, labelled, and arranged, so as to be producible at a moment's warning. A few men, indeed, who have passed a large portion of their lives in examining, or being examined, may be expected to be ready with answers enough to satisfy a score of mad-doctors; but we may assume it as a general rule, that a plain man of retired habits, a young lady of fortune, and many other classes of persons, though not void of understanding, will be utterly unable to sustain the character of catechumen for ten minutes together. Like the medical witness before us, they will be obliged to say, “I am embarrassed, and cannot tell.”

A curious anecdote is told of Yoolow in the evidence of another witness:—

“He used to ask, ‘Are you a doctor? Manna (must not) doctors rise when they are bidden?’ I answered, ‘Certainly.’ Then David asked, ‘Must they do so when it's snawing (snowing)?’ ‘Certainly.’ He then turned to the maid-servant, and said twice exultingly, ‘I hae na (have not) to rise when it's snawing.’ The servant thereupon said, ‘Na, David, ye have not to rise when it's snawing; you're better off than doctors,’ which appeared to give him great delight*.”

This story seems to be cited by the witness as a piece of fatuity; to us it appears rather an instance of shrewdness, exhibited in the natural, but somewhat hard-hearted, triumph of this comfortable landholder over us poor doctors.

* Report, p. 23.

† Ibid. p. 24.

* Report, p. 27.

The plaintiff had thus pretty well put himself out of court with his own witnesses; nevertheless, several were called for the defendant, in order to make assurance doubly sure. The first witness was the Rev. James Flowerdees, who gave an account of a conversation which he held with Yoolow on religious subjects, and in which he acquitted himself to admiration. The students at some of our most celebrated seats of learning might really prepare themselves for their examinations with most of Yoolow's answers.

Dr. John Argyll Robertson deposed to having conversed with the defendant on various subjects; the general result was, that his memory was good, and his powers of comparison good likewise, though his means of drawing comparisons were, from the habits of his life, not equal to those of most men. He understood money matters very well; *e. g.* the meaning of a receipt; the effect, to a bank, and to the holder of a bank-note, when it is destroyed; the meaning of being a *cautioner*, *i. e.* bail, &c. The following traits, too, are not bad:—

“He told me that some medical man had been plaguing him very much, and that he had said to him he had better go home and look after his pills, and not fash (plague) him. I asked him something upon the subject of farming, and he said, ‘I know nothing about it, and you may as well ask me about Latin or Gaelic, which I have never learned.’”*

We shall pass over the evidence of several other witnesses, all exceedingly favourable to the sanity of the defendant, and come to that of Mr. Lowe, (p. 42-3) who found him able to answer many questions in arithmetic and money-matters. He knew how many pounds of beef, at 6d. per pound, a pound sterling would buy; a question which, though simple, would not be

instantaneously answered by all who have been instructed in figures; and he did not know whether two-thirds or three-fifths of any thing were greater; a question which would puzzle three-fifths, or even two-thirds, of those whose coats and hats are received as *prima facie* evidence that they are educated men.

The jury, without retiring to deliberate on their verdict, unanimously found that David Yoolow was not an idiot.

Many of our readers will be struck with the numerous points of resemblance between this case, and the one of Miss Bagster, which we reported at length, and on which we offered some comments, in our tenth volume. In both, the persons accused of being imbecile had gone on for years without molestation, until a change of circumstances made it desirable for some relation to get possession of their property. In Yoolow's instance this change was caused by the death of his sister; in Miss Bagster's, by a marriage which it was thought desirable to dissolve. Under the supervision of a doting grandfather, Miss Bagster's education had been extremely neglected, and she was allowed to learn what she pleased, which, as is common in such cases, was little indeed. Arithmetic is the favourite test in supposed cases of unsound mind, and unfortunately Miss Bagster, as appeared from her own evidence, had never been obliged “to do her tables;” when she felt unwilling to learn them, her grandfather used to send his compliments to the governess, that she might be excused. In like manner, Yoolow's education was neglected, on the erroneous supposition that his paralysis made him incapable of any; though the progress he made without assistance clearly shows what he might have done with judicious management. As it was, his attainments in arithmetic

* Report, p. 31.

tic were decidedly superior to Miss Bagster's; for though sometimes *floored* by easy questions, at other times he succeeded in answering those of a higher order. We may here remark, that their attainments were naturally of a different cast: the careful Scottish landholder, an invalid of more than forty years' standing, inclined to the grave; the petted London belle was more versed in the gay. Next to divinity, in which Yoolow's attainments were very considerable, he knew most about matters concerning his property—such as the sum he had at his banker's, the number of bolls of meal he ought to obtain in exchange for a cow, &c. &c.; while Miss Bagster talked of "the opera, Paganini, Sir W. Scott, and the exhibition*." Miss Bagster's definition of a marriage was not bad, though perhaps not the one to be expected from a grave moralist, or from David Yoolow. She said "she did not consider herself married, for a proper marriage was when they went to church with carriages, and had cake and wine, with favours and bridesmaids†." This manner of defining a marriage by some of its outward signs or ceremonies, is so far from being fatuous, or idiotic, that our readers will recollect, that in the Latin poets, *tæda* (which properly signifies a torch) is made to mean a wedding.

The great error of the witnesses, in both these cases, was the wishing to obtain answers from the supposed imbeciles on subjects in which they took no interest, and in which thousands of persons in their station would also have been found wanting. Thus, in the case of Miss Bagster, a learned Doctor of physic asked her what was the interest of 10,000*l.* four per cent. stock; a question which would pose half the young ladies in London.

Another point of resemblance between the two defendants, is, that they both improved during the examination; the hosts of professional and lay questioners serving as so many tutors in arithmetic and the other subjects of inquiry: plainly demonstrating that there was no incapability of learning. There is, however, one unfortunate difference between the two cases: David Yoolow was unanimously set free, while Miss Bagster was adjudged to be of unsound mind. More than five years have now elapsed since this mistaken verdict, and we would gladly learn if any thing has been done, in this long interval, to complete the education of this neglected girl. Has not the Lord Chancellor the power of directing that the education of nominal or supposed imbeciles shall be attended to?—and may we not imagine instances where the fingering of fifty or a hundred thousand pounds would be a kind of premium for keeping a flighty relation ignorant of the multiplication table?

DEATH OF MR. HENRY EARLE.

It is our painful duty to record the death of Mr. Earle, which took place the day before yesterday, at his house in George Street, Hanover Square. The illness which proved fatal to Mr. Earle commenced as an inflammatory sore throat, which soon put on an unfavourable appearance, and became attended with delirium.

Mr. Earle was a thoroughly straightforward honourable man, zealously devoted to his profession, and a general favourite among his brethren, by whom his decease will be very sincerely regretted. His death occasions a vacancy in the office of Surgeon to St. Bartholomew's Hospital, and also in the Council of the College of Surgeons.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Jan. 9, 1838.

THE PRESIDENT IN THE CHAIR.

The History of a Female who has Four Mammaræ and Nipples. By ROBERT LEE, M.D., F.R.S., Physician to the British Lying-in Hospital, &c. &c.

THE individual in whom the above-mentioned peculiarity presented itself was 35 years of age, and was prematurely delivered of a still-born child on the 21st of July, 1835. The mammaræ having afterwards become excessively painful and distended, she was compelled most reluctantly to permit the author to make an examination of them, by which it was discovered that she had two mammaræ and two nipples on each side. The inferior or pectoral mammaræ were fully developed, and in the natural situation; and their nipples, areolæ, and glands, presented nothing unusual in their appearance. Near the anterior margin of the axilla, a little higher up on each side, was situated another mamma, about one-sixth the size of the others. The nipples of these were small and flat, but when gently pressed a milky fluid flowed copiously and readily from several ducts which opened upon their extremities. When milk was drawn from the lower breasts, a small quantity usually escaped from the nipples of the upper; and when the draught came into the former, the latter invariably became hard and distended. From the flatness of the nipples of the upper breasts the patient had never been able to suckle with them.

The author considers the above case as furnishing one of the best examples on record of quadruple mammaræ in the human subject, and cites from several foreign authors some of the most striking instances he has met with of the same malformation: the cases present no material deviation from the one under consideration. The author remarks, that in some women only one breast has been developed; others have had two nipples placed on one mamma; and a few individuals have had three breasts, two in the natural situation, and a third between them. Only one case has been recorded of five mammaræ in the human subject.

A Narrative of a Case in which the Parotid Gland was extirpated on account of Disease, in the Toronto Hospital, Upper Canada.

By C. WIDMER, Esq., Surgeon to the Forces. Presented by Sir J. McGrigor, Bt.

An elliptical incision having been made in the integuments of the most prominent point of the tumor, its removal was effected without much difficulty, and with little loss of blood, the facility being attributed

by the author to the adoption of the method of separating the mass from the lower part upwards. The external jugular vein and external carotid artery being necessarily divided, were immediately secured by ligatures, the latter being tied at both ends. When the removal of the mass had been entirely accomplished, the styloid process, and the transverse process of the atlas, were exposed to view. The result of the operation was quite favourable, the wound being entirely healed in six weeks.

Two Cases of Tumors pressing upon the Superior Vena Cava, causing Edema of the Face and Superior Extremities. By J. WILSON, M.D., Physician to the Middlesex Hospital.

In the first of the cases here related the compression of the vein was the consequence of an aneurism of the arteria innominata, the sac of which was found to contain a firm mass of fibrin. The vena cava superior was in contact with the sac, and communicated with it by a small opening. Portions of fibrin were found in the vein, which was, however, still pervious.

The obstruction of the vena cava in the other instance related, arose from the pressure of a tumor of large size and anomalous structure, which completely surrounded the vein. The head of the pancreas was, in this case, enlarged to the diameter of four inches.

PHYSICAL SOCIETY, GUY'S HOSPITAL,

January 13, 1838.

DR. HUGHES IN THE CHAIR.

MR. NORMAN CHEVERS read portions of a thesis on *Arteritis*.

In making some introductory remarks upon the structure of arterial tissue, the author described a tunic which he had found distinctly intervening between, and perfectly separated by cellular media from, the lining and contractile portions of the great arteries.

He applied to this the term "aponeurotic," as it appears to be made up of two or three distinct layers easily separable from each other, and from the tissues which surround them, each lamina having a dull metallic aspect, nearly resembling that of fascia, and appearing to consist of many minute fibres disposed in the longitudinal direction of the tube, being easily torn into strips lengthways, and not admitting of separation when strong traction is applied in the line of the vessel's axis; and at last yielding only by a short fracture. This tunic appears to undergo considerable increase of development under certain conditions of arterial disease; its layers become more distinct, its fibres are

more tenacious, and may be seen behind the serous lining, passing longitudinal lines. It becomes hypertrophied, probably for the intention of defending an already dilated and weakened tube from the effects of inordinate distension.

In its normal condition, the aponeurotic tunic appears not only to offer a better surface for the attachment of the serous lining, and the distribution of its vascular supply, than could be afforded by a part of so active function as the contractile coat, but it must also assist greatly by its elasticity in enabling the tube to return from extension in a longitudinal direction, while it prevents it from yielding too greatly under force so applied.

In adverting to the subject of acute aortitis, and detailing the morbid changes induced by that state, distinctions were drawn between the various kinds of reddened marks which so often appear upon the lining arteries after death. As to the supposed effect of the imbibition of blood, the author related some experiments, from which he adduced that blood does not usually produce a stain upon tolerably healthy arteries until after the time at which the average number of examinations are made; and that the marks, when produced, are unlike those resulting from organic change. There is another state of partial reddening which cannot be ascribed either to an inflammatory or staining process. The author endeavoured to account for this appearance by surmising, that during life the main surface of the aorta presents a light pink hue. It has long been proved that in the moment of death the aorta becomes flattened, its opposite surfaces being placed nearly in apposition: during a *perfect* contraction of this kind the vessels supplying the serous lining would become emptied of their contents, leaving the surface, which they covered, perfectly blanched; but should any circumstance occurring during, or even shortly after the agony, as a failure of supply from the organic nerves at any point, prevent the cylinder from exerting or maintaining its tonicity at that spot, the vessel's internal surface would there retain its original aspect, while the remainder became entirely deprived of colour. After advancing facts connected with the symptoms of this disease, and the pathological changes which appear in connection with it, it was submitted that as almost every case of acute aortitis arises in constitutions rendered morbidly irritable by certain vicissitudes, and in conjunction with similar states of inflammation in tissue analogous to the arterial linings in general junction and organisation, the disease in that division of the circulatory system results not from transmission of disease from other parts, but

spontaneously, as an individual effect of general irritation and depression then existing in the system. Upon this ground he strongly deprecated the treatment followed by the French practitioners, the use of extensive depletory measures, as being followed in the majority of cases by aggravation of the disease, and often by death, evidently from prostration.

Considerable difference of opinion existed among the members as to whether the structure described by Mr. Chevers should be regarded as a distinct coat.

Mr. HILTON said that he had listened attentively to the observations contained in the paper, and had also examined the preparations sent round by the author; but was not satisfied that there was any thing either in the description or dissection which could justify Mr. Chevers' conclusions. Mr. H. was inclined to regard the tunic described as distinct, to be nothing more than the cellular membrane connecting the internal and middle coats made more distinct by disease.

Mr. DENDY supported Mr. Hilton's views.

Mr. KEY vindicated the claims of Mr. Chevers to the discovery of a new arterial coat, which was distinct from both the internal and middle coats in the arrangement of its fibres. The preparations which he (Mr. K.) had seen, had satisfied his mind upon the point.

Mr. KING and Mr. GREENWOOD also bore testimony to the completeness of Mr. Chevers' observations.

On the motion of Mr. TWEEDIE, seconded by Mr. KING, a vote of thanks was carried to Mr. Chevers for his very valuable communication.

At the next meeting of the Society, Jan. 27th, Dr. Addison in the Chair, Mr. Aspland will read a paper *On some Diseases of the Heart*.

IRISH COLLEGE OF SURGEONS. PHARMACY LAWS.

THE committee appointed by the college to prepare a bill for the regulation of the practice of Pharmacy, presented their report at an unusually large meeting of the college on Tuesday the 9th inst. The suggestions were agreed to without a dissentient voice, and there was but one opinion as to the necessity of adopting the most vigorous and speedy remedies to meet the present emergency, and to protect the public from the consequences likely to result from the insubordination of the persons appointed by law to prepare the medicines ordered by the members of the profession for the patients under their care.

The first provision suggested by the committee is to enable all qualified practitioners to prepare and administer the

medicines necessary in their practice. Not, however, for the purpose of deriving income from the sale of them, but to secure correctness, and to deprive the apothecaries of the opportunity of meddling or tampering with their patients. The next is to protect and encourage regular apothecaries for the service of those who do not wish to dispense their own medicines, who shall be compelled to attend to the business of their shops, and not engage in the practice of medicine and surgery. The third provision is to prevent all persons practising medicine or surgery from compounding the prescriptions of other practitioners, or in any other way encroaching upon the department assigned to the regular apothecary. The fourth is to visit with severe penalties all apothecaries who employ ignorant, uneducated, or inexperienced apprentices or journeymen, in compounding medicines; such practice being attended with the most lamentable consequences. The fifth is to punish, in a summary and exemplary manner, all frauds and abuses in the preparation or sale of medicine, either by the use of impure, unsound, or inert remedies; or the substitution of cheap and counterfeit articles for those which are genuine and expensive. It is also proposed to enable all apothecaries regularly educated and licensed in England and Scotland, to practice as such in Ireland, and to afford persons of skill and capital so qualified every protection and encouragement to supply the present deficiency in this department throughout Ireland.

The committee also stated that they had received communications from all parts of the country expressing satisfaction at the prospect of a remedy for the present abuses, and affording much valuable information and suggestions.

The committee finally expressed their conviction that the college would probably experience no serious opposition to the proposed measure, except from those interested in the perpetuation of the existing abuses.

PETITION AGAINST QUACKERY.

To the Editor of the Medical Gazette
SIR,

I AM requested by the Leeds Medical Society, to forward you the annexed petition, hoping, should it meet with your approbation, that you will give it a place in your valuable periodical.

I remain,
Yours respectfully,
W. STEAD TAYLOR,
Hon. Sec.

Leeds, Jan. 10, 1838.

The members of the Leeds Medical Society, consisting of legally authorized practitioners, having some time ago had their attention directed to the unprecedented and increasing extent of quackery, appointed a committee to inquire what means could be adopted for its suppression. On receiving the report of the Committee, and at their suggestion, the Society have unanimously determined to petition the legislature for that protection against illegal competition to which an honourable profession is entitled.

It is a fact, that in the borough of Leeds the number of prescribing druggists and other illegal practitioners considerably exceeds that of the regular members of the profession; and the same calculation is applicable to many other places. The uneducated druggists are now in the full exercise and enjoyment of all those privileges which were intended, by the Act of 1815, to be secured to the apothecaries; while the latter, after years of preparatory study and expense, have the mortification of seeing *their* harvest reaped by a set of illiterate pretenders.

The following petition, it is presumed, will point out to the legislature a sufficient remedy for the evils in question; and the Leeds practitioners earnestly exhort their brethren throughout the kingdom to second their efforts, by immediately sending up to Parliament similar petitions, signed by all the legally-authorized practitioners resident in the district where the petitions originate.

As this is a question touching neither sect nor party, it is hoped that all parties will unite in the endeavour to obtain justice, and that no time will be lost in urging upon the legislature the necessity of removing this oppressive wrong.

GEO. WILSON,
Secretary to the Committee.

Leeds, Jan. 1, 1838.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament Assembled.

This Petition of the legally-authorized Practitioners of Medicine, residing in the Borough of Leeds,

Humbly sheweth,

That a very considerable number of individuals are now practising the different branches of medicine in England and Wales, without having undergone any preparatory education, or examination by any legally-constituted authority.

That, in consequence of their ignorant administration of remedies, very serious injury is done to the public health, and many cases have occurred in which their practices have been the undoubted causes of death. Not a few such cases have been

already before the public, as matters for legal investigation.

That the extent of employment which such parties are enabled to obtain among the uneducated classes (by advertising false cases, and various other unworthy means) injures materially the practice of regular members of the profession; and is more especially oppressive to the younger practitioners, who generally depend for their subsistence upon the very classes who are misled by the false statements of pretenders.

That your petitioners are required by law to undergo an expensive preliminary education; and then to engage for several years in severe and unhealthy studies,—subsequently to all which, they are subjected to rigorous examinations by the constituted authorities. Yet the only protection afforded them is by the Apothecaries' Act; which, however, is totally inadequate to redress their grievances, on account of the difficulty of obtaining the required evidence of illegal practice—the great length of the legal process—and the heavy amount of costs attending prosecutions.

That it is therefore inexpedient and useless to waste further efforts towards the conviction of illegal practitioners, under the very insufficient powers afforded by the Apothecaries' Act.

That your petitioners, therefore, beg most respectfully to suggest, as the only means of remedying the above evils, and protecting the public from the dangers of ignorant and empirical practice, that a clause be added to the Apothecaries' Act, empowering magistrates to summon before them any party charged with illegally prescribing or practising any branch of medicine in England or Wales, and in the event of such party failing to produce the license of the Apothecaries' Society of London (or proof of having obtained such license,) to inflict such a penalty as may seem adequate to prevent a repetition of the offence.

And your Petitioners, &c.

—

MEANS OF DIMINISHING QUACKERY.

THE Committee of the Leeds Medical Society, appointed to inquire into the means best calculated to diminish the amount of Quackery, having given the subject their best attention, beg to suggest the following propositions to the society:—

1. That it is expedient to discontinue any further attempts to procure the conviction of individual pretenders; such attempts being calculated, even when suc-

cessful, to diminish the evil in a very partial degree only. As moreover they are generally unsuccessful, the Committee are of opinion that our efforts and time ought no longer to be wasted in that direction; and, in support of their opinion, beg to refer the society to their statement of what has been in vain attempted by them since their appointment.

2. That the Society of Apothecaries, however desirous they may be to protect their Licentiates from illegal competition, are deterred from attempting it by the difficulty of procuring the necessary evidence of illegal practice—the expense of bringing witnesses into court, and the great amount of costs, &c. in case of a verdict being given against them.

In fact, the Apothecaries' Act, while it condemns the honourable candidate to an extensive, and (if properly pursued) a severe course of study, preparatory to his being even admitted to an examination by their court—while it requires such an outlay of money as to exclude from the list of Licentiates all men (however otherwise qualified) who cannot command a considerable capital—this Act affords to the Licentiates who have passed its ordeal, no kind of protection whatever against the rapacity and ignorant pretensions of the lowest dregs of the community.

3. The Committee think, that if a clause could be obtained in addition to the present Act, to make it lawful for any magistrate to summon before him suspected individuals; and, in case of their being unable to produce a diploma from some legally constituted board of examiners, to inflict upon them such a penalty (either fine or imprisonment) as shall be deemed expedient for every offence; such an addition would tend very materially to the suppression of quackery, and would ensure a consequent improvement in the prospects of the profession—more especially the junior members of it, who are necessarily the great sufferers from illegal opposition.

4. If the propriety of these suggestions be admitted, it is obviously the duty, as well as the interest, of the medical profession, to endeavour to obtain such an improvement in the existing laws as will confer a benefit both on themselves and the public. When an advantage is to be gained by any one, he must *himself* seriously strive after it, trusting to the exertions of no second person, and least of all to those of the individual from whom the benefit is to be obtained. This has been abundantly proved in the case of medical reform. The profession, instead of themselves struggling for the possession of those privileges and immunities to which they are reasonably entitled, have trusted

to the efforts of individual members of the legislature, who, having no personal interest in the matter, have allowed it quietly to sink into oblivion.

The committee, therefore, most earnestly call upon the members of this Society to be united in their endeavours, and to allow no party feeling, no foreign consideration, to interfere with their determination of having their grievances redressed. For the attainment of such redress, the Committee beg to recommend that petitions to the two Houses of Parliament be drawn up, and signed by all licensed practitioners in this Borough, setting forth in plain terms the injuries which medical men suffer, from the very insufficient protection afforded them by the Apothecaries' Act; and, secondly, suggesting to the notice of the legislature the summary process of punishing quackery by empowering magistrates to inflict a penalty on the party accused failing to produce a lawful certificate of qualification.

5. When the petitions have been duly signed in Leeds and the out-townships, the Committee recommend that other large towns, such as Manchester, Sheffield, Birmingham, Halifax, &c., be invited to co-operate with us, by preparing similar petitions, and in their turn inviting neighbouring towns to do the like; so that petitions may be presented, as if with one accord, from every part of the kingdom.

6. That it will be desirable to communicate with Messrs. Warburton and Wakley, to ascertain whether they have any intention of introducing this subject during the ensuing session of parliament; if so, what are their specific objects?—if not, whether they will assist the cause when we ourselves bring it forward?

7. That accounts of our determinations and proceedings be sent to the leading medical periodicals, begging their assistance in making the business generally known, and in encouraging the profession to come forward.

Lastly, the Committee would again urge upon you the necessity of being united. The undertaking in which we are about to engage, not only tends, if successful, to the immediate benefit of every present member of the medical profession, but also promises to remove many difficulties from the path of succeeding generations of practitioners. It is, therefore, surely unnecessary to use any arguments to show that it is the duty and interest of the profession to exert themselves in a cause of itself so good, and so entirely their own. The Committee have confined their considerations to the single subject of quackery, but do not therefore wish to

limit the field of improvement. They leave it to the profession generally to determine how far it may be prudent to confine their endeavours to the one object of the suppression of that abuse, or to extend them to the various details of medical reform which have been of late years before the public. They also leave it to this Society to determine on the propriety of calling a public meeting of the Leeds practitioners, for the discussion of this important subject, and the adoption of such measures as may seem calculated to obtain the desired end.

FEES FOR INSURANCE CERTIFICATES.

To the Editor of the Medical Gazette.

SIR,

MAY I request of you the favour of inserting, in an early number of your journal, the accompanying Resolution (with the list of signatures) adopted unanimously by the professional gentlemen of Devonport and Stonehouse.

I have the honour to be, sir,
Your obedient servant,
JOSEPH MAY, Hon. Sec.

Devonport, 11 Jan. 1838.

We, the undersigned Medical Practitioners in Devonport and Stonehouse, resolve that in future, we will answer communications made to us by Insurance Companies, relative to the health of individuals who may have been under our medical treatment, only on condition that such communications be accompanied by a suitable fee, considering the Insurance Companies are parties benefited by the information thus obtained.

TWO CASES OF STRANGULATED HERNIA.

By M. THOMASSIN, OF ST. ETIENNE.

CASE I.—Madame Tricot de Femè, aged 47, of a bilious temperament, deaf, and worn-out with cares, had had a tumor the size of an egg, in the crural region, for twelve years. The tumor was not moveable, and could not be diminished by pressure, nor did it communicate a shock to the hand when she coughed. There was nothing to show that it was a hernia, except the seat of the swelling, and the periodical disturbance which occurred in the alimentary canal. Its size was neither lessened nor increased by walking, or the horizontal posture. The irreducibility of the tumor, from the patient's not wearing a truss, and, in fact, every circumstance, made one think that no harm would happen, when, one day, without any known cause, the patient was seized with violent pain in the tumor; there was exquisite sensibility in the abdomen, with meteorism; and vomiting of all fluids that were swallowed, but not of fecal matter.

On being called to see the patient, I suspected that it was a case of strangulated hernia with adhesions. I applied leeches and ordered the warm bath, but the symptoms continued in spite of my treatment, and my repeated efforts at reduction were in vain. The long weakness of the patient made me dread the operation, yet, as it was certain she would sink without it, I resolved to perform it.

There was nothing unusual in the operation until arriving at the hernial sac; but after making the incision in the skin, and dissecting away the cellular tissue, I was much surprised when, instead of a transparent hernial sac, I saw a sac with radiated fibres, and of semi-cartilaginous consistence. I thought, at first, that I had come to a tumor arising from the abdomen, and causing all these symptoms by compression.

I made an incision, to be certain of the nature of the tumor, and found that the parietes of the sac were half an inch thick, and that my diagnosis had been correct. It contained a portion of omentum and a knuckle of intestine. After having relieved the strangulation, and replaced the hernial parts, which did not adhere, I removed a great portion of the sac; the rest came away, in fragments, from the wound, which became gangrenous. The patient survived.

CASE II.—A man, aged 55, of a lymphatic temperament, was affected with an inguinal hernia on the left side, which he had kept reduced for many years by means of a truss. He grew tired of wearing it,

however, as it incommoded him in business, and he left it off; but, one day, on exerting himself, a large mass of intestine made its way into the scrotum. I was called to the patient, and found him labouring under all the symptoms of strangulated hernia. In spite of the most rational treatment, the protruded parts could not be replaced, and I therefore proposed the operation, but it was not consented to. The patient suffered for a week under the following symptoms: vomiting of fecal matter, inability of swallowing fluids, extreme inflation of the abdomen, pulse wretchedly weak, face attenuated and livid; general infiltration [anasarca]. The patient, seized with alarm, now asked me to operate; but as I was persuaded that the attempt would be hopeless, I refused. All the symptoms continued for two months, and yet the patient recovered. Ever since this occurrence he has been attacked every three months by violent colic, inflation of the abdomen, obstinate vomiting, and general infiltration. This state lasts for eight or ten days, and then ceases.—*Gazette des Hôpitaux*.

POSITION DURING DELIVERY.

To the Editor of the Medical Gazette.

SIR,

I DID not expect my letter to you would have been honoured with the rather ambitious title you affixed to it, still less that it would have called forth precisely the kind of answer it has done from Mr. M'IVOR. As the left position has the sanction of common usage, it is the one I shall always adopt in ordinary cases; but I am still as much in the dark as ever as to the reason why it obtained that sanction. Mr. M'IVOR arranges his reasons under four heads, of which I deny the force of the first, third, fourth, and the greater part of the second. As to his remarks on the *relative position* of the patient and the medical attendant, I have only to observe that (according to my slender logic), while the *absolute position* of both are changed, the *relative position* may remain the same.

With respect to passing the female catheter, as I have practised both methods, I give the preference to the one which I can always accomplish without exposing the patient, having never done so but in one instance, where the diseased state of the parts might have puzzled even the erudite tact of Mr. M'IVOR. I cannot make the slightest pretension to pass the female catheter with "grace and courtesy," and I feel, therefore, the rashness of prolonging the con-

trovery with so highly gifted an opponent. I must decline the unequal contest, and only express my belief, that if Mr. McIvor would spare a little more of the last article, viz. courtesy, to an inquiring country practitioner, he would not find it a ruinous misapplication of that valuable quality.—I am, sir,

Your obedient servant,
HENRY COLES.

Cheltenham, Jan. 15, 1838.

To the Editor of the Medical Gazette.

SIR,
PERMIT me to direct the attention of your correspondents, Messrs. Coles and McIvor, to Nagle's Essay on the Mechanism of Parturition, translated by Dr. Rigby, pp. 12—30. They will find there full and ample reasons why women are delivered on the left side in preference to the right, and decidedly more satisfactory than those advanced by Mr. McIvor in the last number of your journal.—I am, sir,

Your obedient servant,
FORCEPS.

Winds S. by E. & S.W.; the former prevailing. Except the afternoons of the 12th, 14th, and following day, generally cloudy. Snow fell on the 11th, 14th, 16th, and 17th. The very low state of the thermometer has not been equalled during the past eighteen years. Upon reference to our journal for Jan. 1820, we find two remarkable incidences, viz. that during the previous days of the week the wind had been, as now, from the N.E., changing on the morning of the 15th to the S.W.; and the thermometer falling to 1 deg. It is singular enough, that, at the same date of the present year marks the same low degree of temperature, and precisely the same change of the wind. The severity of the frost has, however, been of longer duration than in 1820, having continued, without intermission, from the evening of Sunday the 7th to the present time, Thursday morning, the 15th, and yet no indication of a change.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE XII.

Diseases of the Air Tubes—General Pathology of Inflammation of the Mucous Membrane—Bronchitis—Mild Bronchitis: Signs and Course—Treatment of "a Cold" by Pectoratives—by Opium—by the "Dry Method"—Severe Bronchitis: its Signs and Course; Treatment—Asthmatic Bronchitis—Bronchitis of Infants.

HAVING studied those physical and vital properties of the organs of respiration, which, by their healthy and their disordered phenomena, constitute the general physiology and the general pathology of these organs, we next come to consider the groups or associations of these phenomena as they are presented to us in particular diseases, or special pathological conditions. Now you may judge that we have not time to enter into full descriptions of the various diseases of the chest, nor is it the object of these lectures to do so: these matters are to be found elsewhere, especially in the standard systematic works on the Practice of Medicine, which have appeared within the last few years. Our

notice of diseases will be mere outlines with regard to their general symptoms; and it is only where they can derive light from the newer views of pathology and diagnosis, and from the application of these to practice, that we shall be induced to enter into any details; and here I hope that you will find the principles which we have been already considering continually useful as a key and a guide, both in study and in practice.

Following the same course which we adopted in describing the structure of the organs of respiration, we have first to consider the diseases of the air-tubes; and as the most important class of these we shall commence with inflammations.

Bronchitis is essentially an inflammation of the mucous membrane of the bronchi, and it derives its chief characters from the structure and functions of that membrane. Now you know that mucous membranes are less simple in their structure than serous, and the effect of inflammation on them is consequently different; but, as we shall see by and by, the difference does not exclude many parallels. There are, an enlargement of the blood-vessels, an interstitial effusion, and consequent swelling; there is an exalted sensibility; at first there is a diminished, but, as the irritation proceeds, an augmented secretion from the membrane. This secretion is at first transparent and liquid, but more or less glutinous or ropy; and this uniformly viscid quality generally increases with the intensity of the inflammation. No sooner, however, does the inflammation begin to abate, than there is a manifest change in the secretion; it becomes partially opaque and clotted, and although still viscid, in parts even more so than before, it is not uniform, and the masses do not run together and coalesce into a glairy mass. This marks the transition of the secretion from the mucous,

or muco-serous, to the coagulated albuminous form, which may be simply opaque, muco purulent, purulent, or less frequently of a more solid albumen; and with these changes there are indications of a diminution of the intensity of the inflammation, and of the local swelling and irritation which accompany it. When brought to this state of secretion, the vessels either, having relieved themselves, recover their tone, and gradually return to their ordinary size and function, or if the irritation have continued too long, or have been of a very intense character, they are more permanently altered, and continue to secrete more or less of a muco-purulent or purulent matter, the disease thus becoming chronic.

Now if you bear in mind this general course of inflammation of the bronchial membrane, you will have a key to many of the signs and symptoms of bronchitis; and the character of the disease will in great measure depend on the stage and the extent of this inflammation, and may thus vary from an affection so trifling as not to interfere with the ordinary occupations of the individual, to one of the most serious and dangerous of diseases. Let us quickly go through the history of the more common varieties of bronchitis.

You know that a common cough, catarrh, or "cold in the chest," is a mild form of bronchitis. This commonly begins with a sore throat or a "cold in the head," the inflammation of which seems to travel down to the windpipe and bronchi, there causing pain or tightness under the sternum, and cough; at first with a feeling of roughness or dryness in the throat, but afterwards with a tickling, and the expectoration of a thin, glary salt tasted mucus, which is often profuse in persons of a relaxed habit: this secretion, so far from relieving the cough, obviously aggravates it; and I have no doubt that it possesses the same irritating quality that the humour of coryza has, the contact of which with the membrane that secretes it, causes such an unpleasant tickling, sneezing, and lachrymation, and which excoerates the external parts over which it runs. This has also a salt taste, and probably these and all other thin mucous secretions owe their irritating quality chiefly to the saline matter in them. Well, it is when this is secreted that the cough becomes most troublesome, and from its violence there is not unfrequently abrasion of parts of the membrane lining the trachea or larynx, and streaks of blood are seen in the sputa; these are, however, quite distinct, and do not tinge the mass. Patients are apt to be alarmed at this appearance of blood, but if preceded by a violent cough, this

symptom need cause no apprehension. Even mild bronchitis, in its acute stage, is generally accompanied with slight fever, and some shortness of breath; but I need not dwell more on the general symptoms.

It is by the physical signs that we more clearly mark the condition of the bronchial membrane. In the earliest stage, perhaps before the cough or other symptom of pectoral disease, various dry rhonchi, the sonorous and sibilant, with a diminution of the respiratory murmur, announce the narrowing of some of the air-tubes: more rarely, a total absence of sound in a part of the chest implies that the obstruction there is complete; but the unimpaired sound on percussion shows that the vesicular structure is free. These obstructions, no doubt, arise chiefly from the swelling of the mucous and sub-mucous tissues; we see the like take place in the nasal canals, when they are the seat of the kindred affection, coryza.* The bronchial tubes do not remain long in this dry state; the secretion commencing first, gives a roughness to the other sounds, and then adds to them a sound of bubbling, which is the mucous rhonchus; but this is seldom so loud as the other sounds, and when the disease occupies only the deep-seated tubes, it may scarcely be heard at all. According as the liquid is in the large or the small tubes, the bubbles, and the crackling which they produce, will be coarse and unequal, or finer and more uniform. The usual seat of all these sounds in the milder forms of bronchitis is in the middle parts of the chest, whether in front, behind, or at the sides, where the larger bronchi lie: in the severer forms they extend to other parts. You may suppose from what I said in a former lecture, in explanation of the sonorous and sibilant rhonchi, that the lower tones imply an affection of the larger tubes; but the acute notes do not exclusively indicate an affection of the finer tubes, for they may be produced also in the large tubes where the obstruction is considerable; and when you hear an acute or whistling note prolonged through the whole act of inspiration or expiration, you may be sure that it is not produced in the finer tubes, for the air is not so long passing through them. I believe that the deep sonorous rhonchus is generally seated at the branching off of a large bronchus, and so strong are its vibrations that it is often felt by the hand applied to the exterior, or by the patient, who can point out the spot where

* Dr. Stokes has suggested an additional cause in a spasmodic contraction of the circular fibres, now unduly irritable. It is very probable that this may co-operate.

it is. These various sounds may accompany either the inspiration, expiration, or both.

The decline of bronchitis is announced by a looser character of the cough, and the change before-named in the expectoration to the opaque concocted kind. This is generally first seen in the morning, that being usually the time of day in which most febrile and inflammatory diseases show a tendency to remission. Sometimes, without this opacity, the sputa assume a more consistent form. This renders the cough and expectoration easier, but it is not accompanied with the general improvement so remarkable when the sputa become simply opaque. In either case, the inspissation of the bronchial secretion causes some change in the physical signs. The bubbles are heard to break more rarely, and give more of a whistling or ticking sound, and the sibilant and sonorous rhonchi become remarkable; but they shift and vary with every cough or forcible act of breathing. The same clots of mucus that by their partial obstruction to the air cause this rhonchi, sometimes totally block up one or more of the tubes, and stop the sound of respiration in the part to which the tubes lead. But this stoppage is seldom permanent, and a cough or deep inspiration will often open it, or shift it to another part, and the air is then heard to enter with a whistling or clicking noise, where all had been silent before. The sound, on percussion, is still uniformly good; and this circumstance, with the varying respiration and rhonchi, characterizes bronchitis in this stage.

Before I notice the more formidable varieties of bronchitis, I must say a word or two on the treatment of its common mild kind. "A cold" is generally accounted a trivial complaint; and although the sufferer is often more annoyed and incommoded by it than by affections of a graver name, still it is "only a cold," and he gets little pity, and no treatment beyond that of a few domestic remedies, which may do neither good nor harm. Yet those of you who are liable to colds and coughs, will agree with me when I say that this class of complaints, by their frequent occurrence, by their own evils, and by the many aches and disorders which they often bring with them (tooth-ache, ear-ache, deafness, sore throat, weak eyes, rheumatic pains, indigestion, costiveness, &c. &c.), interfere more with the comfort and occupations of very many individuals than all their other illnesses put together. Surely, then, the subject deserves more attention than it usually gains; and if we cannot make people in general think it worth while to take our

advice for a common cold, we may just as well profit by it ourselves. It is a common notion that a cold must run its course; and Laennec cites a proverb much to the same effect:—"A cold well nursed, lasts forty days; a cold not nursed at all, lasts six weeks." I hope, for the credit of our art, that this is not generally true; I am quite sure that I have not found it to be so, or I would not trouble you with any further remarks on the subject. The ordinary mode of treating a cold attended with bronchial inflammation is certainly rather palliative than positively curative; but it generally mitigates its severity, and hastens its termination. A brisk purgative, conjoined (if febrile or gastric disturbance be present) with a moderate dose of calomel and James's powder, will generally take off the edge of the disease; whilst a sedative and expectorant mixture will be useful to quiet the cough, and to lead it to its natural termination by expectoration. In the mild acute inflammations of the air-tubes, the promotion of expectoration is a primary object of the treatment; and besides those means which reduce the intensity of the inflammation (such as sudorifics, evacuants, counter-irritants, and local depletion, some or all of which may be beneficial in particular cases), great advantage will be generally derived from the frequent use of a cough mixture. Various combinations may answer for this purpose. Formulæ of ipecacuanha, or tartarized antimony, with hyoscyamus, conium, or hydrocyanic acid, for the onset; and squill, ipecacuanha, opium, and camphor, for the subsequent periods, are what have appeared to me to answer best. But the efficacy of these remedies is decidedly increased by combining them with an alkali. From ten to twenty drops of the liquor potassæ, or an equal number of grains of carbonate of soda, or, in more asthenic cases, twenty or thirty drops of the sp. ammoniæ arom. are sufficient; and I am confident that in the greater number of cases the alkaline remedies quiet the cough, and promote expectoration far better than the oxymels and acid linets, or lozenges, that are commonly in use, and which, however they may appear at the time to "cut the phlegm," and cleanse the throat, tend to disorder the digestive organs, and often ultimately to increase the cough. To have their full effect, cough medicines should be taken frequently—at least five or six times a day; for besides that their object is to influence continually the secretion of the bronchi through the circulation, they seem to act in some measure directly on the glottis and its neighbourhood; and in the intervals it is useful to have in the mouth

a bit of gum arabic, or of liquorice, the solution of which tends, also by continuity, to sheathe these same irritated parts.

I have nothing further to add to what you must already know respecting this mode of treatment; the great objection to which is, that for its success it requires more or less nursing and confinement. To give diaphoretics and diluents, and at the same time to expose the body to transmutations of temperature, which are almost unavoidable without confinement, will tend rather to increase a cold than to diminish it; and I am quite sure that I have seen many colds and coughs kept up by this system. Now, many persons cannot afford the time to confine themselves to nurse a cold; and they either let it run its natural course, or make an even worse compromise, by nursing and sweating one part of the day, and exposing and chilling themselves at another. We want, then, a method of treating a cold, more applicable to those who cannot or will not confine themselves, and of this class especially are medical men. Now I know of two methods of this kind; but to be used with any success they must be employed at the onset of the disease, within a day or two from its commencement, and the earlier the better. The "cold," of which I speak, is an inflammation of the membranes lining the air-passages, accompanied by a secretion which, we have observed, is irritating, and tends to keep up the inflammation. Now, although we cannot cut short this inflammation, and stop this secretion by common emetics or antiphlogistics, yet we may, by other means, either remove or modify it so as to lead to a more speedy mode of termination. One method that sometimes has this effect is, by taking, at bed-time at the earliest stage of the cold, (whether the affection be felt in the nostrils, the throat, the chest, or in the system generally,) a full dose of opium in some form, and following it the next morning by a brisk cathartic. Ten or fifteen grains of Dover's powder, or two grains of opium with two of ipecacuanha, or half an ounce of compound tincture of camphor, are the most eligible forms of opiate; and I think it is safe to add a few grains of calomel, or some milder mercurial, to prevent the restraining effect of the opium on the secretions. When this remedy acts well, the patient sleeps soundly, generally perspires freely, and awakes the next morning free from his cold, but often with some headache and nausea, the after effect of the opiate. These are generally relieved by a well-seasoned black draught, and no further ailment is felt but some languor, which another night's rest may remove. I do not know who first suggested this

heroic cure for a cold; but I believe it is pretty generally practised by members of our profession, and it is by no means an unpleasant one, where opiates and strong purgatives do not disagree. But the stomachs of many do not bear this piece of *medicina perturbatrix*; it may disorder the digestive and alvine functions for weeks afterwards. Sometimes, too, the catarrhal irritation may be too strong to be lulled by the opiate, especially if it be in the chest, and in that case this treatment will hardly fail to aggravate it, and, by suppressing expectoration, it might even convert a bronchitis into a pneumonia.

The other method of stopping a cold is by what I call *drying it up*. I first practised this method in my own person, and you shall hear with what success. In early life I was subject to frequent and most violent colds in the head, which, after lasting a week or ten days, generally ended in a cough, which, even when nursed, I could scarcely ever get rid of in less than a fortnight more; and when neglected, has many times harassed me for double that time. Yet I underwent discipline severe enough; did not taste wine, and scarcely meat, for weeks together, and my chest even now bears the marks of the blistering and tartar-emetic counter-irritation which I inflicted on myself. About twelve years ago, on being attacked with one of these colds, I remarked that taking a quantity of tea, or any other liquid, although very comfortable at the time, was invariably followed in the course of an hour by an increased "stuffing in the head," and accompanying flow of scalding irritating humour from the nose and eyes. I thought I would try to prevent these exacerbations at least, by *cutting off the supplies*—by ceasing to drink. For twenty-four hours I did not take a drop of liquid of any kind, and to my agreeable surprise not only did I escape these occasional aggravations of the complaint, but the stuffing and discharge began to show evident signs of abatement, and the handkerchief was in less continual requisition. I persevered for twenty-four hours more, and my cold was gone; there being only now and then a little gelatinous opaque mucus collected in the nostrils and throat, without any stuffing or irritation, just as it takes place at the very end of a cold. What was of still more consequence, no cough followed; the whole catarrhal disease seemed to have been destroyed. This plan of treatment I have been in the habit of using ever since, with a success varying somewhat in degree, but on the whole amounting to this, that I have had no colds which have lasted three days, and never a severe cough, except once, and

that was when circumstances prevented a due perseverance in this dry diet. I have recommended this method of cure to a great many friends and patients; and those who have had the resolution to use it fairly, have generally succeeded in bringing their troublesome colds to a premature end. You may be ready to say, that the remedy is worse than the disease. I would answer, that either you do not really know what a bad cold is, or your appetites hold a little too much of an epicurean sway over you. I do not recommend the plan to those who have only slight or transitory colds; these may not be worth the penalty of any self-denial; but the amount of discomfort entailed by two days' abstinence from liquids is really trifling in comparison with that and the ill-health that a severe cold brings with it; and I have never hitherto seen any bad effects to arise from the practice. As no account of this method of curing colds has been before the public, except a short notice which I gave in the article *Coryza*, in the *Cyclopædia of Practical Medicine*, I will detain you with a few more observations on its mode of action and application.

The great effect of abstinence from liquids is promptly to decrease the mass of the circulating fluids. The natural fluid secretions continue, although in diminished quantity; the urine is still excreted, although its watery part is diminished; and the skin continues to perspire either insensibly, or, under the influence of increased warmth or exercise, in an obvious manner. Not so the morbid secretion from an irritated membrane: the irritation is lessened with the decreasing fullness of the blood-vessels; the morbid flux no longer continues, the scantier circulating fluid being now taxed for the necessary excretions too closely to supply it; and the diseased membrane, no longer irritated by its own secretion, soon returns to a healthy condition. If liquid be freely taken too soon, before the membrane have lost its diseased action, the discharge will return, and the complaint will be as bad as ever. But if, after the discharge has been stopped by twenty-four or thirty-six hours of dry diet, means be taken to keep up the other secretions, as by exercise, with a warm state of the surface, a little liquid may be taken with impunity, the bulk of the circulating fluid being still below the point at which it can supply any demands from the irritation in the diseased membrane.

I think that the physiological principle of the dry method is what I have now stated; and you can easily perceive that

there must be limits to its application. We do not yet know how far it may be pushed, or what may be the extent of its influence on various morbid conditions of the vessels and of secreting organs. I know from experience that partial abstinence from liquids is of great use in moderating many kinds of congestion, hæmorrhage, and local determinations of blood, and especially in diseased conditions of the mechanism of the circulation; but we have yet to find out how far a total abstinence may be carried to control acute affections of a similar character. It is necessary also to bear in mind, that other diseases may arise from a defect of liquid in the system; that the excreting organs may suffer from the undiluted excrementitious matters that would pass through them; that their function being disordered, some of this excrementitious matter may be left in the system, from which very pernicious effects would ensue; that some functions, as that of digestion, would be arrested by the want of a due proportion of water in the secretions that carry it on; and other evils which it is not necessary to enumerate. I say, there is reason to expect that such consequences might ensue from carrying this system too far; but I have never seen any such effects from that amount of the plan which is sufficient to cure the severest cold at its onset. I have more than once passed three whole days without tasting a drop of liquid. The only unpleasant effects were, at the end of the second day, slight headache, with some languor, decided diminution of bodily strength, and a small feeble pulse. These were relieved by a night's rest, returned in the course of the next day, but were entirely removed by two cups of tea at the end of the third day; and all that remained of the effects of the discipline was a desire during the next two days to repair the wants of the system by copious libations, the enjoyment of which was far greater than had been the suffering from abstinence. This suffering is, in fact, rather negative than positive: one certainly does not enjoy one's meals fully without drinking with them; but this is the diminution of a pleasure rather than an infliction of pain; and when the meal is over, one forgets all about it. But without dwelling on this point, which being one somewhat of taste, is not to be argued on, let me say a few words more on the application of this plan to the cure of a cold.

It is very essential for the success of the dry treatment that the cold should be in its early irritative stage, when it generally occupies the nasal and pituitary mem-

brane. If there be any fever, and especially if the state of the bowels require it, an aperient with an antimonial should be given, for this favours that free state of the secretions on which, as we have seen, the efficacy of the dry plan depends. In milder cases, however, this is not necessary. For the same reason it is expedient that the solid food be not of a too rich or heating kind; for this, undiluted by liquid, might be apt to disagree. Bread, or any consistent farinaceous food, with a little butter, vegetables, white fish, and white or gelatinous meats, light puddings, and dried fruits, will do very well for a dry diet; and who can call this starving? In fact, I have sometimes not changed the diet in any particular but in the point of abstinence from liquids; and with regard to this point, although total abstinence is, of course, the most effectual, I have found lately that a deviation to the amount of taking about a table-spoonful of tea, or milk, with breakfast and the evening meal, and a wine glassful of water on going to bed, does not interfere with the success of the plan, and it certainly adds to one's comfort. But a great advantage of this plan is, that it does not interfere with one's ordinary pursuits; it needs no nursing or confinement. In fact, if care be taken to clothe enough to prevent the surface from being chilled, exercise in the open air promotes the success of the plan, by promoting the natural secretions. On the other hand, those who treat their colds by slops and diluents, which act chiefly by increasing the perspiration, will suffer from the least transition of temperature, which will have an increased influence on a perspiring surface. The time necessary to effect a cure by the dry plan will vary in different individuals, according to the present quantity of their circulating fluid, the activity of their secretions, and the intensity of the catarrhal disease; and also somewhat according to the temperature and hygrometric state of the air, longer time being always required when the air is cold and damp. On the average, forty-eight hours of abstinence will be quite sufficient. I have often known thirty-six hours sufficient; but some few severe and obstinate cases required three days. The period may be shortened by exercise and warm clothing, or lying warm in bed, or by commencing with a purgative, or by any other dry means of increasing the natural secretions. The catarrhal affection is generally much relieved at the end of the first day, and only is troublesome at times; but the cure is not complete till all stuffing is gone, and nothing but a consistent mucus, without

irritation, is formed in the nasal or bronchial passages. Sometimes this secretion will continue for a few days; but unless fresh cold be taken, it causes no inconvenience, and soon ceases. In these cases it is generally prudent to take an aperient and diaphoretic on returning to the use of liquids, which it is always best to begin at night, when there is less risk of relapse from fresh exposure. Perhaps you think that I have been taking up too much of your time with this more trivial form of catarrhal disease, and this novel mode of treating it; but it is because the disease is thought too trivial, and because the treatment is novel, that I have been dwelling longer on the subject than its comparative importance would seem to demand.

The intense or severe form of bronchitis differs from the milder kind only in the greater extent of the bronchial tubes which it occupies. Its pathological nature and local signs are the same, but its general symptoms differ, inasmuch as the system suffers more from the greater extent of the functional mischief. This disease presents itself in two forms, the *sthenic* and the *asthenic*. In *sthenic* bronchitis, inflammatory symptoms are marked from the commencement: these are generally pain, and a feeling of tightness across the sternum; hard severe cough, with very glutinous expectoration; much fever; heat of skin; the tongue white and red at the edges; pulse quick and often hard; the breathing much shortened, often oppressed, and the least exertion occasions coughing. The physical signs are like those of the mild form, but are here heard more extensively throughout the chest. The rhonchi are at first sibilant and sonorous, afterwards mucous and submucous, reaching to the inferior portions of the lungs, with a weakened respiratory murmur, announcing the presence of the inflammatory mucus even in the smaller tubes; but the clear sound on percussion declares the vesicular structure still free. If relief be not afforded by expectoration, perspiration, or prompt remedial measures, the disease soon shews a change of character, from the increased dyspnoea and symptoms of partial asphyxia that ensue. Then come on feelings of great depression; the pulse becomes weak as well as quick; the sensorium is sometimes disturbed; the muscular strength is much reduced; the countenance becomes anxious and pallid, or partially livid, according to the quantity of blood in the system; the pulmonary congestion becomes evident by a slightly diminished resonance on percussion in the postero-inferior regions of the chest. The continuance of this state, and

the imperfect arterialization of the blood, further disturb other functions; the secretions become more scanty and vitiated; the tongue is loaded with a brown fur; the thirst is intense; and all these disorders concur in reacting on and aggravating the original disease, and in injuring the natural powers. Such is the loss of balance which ensues from the inroad which severe bronchitis makes on the important function of respiration. The share which the injury of this function has in giving character to the constitutional symptoms, is seen in the fact, that very similar effects are met with in persons who have been subjected to an asphyxiating influence. The step from this condition to death is but a short one, and happens too often, especially in cases that have been neglected at the onset.

Now the advantage of the physical signs is to inform us with certainty of the first coming on of an inflammatory affection of this character. When with the febrile state before described, whether the functional disorder be prominent or not, we find extensive rhonchi in every part of the chest, especially if they extend to the inferior parts, and there be little respiratory murmur audible, we should not hesitate to resort at once to such depletory measures—bleeding, cupping, or leeches—as the individual case will admit, and conjoin with these, mercurial and antimonial medicines to act on the secretions. Generally even moderate bleedings give speedy relief, by removing the congested state of the lung; and in this respect bronchitis differs from pneumonia, in which this congestion is a more fixed part of the disease. It is desirable, however, to produce an impression on the pulse, which will sometimes increase in fulness as the blood flows and relieves the temporary congestion. But large bleedings are not expedient, for the inflammation of a mucous membrane is not removed by them; it involves a certain structural change, probably interstitial effusion, that can be relieved only by a free secretion from it. Expectoration is a necessary process during the remainder of the disease, and there must be strength saved for this purpose. In many cases cupping or leeches are to be preferred to general blood-letting; and they may generally be added with advantage. When the edge of the inflammation has been thus taken off, a very large blister, or the free application by friction of a saturated solution of tartarized antimony on the chest, will keep up the relief given. The latter remedy is well adapted to the more sthenic forms of bronchitis; and to ensure its prompt action, the chest should be first rubbed with a flesh-brush,

or a piece of coarse flannel: it will then generally bring out a small pustulating eruption in the course of a few hours. Of the internal remedies, tartar emetic, in large doses, for the strong, and mercury, with ipecacuanha and James's powder, for the less robust, are the most effectual. I shall have an opportunity of noticing the antimonial treatment when speaking of pneumonia; and I will not enter now into common details of the treatment, as you will find these given in the standard works on practical medicine—as in the article *Bronchitis*, in the *Cyclopædia*, or more fully in Dr. Copland's *Dictionary of Practical Medicine*.* The good effect of the treatment will be apparent in the general symptoms before it is evinced in the physical signs. The breathing becomes less laboured, the countenance improves, the pulse becomes steadier and fuller. On listening, we may find that the air enters more freely into the lungs, but the mucous and other rhonchi are still present, and continue for some time; and it is only when the improvement is considerable that we can perceive that they diminish, and that the obstructions become less general; that instead of bubbling over the whole, or a considerable portion, of the chest, the respiratory murmur is heard, still mixed with clicking, whistling, and humming sounds.

The chief difference presented by the *asthenic* or *lunatic* form of bronchitis, or *peip ematica nostra*, as it was formerly called, is the early appearance of signs of depression, generally attended with gastric derangement, nausea, headache, &c.; and by the physical signs we learn, from the universal mucous rhonchus, the early presence of a profuse secretion in all the tubes. I have often observed a temporary dulness on percussion produced by this effusion, or by the pulmonary congestion that ensues in consequence of it: nay, I have known it to cause bronchophony and bronchial respiration, which lasted only during the evening exacerbation, and were gone the next morning. The transient character of these signs is enough to show that the increased density of the lung that caused them results merely from an increased quantity of liquid only, this liquid, probably, being the blood congested in the great pulmonary plexus of vessels, as well as the mucus in the bronchial tubes. This secretion is the great cause of the depression and danger; and its diminution or free expectoration is a chief object of the treatment. Bloodletting is scarcely

* To these must be added the valuable and comprehensive chapter on *Bronchitis*, in Dr. Stokes' work, published since this lecture was delivered.

borne here; the most available remedies are large blisters of a size to cover the whole chest; mercurial purgatives, and tartaric emetic in nauseating or larger doses, with expectorants of a somewhat stimulating kind, such as the decoction of senega, and the liquor ammoniæ acetatis, which do not increase the quantity, but facilitate the act of expectoration. Where the depression is greater, and the act of expectoration begins to fail, more stimulating remedies, such as the carbonate of ammonia, must be given, and the preservation of life will often depend on the judgment with which these are, from time to time, administered. Referring you to the works before named for further details, I shall now only add, that a certain degree of abstinence from liquids is highly serviceable here, not only by diminishing the mass of blood that has to pass through the now choked lungs, but also, as in the milder catarrh, by reducing the quantity of the bronchial secretion. That it has this latter effect I am convinced by repeated trials; and, on the other hand, I have many times seen a marked aggravation of dyspnoea take place in this and in other diseases of the chest after copious draughts of linseed tea, and other mucilaginous liquids, that are popularly taken with a view to *loosen* the phlegm.

In young children, a very dangerous kind of bronchitis sometimes come on very insidiously. A certain degree of drowsiness or stupor is present, which keeps the little patient from complaining or coughing. A close attention will, however, detect a great frequency in the breathing; and on applying the ear to the chest, the universal rhonchi, sibilant and mucous, at once declare the latent evil. Emetics and mercurial purgatives are the most successful remedies in these cases. The former must not be too frequently used, as they cause considerable determination to the head, and exhaustion; but they are eminently successful in emptying the bronchial tubes of their secretion; and I suspect that they do this not only by the action of the external muscles of expiration, but also by exciting the bronchial muscles to contract, as we know that the glottis is most forcibly closed during the act of vomiting. In the milder cases small doses of ipecacuanha may suffice. The utility of the physical signs is thus most evident in these cases; and in no instance of febrile disease in infants or young children should the practitioner omit to examine the state of the chest.

ON THE

OVA OF MAN AND MAMMIFEROUS BRUTES,

AS THEY EXIST IN THE OVARIES BEFORE IMPREGNATION;

AND ON

THE DISCOVERY IN THEM OF A VESICLE

Analogous to that described by Professor Purkinje in the immature Egg of the Bird.

BY THOS. WHARTON JONES.

Read before the Royal Society, June 18, 1835*.

THE organs in female mammiferous animals known by the name of *ovaries*, were at one time considered analogous in their function to the testes of the male. This opinion, however, has been long given up, and physiologists now universally admit that the function of the ovaries of the mammalia is the same as that of the ovaries of birds and other ovipara.

It was in the seventeenth century that this analogy was fully determined. Douglas (Bibliographiæ Anatomicæ, Specimen, p. 42), however, affirms that the true nature of the ovaries was known to John Mattheus de Gradi, professor of anatomy at Pavia, in the fifteenth century; and in this assertion he is followed by Portal (*Histoire de l'Anatomie et de la Chirurgie, passim*; and *Cours d'Anatomie Médicale*, vol. v. p. 506) and Cruveilhier (*Cours d'Etudes Anatomiques*, vol. i. p. 66.) In proof of what he advances, Douglas gives the following as a quotation from the work of Mattheus de Gradi:—"Testiculos muliebres duo ova carnis glandulosis cooperta." In the work to which Douglas refers (*Practica D. Magistri Johannis Matthei ex Ferrarii de Gradi, &c. Venice, 1520*), I have not been able to find any such expression. On the contrary, in a paragraph (charta 342, col. 1), with the marginal title, "*Muliebres habent duos testiculos ut viri*," we read the following:—"In matrice etenim sunt duo ova; ut dictum est supra, quæ sunt dictæ carnes glandu-

* See London and Edinburgh Philosophical Magazine, vol. vii. p. 209.—ED. GAZ.

losæ; et sunt duo testiculi mulieris ad rotunditatem magis declinantes quam testiculi viri et minores sunt testiculis virorum; et in eis fit generatio spermatis sicut et in testiculis viri secundum sententiam medicorum." The words *duo ova*, in this quotation, mean merely *two bodies of an oval form*. It thus appears that Matthæus de Graaf entertained no other opinion on the subject than the one commonly received in his day, and which continued to prevail for two hundred years after.

Of the distinguished anatomists who, in the seventeenth century, supported the doctrine that the mammifera are reproduced from ova generated in the ovaries, Steno and De Graaf deserve to be particularly noticed. I do not mention our great Harvey; for although he asserted that all animals, even man himself, are propagated by ova, he did not suppose that, in the mammifera, these ova are developed in the ovaries, but that they are first formed in the uterus. To the ovaries he ascribed an inferior function.

Nicholas Steno was professor of anatomy at Copenhagen, and afterwards Bishop of Titopolis, and Vicar Apostolical in the countries of the North. In his "*Observationes Anatomicæ Spectantes Ova Viviparorum*," he affirms that from the ovaries are produced the rudiments of the ovum, and that the uterus affords whatever is required for the perfect development of the fœtus. These propositions Steno supports by proofs drawn from human as well as comparative anatomy.

Regnerus de Graaf, who was a physician at Delft, gave in his treatise "*De Mulierum Organis Generationi inservientibus*," a very good account of the structure of the ovaries, describing more correctly than had previously been done the vesicles they contain. For this reason they are now commonly called the *ova*, or *vesicles of De Graaf*.

It thus came to be generally admitted, that the vesicles of the ovaries were ova, or rather that these vesicles contained something analogous to ova. But it was a question what the nature of that substance was; whether it had a determinate figure, or was a mere amorphous mass. As nothing but a drop of albuminous fluid could ever be observed in the vesicles, the latter opinion prevailed.

De Graaf, in 1672, discovered ova of

a definite shape in the fallopian tubes of rabbits three days after impregnation; these he delineated. But as they were so minute, so disproportionate in size to the vesicles of the ovaries, and as subsequent investigators failed in detecting them, De Graaf for a long time lay under the imputation of having asserted what was not true. To this injustice the authority of Haller, who failed in detecting ova in the sheep, mainly contributed. All doubts on the subject were, however, removed by the experiments of Cruikshank, performed in 1778, and published in the *Philosophical Transactions* for 1797 (p. 197). These experiments established the truth of De Graaf's assertion.

Prevost and Dumas, in their researches into the generation of the mammifera, found small ova in the horns of the uterus of a bitch eight days after impregnation, similar to those observed by De Graaf and Cruikshank in the rabbit on the third day. But that they had seen similar bodies in the fluid of the Graafian vesicles, without being fully aware of their nature, is rendered probable by the following extract from their memoir, entitled, "*De la Génération dans les Mammifères, et des premiers indices de développement de l'Embryon*," published in the third volume of the "*Annales des Sciences Naturelles*," Paris 1825:—

"Les ovules qu'on rencontre dans les cornes sont remarquable par leur petitesse. Ils ont en effet un ou deux millimètres de diamètre au plus, tandis que les vésicules de cet organe en possèdent un de sept ou huit millimètres, au moins. Ce sont donc deux choses qu'il ne faut pas confondre, et très-probablement les vésicules ou les œufs de l'ovaire, contiennent dans leur intérieur, les petits ovules des cornes, qui s'y trouvent environnés d'un liquide destiné peut-être à faciliter leur arrivée dans l'utérus. Il est survenu deux fois, en ouvrant des vésicules très-avancées, de rencontrer dans leur intérieur un petit corps sphérique d'un millimètre de diamètre." Notwithstanding these important steps in the investigation, it was not till 1827 that ova were first unequivocally demonstrated in the ovaries of the mammifera.

To Carl Ernst von Baer*, professor

* *De Ovi Mammalium et Hominis Genesi*, Lipsiæ, 1827. This memoir, which was addressed

of zoology in the University of Königsberg*, belongs the honour of this discovery, certainly the most important ever made in the history of generation.

Sir Everard Home and Mr. Bauer, in a paper on *Corpora Lutea*, in the Philosophical Transactions for 1819, describe and delineate what they considered an ovum in the human ovary. The supposed ovum was in the cavity of a corpus luteum; and from the presence of the hymen they imagined the woman had died a virgin. There can be no doubt that Sir Everard Home and Mr. Bauer were mistaken regarding the nature of the body they describe; it corresponds in no respect with the human ovum as it exists in the ovary.

I may here also mention, that Dr. Plagge, of Benthaim (Meckel's Archiv. vol. vii.; and Meckel's Deutsches Archiv. for 1829), endeavours to shew that not only he anticipated Baer in the discovery of the ovum in the ovary, but that it had also been previously described by De Graaf, as well as Sir E. Home and Mr. Bauer. On these pretensions I may remark, that De Graaf's claim to the discovery is not better founded than that of Sir E. Home and Mr. Bauer; and as to the claim of Dr. Plagge himself, I can only say with Baer, that "notwithstanding the most perfect willingness to do so, I cannot understand what it is he says he saw."

In our examination of the ova of the mammifera, an acquaintance with the structure of the ovum of an oviparous animal will assist us much. With this view I shall mention the points most worthy of notice in the structure of the hen's egg in the first stage of its formation. But as it is at this period contained in the ovary, it will be necessary to premise a short description of that organ.

The parts common to every ovarium are a parenchyma and an investing membrane. To the former, Baer proposes to give the name of *Stroma*, and to the latter that of *Indusium*. In the stroma are imbedded the capsules, in which the ova are formed. In the vertebrata each ovum has a proper capsule; but in some of the invertebrata,

one capsule contains several ova. In this case, there is within the capsule, besides the ova, an almost amorphous substance, which Baer calls *stroma internum*. The capsules he calls *thecæ communes*.

In birds, the yolk and its membrane are the only parts of the egg which are formed in the ovary. The chalaziferous membrane, the chalazæ, the albumen, the membrane of the shell, and the shell, are added in the oviduct. The ovary of the bird may be described as a cluster of capsules with their contained yolks, varying in magnitude from that of a millet-seed to the full-sized yolk. The stroma, which surrounds these capsules, is a laminar cellular tissue, delicate, and in small quantity. The indusium is derived from the peritoneum. It envelops almost entirely each capsule, and forms along with the vessels of the latter a pedicle, by which the capsule is attached to the body of the ovary. The very small capsules not being so completely enveloped by indusium, are not pedunculated, but sessile. The capsule in which the yolk and its membrane are found, is composed of two laminae, an outer cellulo-vascular, and an inner, soft and spongy, which receives small vessels from the larger branches ramified in the outer.

The yolk consists, at first, of a granular membranous sac, within which is contained a fluid with granules suspended in it. The vitellary membrane is at this period extremely thin and transparent, and adheres very closely to the inner surface of the capsule. From these circumstances it is not readily seen, unless carefully looked for with the assistance of a magnifying glass. It is from not having noticed it at this early period, that Baer has mistaken the granular membranous sack of the yolk for it. "Thus," he says, "*vitelli membrana hoc tempore crassissima et granulosa est ita, ut optime mereatur nomen membranae granulosa, quam Purkinje quoque ita describit.*" This granular membrane, he supposes, divides afterwards into the proper vitellary membrane and a granular layer, forming the periphery of the yolk. His words are, "*Posthac membrana granulosa in stratum externum laeve, continuum—membrana vitelli puta—et stratum granulosum, vitelli peripherium efficiens, sejungi mihi visa est.*" Burdach (Die Physiologie als Erfahrungs-

in the form of an epistle to the Imperial Academy of St. Petersburg, was followed a year after by a commentary, illustrating more fully the author's views.

* Now of St. Petersburg.—ED. GAZ.

wissenschaft, vol. ii. p. 54.) follows Baer in this mistake; and Baer himself repeats it in his "Memoir on the Exfoliation of the Epidermis of the Embryo of the Mammifera, applied to the knowledge of the metamorphosis of Insects."

It is not until it has attained a considerable size, that the yolk presents the colour and structure which it is found to possess in the perfect egg. On one or other side of the yolk, generally near the pedicle by which the capsule is attached to the ovary, the cicatricula is observed. At this place the grains composing the periphery of the yolk being more aggregated, form a zone or disc, the inner surface of which presents a mammillary eminence or cumulus, turned towards the interior of the yolk. In the apex of the cumulus is a pellucid pore, which may be seen on either side of the cicatricula. This pore, which is quite circular, has a diameter of about one-seventieth of an inch. It is occupied by a very small vesicle, which is imbedded in a cavity in the granular substance of the cumulus. This vesicle was first particularly described by Professor Purkinje, of Breslau (*Observationes nonnullæ ad Ovi avium historiam ante incubationem*: Vratislaviæ, 1825.) It is, therefore, commonly known by the name of the *vesicle of Purkinje*. It consists of a thin transparent envelope, within which is contained a fluid, not perfectly limpid, as Purkinje says, but somewhat granular. When the yolk has left the ovary, the vesicle is no longer to be found.

Fig. 1 is a diagram representing a section of the hen's egg within the capsule of the ovary, and the position of the vesicle of Purkinje.

- b, The vesicle of Purkinje imbedded in the cumulus.
- c, The vitellary membrane.
- d, The inner and outer layers of the capsule of the ovum.
- e, The indusium of the ovary. Betwixt the indusium and the capsule the stroma is seated.
- f, The pedicle by which the capsule is attached to the ovary.

Leaving out of view altogether the ova of the marsupial animals and monotremata, as I have never had an opportunity of seeing them, and as they have not yet, so far as I know, been minutely examined in the recent state, I proceed to the description of the ova of man, and mammiferous animals in general.

As in birds, so in the ovaries of man and mammiferous brutes, we find a parenchyma or stroma, and an envelope or indusium, derived from the peritoneum. But the stroma, immediately underneath the peritoneal envelope, is condensed into the form of a tunic, to which the peritoneum closely adheres. This is known by the name of the *tunica albuginea* of the ovary. Baer proposes to call it *indusium proprium*. The stroma in general is much denser in its texture than in birds. In the human ovary, which I assume as a type of that of the mammifera, the stroma is a dense laminar cellular tissue. Imbedded in it, and for the most part situated near the surface of the ovary, are found the vesicles of De Graaf. In the sow these vesicles rise considerably above the surface of the ovary; and in the hedge-hog they project so much, that the ovary resembles the raceme of the bird. The Graafian vesicles vary in size. The largest in the human ovary are about one-fifth of an inch in diameter. They sometimes project slightly above the surface of the ovary. As to the number of vesicles contained in one human ovary, that varies according to circumstances. In the ovary of a young adult as many as fifteen may be counted.

The proper capsule of the Graafian vesicle is composed of two layers. The outer is formed of dense cellular tissue, in which are ramified many blood-vessels. The inner layer is thicker, softer, and more opaque, than the preceding, to which it is closely united, and from which it receives vascular twigs.

The contained part or nucleus of the

vesicle of De Graaf consists of: 1st, a granular membrane, enclosing, 2ndly, a coagulable granular fluid; 3rdly, connected with the granular membrane on one side is a circular mass or disc of granular matter, in the centre of which is imbedded, 4thly, the *ovum*.

Fig. 2 is a diagram of a section of the Graafian vesicle and its contents, shewing the situation of the ovum.

- a, The granular membrane.
- b, The proligerous disc.
- c, Ovum.
- d, The inner and outer layers of the wall of the Graafian vesicle.
- e, Indusium of the ovary derived from the peritoneum, the stroma immediately underneath which is condensed so as to form the *tunica albuginea*.

The granular membrane is more tenacious and thicker the smaller the vesicle is. The disc of granular matter connected with it on the prominent side of the vesicle, appears to be at first quite distinct from it. This disc, called by Baer the *proligerous disc*, presents in its centre, on the side towards the interior of the vesicle, a small rounded prominence, called the *cumulus*; and on the opposite side a small cup-like cavity hollowed out in the cumulus. The cavity is for the reception of the ovum. To examine the ovum properly, it is necessary to separate entirely the proligerous disc from around it. A separation sometimes takes place spontaneously, particularly if the ovary has lain a day or two in water. It may, however, always be effected by careful manipulation with fine instruments under the microscope. I am surprised that Baer says he only succeeded once in doing this.

OF THE OVUM.—Baer calls this *ovulum*, not so much on account of its very small size, as from considerations which, in the course of this memoir, I

shall attempt to show are unfounded. I apply to it the name *ovum*, in the same sense as I would apply the term to the egg in any other class of animals.

The human ovum is so small, that it is just perceptible to the naked eye. It is about the one hundred and fiftieth part of an inch in diameter. Its shape is spherical, when suspended in water; but, in consequence of its softness, it falls into a lenticular form when there is not sufficient water to support it. When examined with the microscope it has the appearance delineated in figure 3. Figure 4 represents it still surrounded by the proligerous disc. The ovum has a soft external envelope, which is transparent, and very thick; hence is produced the appearance of a broad transparent ring forming its circumference, when the ovum is viewed with the microscope by transmitted light. Within this transparent external envelope is seen a substance composed of grains adhering together by the intervention of a delicate mucous tissue, so as to form a sac, which I have sometimes succeeded in withdrawing entire. (See figure 5.) Sometimes the grains do not hold together; hence, when the external envelope is torn, they escape, and diffuse themselves in the water surrounding the ovum. Baer appears to have misconceived the structure of the external envelope, for he describes it as a hollow sphere with thin walls, separated by a transparent interval from the central part of the ovum.

Besides the parts above mentioned, there is still another which enters into the structure of the ovum. It is a delicate transparent vesicle about 1-900th of an inch in diameter. It is seated at the inner surface of the granular sac. On one side of the vesicle there is a small elevation*, which, projecting among the grains composing the walls of the granular sac, fixes the vesicle in its place. This vesicle, which I had the fortune to discover (I made the observation in the beginning of September, 1834,) I consider analogous to that described by Professor Purkinje, in the cicatricula of the immature eggs of birds, and which exists also in the ova of other ovipara. Figure 7 represents the vesicle removed from the ovum. In figures

* I shall not at present venture on any speculation regarding the nature of this part, but that it performs an important function there can be no doubt.

3 and 6 the small elevation on the side of the vesicle is observed projecting among the grains of the granular sac. In figures 8 and 10 the whole vesicle is seen *in situ* in consequence of the grains composing the granular sac being few in number, and not adhering closely together.

As it is convenient to have a name for an object, I shall for the present employ for this vesicle the name of *germinal vesicle*, already given by Baer to the analogous part in the ova of the ovipara.

Besides the human ova, I have examined those of the cow, sheep, sow, rabbit, rat, and mouse. They differ in no essential particular. Those of the rat and mouse are smaller and more transparent. In all I have found the germinal vesicle, the size of which to that of the ovum is as 1 to 6.

Baer says he once found two ova in one Graafian vesicle of a bitch, and on another occasion he observed the same thing in the Graafian vesicle of a sow. If there is no mistake, this would be an approach to what is observed in some of the inferior animals, in which a single capsule contains several ova. I have found in the Graafian vesicle of the human ovary, an ovum somewhat like two joined together, but I could only perceive one germinal vesicle*. (See figure 10.)

Baer winds up his description of the ovaries and ova of the mammifera with the following parallel between them and those of other animals:—

“But these are sufficient for establishing a comparison between the ovaries of the mammalia and their contents on the one hand, and the ovary and ova of other animals on the other. We have in the mammalia a dense *stroma*, in which are imbedded the Graafian vesicles. If we look to the constituent parts of these vesicles only, we shall be struck with the remarkable resemblance they bear to the ova of other animals. Let us compare, for example, the ovary of any mammiferous animal with the ovary of a bird and a frog. There are present the indusium, stroma, and capsules, with this difference only, that the indusium and stroma in birds and frogs are more delicate than in the mammalia; that in frogs, moreover, the indusium being internal on

account of the internal cavities, appears very delicate; and lastly, that in frogs the capsules open towards the interior, and leave an internal calyx easily to be distinguished. Then comes the vitellary membrane, which in the mammalia exists under the form of a granular membrane. Seeing that the vitellary membrane in birds and reptiles appears at first under the form of a granular membrane, and is by and by exfoliated from it, I do not hesitate to compare the Graafian vesicle of the mammalia in this respect with the immature ovum of the other vertebrate animals. The yolk of birds and frogs is composed of many vitelline granules and a small quantity of fluid albumen. The Graafian vesicles differ only in this, that they have a smaller quantity of grains; but, on the other hand, a larger quantity of native albuminous fluid. In other respects they are similar to ova. They contain, in fact, a vesicle (the ovulum of the mammifera) imbedded in the *caulus*, and a proligerous stratum, at one time surrounding the vesicle, at another lying over it. *Therefore the Graafian vesicle, in reference to the ovarium and the body of the mother in general, is indeed the ovum of the mammalia.* But as regards evolution, it differs very much from the ovum of other animals, in which the whole nucleus of the ovum is carried off from the ovarium, to afford not merely a nidus to the future fœtus, but rather to be transformed into the fœtus itself. But in the mammalia the innate vesicle (*vesicula innata*) contains a more developed yolk, and, *in reference to the fœtus about to be formed, proves itself the true ovum. A fetal ovum, it may be called, in a maternal ovum.*” (De ovi mammalium et hominis genesi, p. 31.)

There can be no doubt that the capsule which contains the yolk in the hen's ovary is analogous to the capsule of the Graafian vesicle. At first sight, also, the nucleus of the vesicle of De Graaf resembles very much the immature yolk of the bird's egg. But I think there is no analogy between them. Thus there is no membrane similar to the vitellary membrane surrounding the nucleus of the vesicle of De Graaf. Baer's assertion that the vitellary membrane appears first under the form of a granular membrane, I have in a former part of this paper disproved. Therefore his comparison between the granular membrane of the nucleus of the vesicle of De Graaf and the vitellary membrane of

* In one instance, I think I have found two germinal vesicles in one human ovum.

the bird's egg, does not hold. As to the analogy which Baer has attempted to draw between the ovum of the mammifera and the vesicle described by Purkinje in the immature egg of the bird, I would remark that although, in its situation and mode of connexion within the Graafian vesicle, the former bears considerable resemblance to the latter in its situation and connexion, still these are the only points of resemblance. In all other respects they differ widely, as may be inferred by comparing the descriptions of them which I have given in this memoir. The vesicle of Purkinje, in fact, consists merely of a delicate capsule containing a fluid, while in the minute ovum of the mammifera we have all the essential elements of the egg of the bird and that of other ovipara—viz., 1. an external membrane which is analogous to the vitellary membrane of the bird; 2. a granular membranous sac, containing a thin fluid, together representing completely the immature yolk of the bird's egg; 3. a vesicle in every respect analogous to that described by Purkinje in the hen's egg, while still in the ovary*. On the existence of this latter part I would particularly insist.

From what I have said, I think I am justified in concluding, that in the small body discovered by Baer, in the Graafian vesicle, and which I have described in this memoir under the name of the *ovum of the mammifera*, we have the analogue of the egg of the bird, and that of other ovipara. I might also add, that the granular membrane, proligerous disc, and granular fluid of the Graafian vesicle, are probably superadded parts, of which there is no trace within the capsule of the bird's ovary†. They might, perhaps, be compared to the internal stroma of the acephalous mollusca. The occurrence of more than one ovum in a single capsule, as seen by Baer, would appear to favour this conjecture; for the internal stroma is found in capsules common to several ova.

From the above quotation it will be seen, that besides considering the ovum analogous to the vesicle of Purkinje, Baer correctly views it as a real ovum.

* Figure 9 is a diagram of a section of a human ovum.

† In the smaller Graafian vesicles of the mouse, I have found the ovum so large as to fill nearly the whole vesicle; so that there was very little granular matter corresponding to the granular membrane and proligerous disc.

It is, indeed, in it that the embryo is first formed. But to reconcile this fact to his hypothesis, he says that "the vesicle of the germ in the mammifera (as he calls the *ovum*) is developed in a preponderating manner, and draws to it all the generative faculty of the egg (*nucleus of the vesicle of De Graaf*).¹" In accordance with this notion, he calls the ovum of the mammifera, *ovum fetale*; and the nucleus of the Graafian vesicle, *ovum maternum*. "Mammalia ergo," says he, "habent ovum in ovo aut, si hæc dicendi formula uti licet, ovum in secunda potentia." To this, Baer adds, in a note, "Quapropter in vesicula Graafiana describenda voce *ovuli* semper usus sum, quia vesicula Graafiana ipsa ovum refert, respecto ovario, ex ovulo autem fit ovum fetale." The reason why I have used the term *ovum* is already obvious.

I cannot agree with Baer in his determination of the parts of the *ovum fetale*, as he calls the ovum of the mammifera. He considers the outer membrane of the ovum analogous to the membrane of the shell in the bird's egg, and accounts for a vitellary membrane, by conjecturing that there forms on the outer surface of the granular membranous sack, which is the vitellus of the ovum, a thin pellicle, in the same manner that he erroneously supposes the vitellary membrane of the bird's egg is produced. There is no such pellicle as that spoken of by Baer, and all analogy leads us to suppose that the external envelope of the ovum of the mammifera does not correspond with the membrane of the shell of the bird's egg, but rather with the vitellary membrane; although it, at the same time, appears to perform a different and a higher function*.

POSTSCRIPT †. — Since writing the preceding memoir, I have learned that M. Coste, in a work entitled "*Recherches sur la Generation des Mammiferes*," mentions his having observed, in the ovum of the rabbit, a vesicle which he compares to that described by Purkinje in the bird's egg. From this it would appear that M. Coste has antici-

* Mr. Jones here alludes to the opinion he entertained at the time this memoir was written—that the vitellary membrane of the mammiferous ovum afterwards formed the chorion. Mr. J.'s subsequent researches, as detailed in his second memoir, have proved this opinion incorrect.—ED. G. & V.

† This postscript was read before the Royal Society, along with the rest of the paper.—E. G.

pated me in the discovery of the germinal vesicle in the ovum of the mammifera.

The results of M. Coste's researches, however, which appear to have been confined to the ova of the rabbit, do not altogether correspond with what I have observed in the numerous examinations which I have made of the ova of man and several other animals, besides those of the rabbit. I am, therefore, not without the hope that my memoir will be found still to contain something both of novelty and interest.

M. Coste states, in his memoir, that he had examined 200 ova of rabbits before he observed the vesicle. He then goes on to say — “Je commençais à croire que les mammifères en étaient privés; lorsqu'un jour ouvrant une lapine non fécondée, dans le seul but d'étudier les œufs dans l'ovaire, je remarquai pour la première fois, un petit point transparent, parfaitement sphérique, placé à la surface du vitellus. Ce fait nouveau devint l'objet de l'examen le plus attentif, et après quelques instans d'observation je vis le petit point transparent se déformer et s'effacer complètement. Un second œuf fut placé sous le microscope et me presenta un phénomène semblable: il en fut de même pour presque tous ceux que renfermaient les ovaires de cette lapine. Le petit point dont il est question n'est

autre chose qu'une vesicule d'une ténuité et d'une transparence telles qu'il est impossible de rien voir qui ressemble davantage à une bulle de savon, dont elle a toute la fragilité.”

In the above extract from M. Coste's work, the vesicle is described as lying at the surface of the vitellus. I have always found it within the granular membrane composing the periphery of the vitellus, and distinctly visible at the surface only in those cases in which the grains of the vitellus were not coherent. In all my examinations of the ova of the mammifera, I never saw the germinal vesicle shrink and disappear, as M. Coste describes it to do; but I have generally been able, by tearing open the ovum under the microscope, to separate the vesicle quite entire, and examine it in the detached state. This M. Coste seems never to have done, although, without doing it, the vesicle, from its situation, can seldom be seen. The germinal vesicle is certainly very delicate and transparent, but I have not found it so fragile as M. Coste represents it to be. As to what M. Coste says about the necessity of looking for the vesicle soon after the death of the animal, I must remark that I have found it as distinct a week or ten days after the death of the animal, as at an earlier period.

Fig. 3 represents the human ovum as seen under the microscope by transmitted light. It is magnified forty-five diameters. On one part of its surface a small spot is seen, which is the elevation on the side of the germinal vesicle.

Fig. 4 is the ovum still surrounded by the proligerous disc, magnified fifteen diameters.

Fig. 5 represents the outer envelope of the ovum lacerated, and the granular membrane sac, composing the yolk, drawn out.

Fig. 6 exhibits a human ovum magnified forty-five diameters, in which the granular sac is so much contracted, that it does not fill up the whole cavity of the external envelope. The spot on the surface of the granular sac, which may be considered as the cicatrícula, is the elevation on the side of the germinal vesicle.

Fig. 7 represents, within a square area, the human germinal vesicle magnified forty-five diameters. On one side of it is seen the small elevation.

Fig. 8, a human ovum magnified forty-five diameters. In it the grains composing the granular sac were in such small quantity, and adhered so little together, that the whole germinal vesicle is seen shining through the outer envelope.

Fig. 9 is a diagram of a section of an ovum, representing the thick external envelope, within which is the granular sac, and, connected with the inner surface of the latter, the germinal vesicle.

Fig. 10 represents a human ovum, which I found in the ovary of a married woman of about thirty. It is somewhat like two joined together, but there is only one germinal vesicle.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

BY WILLIAM GRIFFIN, M.D.

Limerick.

Mortality of Cholera.

No. IV.

BEFORE entering on the consideration of the effect of remedies in cholera, it is above all things essential to have clear notions respecting the usual mortality of the disease in various circumstances. From the extraordinary fact

that the average mortality has been nearly the same in all countries, varying between one-third and half, those who reason on loose and general observation of the disease have been naturally led to conclude the medical art is altogether unavailing in its treatment; while others, whose views are limited to the narrow circle of their own experience, see, in the occasional diminution or increase of deaths, either new and successful modes of management or utter failures in practice. We shall not be so ready to complain of these or other erroneous opinions entertained on the subject by the public, when we consider that few, even among medical men, have sufficient facts before them to reason correctly at all in the case, and that those who are out of the profession have little other means of forming an estimate of medical practice except the amount of mortality. A prevailing and very natural error among the latter, is the belief that medicine cures, not merely by interrupting or altering some destructive process, or by assisting some spontaneous vital efforts at recovery, but by some inherent and absolutely restorative virtue. They do not know, or they do not consider, that the constitution is maintained in its healthful condition by a self-preserving influence, ever silently at work, but openly displaying its energies when called upon to repair the effects of injuries, whether inflicted by physical violence, by poison, or by disease; that the medical art can only be of use in proportion to its capability of assisting this influence, and must necessarily fail wherever the latter is exerted feebly or unequally, since medicine may sustain the vital efforts of the system in resisting any destructive process, but cannot possibly altogether supply their place.

A knowledge of this fact leads readily to the reflection that, in all severe diseases, the weak, the sickly, and diseased, must die under any treatment, and even a proportion of the strong and full-blooded, probably for a reason the very opposite to the former—that the actions which the preservative influence calls up, are, in such habits, apt to exceed the requisite amount, so that life is extinguished by the very violence of the natural effort to resist or repair the injury. There is thus a very certain and known average of deaths in almost all dangerous maladies, under the best

treatment. In typhus fever, this inevitable mortality varies according to the virulence of the epidemic; among the poor, from one in ten to one in thirty-two—among the rich, from one in five to one in twenty; being generally the same in the same epidemic. The mortality in the simply confluent small-pox, is (according to Dr. Gregory, of London) three in five; which is little short of that occurring in the collapse of cholera, when judiciously treated. In the coherent description, the mortality is one in four; and on the whole, it has been computed that out of every six persons who take small-pox in the natural way, one inevitably dies.

Cholera is a malady so rapid in its progress, and the consequent mortality is so great, that even successful treatment in its advanced stage is unsatisfactory, and has, indeed, the appearance of absolute failure. The fact nevertheless is, that no severe disease with which we are acquainted is so curable, or so capable of being influenced by medical treatment, if under judicious management from its commencement. Our judgment on this subject has been misled by our aptitude to form general conclusions, without comparing the actual results with those which we might rationally anticipate. All formidable diseases, if uninterrupted, commit much mischief in the frame, and the time comes, earlier or later, in which that mischief is irreparable. The previous period is obviously the only one in which we can hope for any success from our remedies; and this, in cholera, extends sometimes but to a few hours. It is essentially a rapid disease, like those which follow the exhibition of poisons, and we should no more consider it incurable, or beyond the control of medicine—because in its last stage, which it reaches so speedily, we are seldom able to bring about recovery—than we should that a person who has swallowed opium, or prussic acid, is irrecoverable, because those who have taken extravagant doses, or have had assistance too late, invariably die.

In estimating the mortality in cholera, it is highly important to inquire, first, what its amount might be in cases abandoned to nature; and secondly, what it has been under the most successful medical treatment. The extreme difficulty of attending an inquiry of this kind, can only be conceived by those

who are familiar with the variable character of the disease itself at different periods and places, and with the loose and uncertain nature of even medical records, or evidence. In considering the first point, it is necessary to hold in view the following habits of the disease:—

When first it sets fairly in, in any district, it is usually of a virulent description, that is, of the rapid type, all the cases in which medical assistance is not resorted to, speedily terminating in death, and more than half running into collapse before it can usually be obtained.

It generally mitigates in severity after some days or weeks: cases will then recover, under treatment, which, in the rapid type, would prove utterly ineffectual, and in some rare instances without any treatment at all.

It generally returns with sudden and renewed malignancy to any place it has once visited, and again as unexpectedly becomes mild and disappears.

While it prevails in any town or village, it is more or less variable in its character. The cases occurring in one night, or in one street, may run their course with frightful fatality, and in the very next assume the milder or protracted form. An hospital physician, in this way, may sometimes, on seeing a patient brought in, tell in what part of the city he was taken ill, or on learning the locality predict his recovery or death.

From this variable character of the disease, one may readily apprehend the difficulty of instituting any fair comparisons between different modes of treatment, and the danger of drawing inferences from a small number of cases, or without reference to the place or period of their occurrence: it would, in fact, be impossible to avoid error even with vast records before us, if we had not besides some certain mode of ascertaining in all cases at what stage of the disease it had fallen under medical care, such as we are furnished with in the temperature of the tongue and skin and in the state of the pulse. It is universally acknowledged that when it can no longer be felt at the wrist, the recoveries are few under any known treatment. But in those instances in which the pulse is still perceptible, many remedies, as we shall hereafter show, are highly influential, and some almost certain in arresting its course. In comparing the

results of cases abandoned to nature with the results of these medically treated, it is therefore necessary to consider separately such as are treated previous to, and after, the extinction of the pulse.

It was said by practitioners in India that no one recovered from cholera without medical assistance, and it certainly appeared to me, from my earlier experience, to be equally true of the disease in this country; for many months during which I witnessed the progress of hundreds of cases, both in and out of hospital, I did not meet with a single instance of natural cure; nor could I ascertain, on most diligent inquiry among medical friends, that any such had fallen under their observation. When, afterwards, the complaint partially subsided in Limerick, and began to attack the towns and villages throughout the surrounding country, where the people evinced the strongest objections to go into hospital, there was a still better opportunity of estimating the probability of natural cures. In all of these places, however, the mortality was reported as universal. In Scariff, Kildysart, Castle-Connell, Bruff, Croom, Hospital Rathkeall, Adare, Askeaton, and other small towns, I could not learn that a single recovery had taken place where medical means were wholly rejected. If considerable information, and even very extensive personal experience of this disease would allow of my forming any absolute inference, I might at this period have fairly concluded, with most medical men, that natural recovery from cholera was impossible. I had, however, some doubts remaining suggested by the many cures I had seen effected under very different, and sometimes opposite modes of treatment, and still more by a few extraordinary ones which had occurred in the hospitals in circumstances of such extreme neglect as made it quite allowable to consider them abandoned cases. At length, on the second violent irruption of the disease in Limerick, after it had been desolating the city for three months, I first witnessed the natural recovery of three individuals in one family in the neighbourhood of Garryowen. On visiting the house, I found the mother and son lying upon straw, with the usual symptoms of the complaint; an infant was stretched on his face and hands in the middle of the floor, where it had crawled from the bed, and was purging pro-

fusely. The matter ejected was bilious, as if the attack was only commencing. The mother would not allow any of them to be removed to the hospital, in consequence of her husband having died there a few days before. As they had no attendance, and even no drink, except what the humanity of their neighbours induced them occasionally to lay near the bed, I concluded that they would all shortly run into collapse and die. To my great astonishment, however, on the second day after, when standing in the ward of St. John's Hospital, I saw the three brought in; the mother and infant in light fever, the boy more severely affected, but all in a state that led me at once to predict their recovery: the latter, in fact, was the only one who required any serious treatment. I could not ascertain whether they had ever gone into perfect collapse; the mother could scarcely have done so, having all through taken care of the child. Since then I have seen two or three other instances in which the patients did well merely by slight medical assistance in the febrile stage. Indeed, it was now evident to me, that many patients survive collapse if merely supplied with diluent drinks—perhaps from a fifth to a third of all who fall into it; and that the almost universal fatality in neglected cholera arises, not from their invariably dying in the most destructive stage of the malady, but from their sinking in the subsequent fever.

The difficulty of establishing the possibility of natural recovery furnishes us with sufficient evidence of its extreme rarity; but this will be yet more clearly seen on advertent to what might be considered a law of the disease, if any rule could be called a law to which it can be justly said some exceptions have occurred:—*That without medical treatment every person attacked with it will fall into collapse, although they may not eventually die; and that such as recover do not do so by an arrest or cessation of the disease, but by struggling through, and outliving all its stages.* It hence follows, that in estimating the probable chance of recovery in all cases left to nature, we may regard them as cases of collapse, to the frightful mortality of which we have before alluded.

It shall now be shewn, by a reference to the hospital reports, that this rule or

law does not at all apply to cases actively treated; that medicine is not simply influential, as in fever, in mitigating symptoms and assisting the patient through its different stages, but that it commonly, and almost certainly, arrests the disease if resorted to in time. This is so true, that if it does not arrest it—if the progress of the disease is not absolutely interrupted—if it goes on through collapse and fever, the patient is almost sure to die. In proof of these assertions I must confine myself to the reports of the hospitals in Limerick, to which I was myself attached. Singular

to say, the reports transmitted to the London and Dublin Boards of Health, from all parts of the kingdom, are entirely useless as materials for medical reasoning, the distinction of cases as they happened to be admitted with or without a perceptible pulse having never been observed. If it was the general design to mystify the subject, and prevent the possibility of fair comparison under different modes of treatment, it could not have been more effectually done than in those loose and useless records.

THE STRAND HOSPITAL*.—*From June the 8th to June 22d, 1832.*

	Admitted.	Died.	Recovered.
In the primary stage	24	4	20, being 16 deaths in 100.
In collapse	20	17	3, being $1\frac{1}{2}$ recoveries out of 10.
Total	44	21	23

Making the mortality nearly one in two upon the whole, the cases in collapse amounting nearly to half the total admissions.

ST. MICHAEL'S HOSPITAL.—*From June 14th to July 1st, 1832.*

	Admitted.	Died.	Recovered.
In the primary stage	74	12	62, being 16 deaths in the 100.
In collapse	80	67	13, being $1\frac{1}{2}$ recoveries in 10.
Total	154	79	75

Making the mortality one in two upon the whole; the cases brought into hospital in collapse exceeding half the admissions.

From July 1st to August 1st, 1832.

	Admitted.	Died.	Recovered.
In the primary stage	119	5	114, being only 4 deaths in the 100.
In collapse	46	42	4, being only 1 recovery out of 10.
Total	165	47	118

Making the mortality less than one-third upon the whole; the cases brought in in collapse exceeding one-third.

THE NUNNERY HOSPITAL.—*From June 8th to June 22d, 1832.*

	Admitted.	Died.	Recovered.
In the primary stage	128	7	121, being 6 deaths in the 100.
In collapse	154	117	37, being little more than $2\frac{1}{2}$ recoveries out of 10.
Total	282	124	158

Making the mortality one in two and a quarter upon the whole; the cases brought in in collapse exceeding half.

ST. JOHN'S HOSPITAL.—*From June 8th to July 18th, 1832.*

	Admitted.	Died.	Recovered.
In the primary stage	419	29	390, being 7 deaths in the 100.
In collapse	264	195	69, being over $2\frac{1}{2}$ recoveries in 10.
Total	683	224	459

Making the mortality, upon the whole, one in three; the cases brought in in collapse amounting to more than a third of the admissions.

* In these reports there is no separate column for bilious diarrhœa; such cases were regarded as merely premonitory, and usually treated at the Dispensaries. The stage of rice-water discharges is called the primary stage.

ST. JOHN'S HOSPITAL.—From its re-opening, Aug. 21st, to its final closure, Sept. 13th.

	Admitted.	Died.	Recovered.
In the primary stage	59	8	51, being 16 deaths in the 100.
In collapse	61	43	18, being 3 recoveries in 10.
Total	120	51	69

Making the mortality, upon the whole, considerably less than half, or about two fifths; the cases brought into hospital in collapse, being nearly three-fifths of the total admission.

BARRINGTON'S HOSPITAL.—From Sept. 23d, 1832, to April 17th, 1833.

	Admitted.	Died.	Recovered.
In the primary stage	114	121	96
In collapse	103		

Making the mortality, upon the whole, more than half; the cases brought in in collapse having been less than half. The proportionate deaths of those admitted in the primary stage and in collapse are not recorded.

The cases running into collapse, on admission, which were yet arrested, are not given in any of these tables; they were usually classed with those in the primary stage. In the last cases admitted into St. John's (from the 28th of August) they amounted to 8, with the 8 (primary stage) which terminated fatally, making 16. This would give on the whole, cases admitted in collapse and running into collapse, 77; deaths, 51; being 26 recoveries, or nearly 4 in 10.

I have already mentioned that the perceptibility or imperceptibility of the pulse was agreed on, by the medical

gentlemen engaged in these hospitals, as the criterion by which collapse was established. The rice-water purging and vomiting were regarded as the diagnostics of confirmed cholera. All patients with perceptible pulse, however sunk or cold, were recorded in the primary stage. It was, of course, impossible to avoid occasionally admitting persons with mere premonitory diarrhoea and vomiting; but these, I believe, seldom exceeded a tenth of those registered as admissions previous to collapse, and in the last instance, in St. John's Hospital, did not amount to more than five in the hundred.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégier.” — D'ALEMBERT.

On the first Changes in the Ova of the Mammifera, in consequence of Impregnation, and on the Mode of Origin of the Chorion. By THOMAS WHARTON JONES, Esq.

SUCH is the title of a paper in the Philosophical Transactions for 1837, Part II. The subject is one of so much interest, that we shall copy the paper into our journal; but as about two years and a half ago, another paper by the same gentleman was communicated to the Royal Society, on the Ova of the Mammifera before impregnation, we have given it first, for the better understanding of the other, (see present No. page 689.) This we the more readily do, as in the paper communicated two years and a half ago, which was only

read, not published, is detailed a discovery of great importance in reference to the physiology of generation. We mean the discovery which Mr. Wharton Jones made in the human unimpregnated ovum as well as in that of other mammifera, of a vesicle analogous to that first described by Professor Purkinje, of Breslaw, in the immature eggs of birds and other ovipera. It appears that some time before Mr. W. J. made his discovery, the existence of such a vesicle was asserted in France by M. Coste, of Paris, from some observations he had made on the ova of the rabbit; but an examination of his work will show that he rather vaguely indicated than unequivocally demonstrated the existence of the vesicle. This indication of it, however, by M. Coste, was an inducement to Professors Purkinje and Valentine to recommence their investigations on the subject. The result was a very elaborate description of the vesicle by Valentine, though still incomplete, for he had overlooked one important point,

the spot on the side of the vesicle. This deficiency in Valentin's description was afterwards supplied by Wagner.

Hence, it appears that, like many other discoveries in science, the germinal vesicle of the mammiferous ovum was discovered about the same time in this country and on the continent. But it will be seen from Mr. Jones's Memoir, that he had investigated the subject so fully and successfully, as to be able to give such a description of it as is only to be drawn from the united labours of Coste, Valentin, and Wagner.

A comparison of dates will determine the mere matter of priority. Mr. Wharton Jones's observations were made in the beginning of Sept. 1834, and his memoir read before the Royal Society, 18th June, 1835.

We may mention that MM. Coste and Valentin received the great prizes of the French Institute for their communications on the subject.

the rate-payers half a sovereign, and ruined the patient for life.

The cases of this sort reported in the newspapers form, of course, but a small fraction of those actually occurring. For though the supporters of the new law seem to think this kind of homicide very justifiable in the abstract, yet, when it comes to individual instances, neither guardian, surgeon, nor master of workhouse, is much inclined to boast of his share in the transaction. In plain English, there is no doubt that most of these cases are hushed up. Yet those which make their appearance in the daily papers are so numerous, that if we were to insert them all, we should have little room for aught else. On the other hand, it would be a base dereliction of our duty as medical journalists to pass them over entirely: for it must never be forgotten, that these horrors cannot be perpetrated on the large scale without the subserviency of medical practitioners. In single instances, indeed, as at Bridgwater, a board may run its wild course in direct opposition to the medical officers; but, on the long run, if surgeons would imitate the plain-speaking honesty of the one in the Portsea Union, who wrote down *starvation* as the cause of a patient's illness, some mitigation of the present cruelties must take place. Unsupported by professional authority, the boards would be forced to give up their water-gruel experiments, and would no longer be able to boast that, in grinding the faces of the poor, they were backed by those who ought to be among their most zealous protectors. The case which has elicited these reflections, and which is reported in the *Times* of January 16, would formerly have been called one of the most aggravated cruelty and oppression. In the present day, however, we suppose that some milder name must be found for it; for cases of a blacker

CICERO.

ANOTHER DEATH FROM STARVATION.

WE had almost given this article the title of *another half-crown saved*; for the practical working of the Malthusian Act has made the loss of a life and the gain of a piece of money convertible terms. When the Poor-Law Commissioners point with triumph to the savings effected by the new system, they ought in candour to tell of the mortality from typhus fever in their workhouses; and if the Bridgwater Guardians are allowed to exult at the dexterity with which they baulked their surgeons of their fees, they should at the same time narrate the case of Charlotte Allen, where their frugality gained

dye occur so frequently, that the death of an aged woman by hunger and cold, from the refusal of all efficient relief, shews fair in comparison.

The inquest on this victim to the new boon to the poor was held at the Plough Inn, Clapham Common, on the 12th and 15th of January. Her name was Mary Stonard, and her age 61. The evidence was as follows:—

Charles Hughes, waiter at the Plough, deposed that on the 11th the deceased and another woman came into the tap-room; the former was so exhausted that she could hardly walk; her companion called for a pint of warm beer, and gave it to the poor old woman, but she was unable to take any. *“Some parings of potatoes were on the table, which the female who was with the deceased solicited to have, observing that herself and the deceased were almost starved to death. The latter at this moment fell upon the floor insensible.”*

A surgeon now attended, who adopted the almost universal practice in all cases of apparent death, or insensibility from accidents*—that is, he opened a vein; but the unfortunate woman was past all human aid.

A police constable then produced twenty-two duplicates, and a snuff-box of no value, which he found on the person of the deceased; with a few pieces of coke, and a farthing in money.

Mary Ann Stonard, daughter-in-law of the deceased, deposed to the privations which the deceased, her husband, and the witness, had suffered together for some months; the old man having long been so lame and infirm as to be incapable of work, and the occasional relief obtained from the parish of Putney having been so trifling, as scarcely to keep them from starving.

“On Thursday morning the deceased

applied for relief, but was refused, the relieving officer observing, that if she wanted any she must go to the Board of Guardians of the Wandsworth Union, at Clapham; *her mother started to go, although the distance was four miles.* A female, named Sarah Beadle, accompanied her, as she was in a very weak state from want of nourishment.”

Daniel Stonard, the husband of the deceased, a poor emaciated old man, who could not walk into the room without assistance, stated that he had long been out of employ, and that his family lived by a little washing, which his daughter and late wife occasionally obtained, but which was scarcely enough to keep them from perishing. The relief given by the parish was so scanty as to be of very little avail. On the Saturday previous to the death of his wife they obtained 1 pound of mutton, and two 2 pound loaves. *This was the first relief for several weeks.*

“A few months back himself and his wife were sent to the Board of Guardians at Clapham for relief; they waited from 9 o'clock in the morning until 6 o'clock in the evening, but obtained none.”

Relief, indeed!

He also said that the parish of Putney consented to take him and his wife into the workhouse, but that she refused, *dreading the regulations which are enforced by the new system.*

James Unwin, the relieving overseer, said that the deceased applied for relief about a month ago, when, in pursuance of instructions from the Board of Guardians, he told her he would give them an order to go into the workhouse, which she refused to accept. She was a hard-working, deserving woman.

Mr. Greenwood, a surgeon, stated that he had examined the body of the deceased, and found all the internal organs healthy. The stomach was contracted, and quite empty. The witness

* Vide MEDICAL GAZETTE, vol. ii. p. 214.

was decidedly of opinion—that Mary Stonard died from exhaustion, owing to the want of the common necessities of life, coupled with the extreme severity of the weather.

The jury returned as their verdict, “That the deceased died from exhaustion, induced by the extreme severity of the weather acting on a frame very thinly clad, fatigued, and in want of the common necessities of life.”

Few, we should hope, of those who voted for the Poor-Law Bill, imagined that we should so soon reach such an *acmé* of cruelty. Little did they think it would so soon be the glory and the shame of our legislators to make the workhouses of England so terrible, that lingering death, by starvation, was to be preferred to them. Mary Stonard's choice was a natural and a common one.

It appears that from the severity of the weather, and the consequent suspension of labour, the distress among the poor of Maidstone has been most alarming. A meeting, to take their state into consideration, was held in the town on the 15th instant, with the senior churchwarden in the chair. He observed that representations had been made to the Commissioners on the subject, and their reply was, “Fill all the workhouses, but relieve no one.” In consequence, at the last meeting of the guardians, orders had been made out for the admission of about 100 persons who had applied for relief, but with two or three exceptions, the poor had refused to accept them. In one case a gardener, whose employment was put an end to by the weather, applied for relief, and received an order for himself, his wife, and six children, to be received into the workhouse; he and his two eldest children to go to one house, and the mother and the younger children to another. “He resisted this separation as long as he could, but at last he went,

and said it was impossible to exist in the state in which they were,—they had no fire, and had been living on cold potatoes for a week! His wife, true to a mother's feelings, still refused to go into the workhouse.” Had it not been for the exertions made in behalf of this poor gardener by the worthy churchwarden, eight more inquests must have been held, and eight more items added to the long catalogue of Poor-law slaughters; while the Commissioners would have pointed with triumph to the immense savings effected in the Maidstone Union.

The triumvirate refuse to give outdoor relief, they do their utmost to make the workhouses intolerable, and then they cry out with a sneer, “Why don't you go into the workhouse, if you want relief? You'll find shelter there, and plenty of physie, and some water-gruel.”

We scarcely know where to find the counterpart of this system; but it has some resemblance to a strange story which we have read, but which we certainly never expected to find paralleled in real life, and above all in England.

The inhabitants of a certain town complained that their hospital was too full, and consequently too expensive; on which a vigorous economist undertook to relieve them. He went into the hospital, and whispered it among the patients as a great secret, that it was the intention of the governors to sacrifice the patient who was most desperately ill, for the benefit of the rest. In fact, the sick man most utterly despaired of was to be put to death, and administered in the form of *spiritus cranii humani*, &c. &c. to his fellow patients. The man who supposed himself to be intended by this description, got out of bed as well as he could, and crawled home. The frightful report still continued, and one after another made his escape, till the hospital was cleared. The satisfaction of some of the rate-

payers is said to have been extreme, but we do not recollect whether the feat was called a boon to the sick. The great difference between this story (which we used to consider as a mere extravaganza) and the present method of clearing workhouses is, that in the former case the patients were driven out by the fear of an imaginary ill; in the latter, the indigent are thrust out, or deterred from coming in, by real and tangible miseries. The wretched woman at Putney, or the hundred victims of Malthusian principles at Maidstone, were not scared away from the Union bastiles by ideal fears, nor even by reading dietaries in Poor-Law Reports; but they had heard from friends and relations who had escaped from these dens, of the meagre broth, the minute slices of bread, the "never-ending, still-beginning" doses of water-gruel; and, worse than all, of the contempt of all the charities and decencies of life—of the separation of husband from wife—of mother from child!

Let us hear, then, no more of the savings of the new system; or if Mammon cannot refrain from counting his gains, let him be reminded at each page of his balance-sheet, that even gold may be bought too dear; and that those who coin the blood of the poor for drachmas, are not better than speculators in human flesh, and must rank with kidnappers and slave-dealers.

UNIVERSITY OF LONDON.

It is amusing to learn, that, by one of those numerous happy circumstances which have characterised the rise and progress of this institution, the charter was so framed as to expire with the demise of the crown. The consequence of this was, that from the death of his late Majesty until last week (when a new charter was completed), the University had virtually become a nonentity.

Two of those originally nominated

having declined to act—namely, Mr. Sheepshanks and Lord Brougham—the places have been severally filled up by the addition to the Senate of the Bishop of Norwich and Dr. James Somerville. The latter gentleman, it may be remembered, was proposed by Mr. Warburton, as secretary, or registrar, to keep the records of the institution, but it was understood that the other members of the University could not be induced to concur in the appointment. At that time it is evident that the idea of his being made one of the Senate had not yet suggested itself. Those in the secret assure us that the nomination has been made in order to give *weight* to the medical department.

CLINICAL LECTURE

Delivered, Dec. 16th, 1837, at the Middlesex Hospital,

By DR. WATSON.

Pleurisy—Signs of Effusion—of Distension of the Pleura—Diagnosis—Treatment—Question of Paracentesis—New Auscultatory Signs consequent on the operation—Period when it should be performed—Results of the operation in several cases.

GENTLEMEN,—The case of the patient whose dead body we examined last Monday, has been one of painful interest. You expect, I am aware, that I should make it the subject of my lecture to-day; and though I have little more to say than what I have said already, and many times, in our familiar and more strictly *clinical* confabulations, it may be useful to some among you, if I review the whole case collectively, and again point out the various lessons and practical considerations, which it appears to me to furnish.

Thomas Coggs, aged 25, was admitted on the 20th of September, with the ordinary symptoms of acute pleurisy, namely, a stabbing pain beneath the left breast, shooting round at times to the spine, increased by movements of the body, and by a deep inspiration; frequent breathing; inability to lie on the painful side; thirst and fever.

The pain came on suddenly in the night of the 16th; at first it was unattended with cough.

On his admission we discovered the physical signs of effusion into the left

pleura; dulness on percussion over the lower part of that side; and what is called *œgophony* about the inferior angle of the scapula. In spite of treatment, fluid continued to be poured forth, until the whole of the pleura was distended with it, and the lung of that side rendered useless, and the heart dislocated.

The treatment consisted in venæsection, leeching and cupping the affected side, purgatives, calomel and antimony, calomel and blue pill combined with opium.

How did we know that the left pleura was full of fluid—was *distended* by it?

By the following circumstances, to which I beg your attention:—Complete dulness on percussion of the whole of that side; a total absence of the vesicular breathing; the bronchial voice and tubular respiration, along the side of the vertebral column; inaction of the left side during respiration.

But perhaps you will object that the circumstances I have just mentioned might result from some other condition of the parts within. Suppose the whole lung rendered solid by inflammation (hepatized, as they say,) so as to admit no air; this, also, would cause dulness on percussion, bronchial voice and breathing, immobility of the diseased side. True. And how, in such a case, is the diagnosis to be made? We had unequivocal additional signs to guide us. But supposing we had not; let me take this opportunity of telling you the points to be looked to in a more ambiguous case than ours.

First, then, we distinguish such cases, whereof the physical signs are much alike, by their *history*. In Cogg's we had the history of pleurisy: sharp pain without cough, without expectoration, preceded the dulness, and so on. And we had *not* the history of pneumonia—no crepitation—no rusty expectoration.

But setting that help aside also, for we may sometimes be called upon to treat a case of which we can obtain no previous history, we still may be assisted to the discovery of the true nature of the disease by attending to various particulars, some of which I will now mention:

1st. The dulness was *complete* and *uniform*. This is seldom the case when the lung has been solidified by pneumonia, still less when by tubercular deposit. The dulness is then partial; or if it extend over the whole side, it is unequal in degree in different places.

2d. The intercostal depressions were effaced; the diseased side was smooth and level: on the other you could trace the ribs, and the furrows between them, by your eye. This is a sign of distension: the intercostal muscles are stretched, and contract no longer. There was no *bulging* of the intercostal spaces; they never, I

believe, become prominent, but they are raised to the level of the bones, and the surface is even. Now when the lung itself is rendered solid by disease, it does not thrust outwards and obliterate the intervals between the ribs. This, consequently, is an important circumstance to notice in doubtful cases. It has been particularly studied by Dr. Stokes, who attributes the yielding of the intercostal spaces to the effect of the *inflammation* of the costal pleura upon the muscular tissue in contact with the inflamed membrane. It seems to be his opinion that the muscles are involved in the disease, and lose their contractile power. The same physician states that the elevation of the intercostal spaces does not occur in simple hydrothorax, independent of inflammation. But in simple hydrothorax we do not meet with a sufficient quantity of fluid to compress the whole lung, and then to exercise a centrifugal distending force; and this appears sufficient to explain the difference.

3d. The dulness on percussion did not stop short at the middle of the sternum, as it does when it results from a solid state of the lung, but extended some way beyond it, towards the right side. This is another valuable sign of distension. The mediastinum is forced out of its natural place.

4th. When one's flat hand was laid upon the patient's left side, and he spoke, no vibration of his voice, or next to none, could be felt; while on the right side, where the vesicular respiration was loud and *puerile*, and the voice natural, the thrill was strong. This would not have been so had the lung been *solid* on the diseased side; the difference would have been the other way; the thrill would have been stronger on the dull than on the resonant side. When the lung is merely rendered solid, the larger bronchial tubes are not compressed, as in a greater or less degree they are when the pleura is distended by a liquid; and the vibration occasioned by the voice is more readily conducted, as its sound is, through the solidified than through the spongy lung. Of this I had painful evidence (though I had noticed the fact before) in the person of one of my colleagues at King's College, the late Professor Burnett. He first asked me to examine his chest, during the Christmas holidays in 1834. The right side was perfectly dull, from the clavicle to the mamma; the voice heard in the same part, by means of the stethoscope, was startlingly harsh and loud; and the thrill, felt by the hand, much more manifest than on the left side, which was comparatively exempt from tubercular deposit.

I reckon this a most valuable distinctive mark, for it is within the reach of the

most ordinary observation. It requires no tact or practice, or education of the senses; but when once the attention has been called to it, is as readily perceptible by a nurse, or by the patient in the next bed, as by ourselves. If one side be morbidly dull, and the thrill is greater than on the other side which sounds healthy, the dullness denotes solidity of the lung; if the thrill be palpably less, the dullness signifies that there is liquid in the pleura. This simple test may often decide the question between the consequences of pneumonia, or of pleurisy. I observe that it is mentioned by Dr. Williams, in his lectures now in the course of publication, and his observations are generally very exact. Dr. Stokes notices, also, this vibration; but is, I apprehend, in error, when he says, that "hepatization of the lung seems to *diminish*, but not to remove it." But this thrill is not always present in the healthy state, and then we can infer nothing from its absence on the diseased side. I could discover none on either side, in Dr. Hawkins's patient, on whom paracentesis thoracis was performed yesterday. This was owing, I believe, to the feebleness and higher pitch of her natural voice. The deeper and louder the voice, the greater *ceteris paribus* will be the vibration.

I have pointed out, then, certain signs, for which we look to assist us in equivocal cases. But Coggs's case was not equivocal; there were other signs that made it plain, even if we had not known, as we did know, his history.

One of these was the situation of his heart. I have told you that the dull sound produced by striking his chest extended some way beyond the middle of the sternum, and certified that the mediastinum was pressed over in that direction; and the heart could be heard, felt, and seen to pulsate, quite on the right side of the sternum, near to, and just within the right nipple; and it could not be seen, felt, or heard, in its proper situation. This circumstance, taken in conjunction with the rest, was conclusive of the fulness of the left pleura, even to distension. The heart is, indeed, sometimes naturally placed on the right side, all the viscera being transposed; such was the case in a patient of mine who died in the hospital two years ago. But such deviations from the general rule are very rare; and the morbid signs co-existing with the displacement of the heart in Coggs, as well as his history, forbid any suspicion of its being natural.

Another conclusive circumstance was, that the left side of the thorax was found, by measurement, to be larger in circumference than the right,—nearly or quite an

inch larger. Now Dr. Stokes has ascertained that, in right-handed persons, the right side is often the larger of the two, mainly, perhaps, by reason of the greater bulk of the muscles spread upon it; and a French writer (M. Woillez) has recently put forth a similar statement as the result of numerous measurements.

That the *left* side is the largest in disease is therefore a strong circumstance, and, taken together with the other signs, quite decisive. You are to remember, that the chest may enlarge on one side under other conditions of disease—in emphysema of the lung, for instance; but then percussion and the stethoscope will furnish very different information from what they gave us in Coggs's case.

It often happens that the integuments of the distended side are œdematous; but no œdema existed in this instance.

The case, then, was clearly a case of large effusion, the result of acute pleurisy; and when the inflammation was at an end, this new phenomenon occurred. At first the patient could not lie on the left or diseased side; after the pleura became distended he could not lie on the right, or sound side. His favourite posture was *towards* his left side; not *on* that side, nor on his back, but between the two positions.

It is a circumstance also well worthy of notice, how little this state of things—this abolition of the use of one lung, and this encroachment on the space in which the other had to play, by the heart and mediastinum—interfered with our patient's respiration. Lying at rest in his bed he did not complain of, nor did he manifest, any shortness of breath or embarrassment in respiring. Probably he would, if he had got up or made exertions; but you will sometimes meet with persons who move about briskly in their ordinary way, without distress, though one pleura is full of fluid. Andral relates examples of this; and I had one here some time ago in a butcher, who could not be persuaded that any thing remained the matter with him, and insisted on going out. On the other hand, in some the dyspnoea is extreme.

On what does this difference depend? Partly, perhaps, on the suddenness or slowness of the effusion; yet that cannot be all; partly on the soundness or unsoundness of the other lung; partly, I conjecture, on the fact that some persons seem to have an excess of the power of breathing—more lung in reserve than under ordinary circumstances they want. Dr. Latham has glanced at this peculiarity in his valuable little book on Clinical Medicine.

In the present case the means em-

ployed had failed to prevent or check the effusion; and the effusion having taken place, what was next to be done?

Why, to put the patient into the state most favourable for the reabsorption of the fluid. For that purpose I kept his blood-vessels empty by low diet; I gave him diuretics, mercury till his gums were affected, blistered his side repeatedly, and rubbed upon it a combination of mercury and iodine.

But in vain. The treatment had little or no influence upon the amount of the effusion. He grew thinner and weaker; his pulse became more and more frequent, and feeble. Although he had no distinct paroxysms of hectic fever, no succession of chilliness, dry heat, and sweating, his face wore a hectic flush. All this while his breathing was tranquil.

And now was pressed upon me the question, whether my duty to the patient did not require that I should have the fluid removed by mechanical means—whether I ought not to request my colleague, Mr. Arnott, to puncture his thorax? A most grave and anxious question; and one so difficult, that even now I am fearful of leading you wrong by giving any decided opinion respecting it. But I feel bound to tell you what is passing, and has passed, through my mind on the subject; and having told you this, I must leave the matter to your own future judgment.

It has been a sort of rule with me, not to propose the operation of paracentesis thoracis in cases of pleuritic effusion, except in one or the other of the two following conditions:—1. When the effusion is increasing, and embarrassing the patient's breathing, and threatening to suffocate him, or to put a stop to the action of his heart; and, 2. When the patient is obviously losing ground from day to day, and early death, without the operation, appears inevitable, even although his respiration is not materially affected*.

Such has been my rule for these reasons:—

1. Persons who have been attacked by the disease we are now considering generally recover. It is an uncommon thing to have a patient die of *simple uncomplicated pleurisy*. The effused liquid is for the most part reabsorbed; the lung expands again, or the walls of the chest shrink in-

wards; and the ultimate state of such a patient is as good as it probably would be after a successful tapping.

2. The operation is attended with some pain (though that is trifling), always with some risk, and not seldom with considerable hazard. Not risk belonging to the operation itself, which is simple, and does not concern vital parts; but risk from its consequences. It may rekindle the inflammation; the admission of air into the pleura, which cannot, I believe, be prevented, is apt to convert the adhesive inflammation into the suppurative, or to produce decomposition of the effused liquids; and either of these possible consequences would certainly augment the danger of the patient. It is satisfactory to me to find that Dr. Stokes, in his recent most instructive work on Diseases of the Chest, expresses similar opinions. "The cases," he says, "which seem to demand the operation are those where a rapid acute effusion threatening life occurs; and next, chronic cases which resist treatment. But even in these cases, *if life is not threatened*, it seems much better not to operate, but rather give the patient the chance of the ultimate absorption of the fluid."

In our case life was threatened. Cogg was gradually but evidently sinking under the disease. He became more and more emaciated, although, after the failure of the abstinent system, I had given him tonics, and a full supply of nourishing food. His hips were beginning to get sore. I then explained to his father, that he would certainly die if the operation were not done; and that the chance of his being saved by it was small; yet it offered that small chance. And I stated the same thing, with as much plainness and delicacy as I could, to the patient himself; and I suffered them to determine. They both wished for the operation, which Mr. Arnott, as you know, performed on the 29th November, eleven weeks all but two days from the commencement of the pleurisy. A grooved needle, as recommended by Dr. Thomas Davies, was first introduced between (I think) the sixth and seventh ribs. This is to ascertain whether there is fluid within the reach of a trocar at the place of the puncture; and if so, the nature of that fluid. A collection of pus would require a larger trocar for its evacuation than a collection of thinner fluid. A serous liquid trickled out when the needle was withdrawn. Then a trocar was inserted, and upwards of five pints of a transparent but reddish liquor were let out, quite free from flakes or any puriform admixture. Air entered and escaped freely, as he breathed, during the emptying; and whenever he coughed the fluid spurted out with great force. I kept my

* Those cases of empyema are here excepted, in which a soft inelastic tumor presents itself, generally in the fore part of the chest, shewing a tendency in the confined liquid to make its own way outwards. Such a tumor should be punctured at once, for the liquid is always pus; there is no chance of its being re-absorbed; and if the swelling be left to itself, troublesome burrowing sinuses will be apt to form in the thoracic or abdominal parietes.

hand on his right side, where the heart was beating, and I observed that it did not move off in any degree to its natural place. When the fluid ceased to escape, except in minute quantity, even during the act of coughing, the opening was closed by adhesive plaster, care being first taken to expel, by desiring him to cough, as much as possible of the *air* also that had entered.

He was much troubled with cough during the operation, and immediately after it he had an opiate.

When I visited him in the evening he had had some sleep, and said he felt lighter; and seemed pleased to tell me that the moment he lay down after the operation, he found he could lie on his right side, which he was previously unable to do.

This has been noticed in other cases. What does it shew?

You must know that differences of opinion have existed as to the cause of the patient's inability, in *most* cases, (for it is not so in all,) to lie on the sound side, at an advanced period of the disorder. Some have thought that it is because the weight of the supernumerary fluid presses down the mediastinum, and so oppresses the healthier lung. Others have attributed it to the impediment which lying on the sound side offers to its own expansion: the muscles that dilate the healthy side have to lift, as it were, the weight of the body, and are, some of them, it is said, pressed upon and impeded in their action by that posture. Now the immediate effect of the removal of the fluid, in enabling the patient to lie on his right side, confirms the one of these two opinions, and completely disproves the other. The same, or very nearly the same, impediment as before to the elevation of the ribs on the healthy side would arise from lying upon that side. Doubtless the gravitation of the supernumerary fluid is the chief cause of the dyspnoea. Something may probably be due also (as Dr. Stokes suggests) to the pressure which that posture allows to be produced by the weight of the abdominal viscera upon the available portion of the diaphragm.

I was sorry to find that the heart was just where it had been before the operation. Percussion on the fore-part of the left side, which had previously given a perfectly dull sound, now gave a sound quite hollow and drum-like; much more resonant than the sound of the comparatively healthy side. The pleura evidently contained air in the place of that liquid which had occupied it in the morning.

I should have told you that on the patient's admission I could detect nothing wrong in the breathing on the right side;

it was clear, uniform—exaggerated, indeed, and puerile, as might be expected, but pure and equal every where. By degrees, however, we began to suspect that the lung contained tubercles; not only from the non-absorption of the effused fluid, but from the result of auscultation. A slight wheeze was occasionally audible at the upper part of the right lung. He coughed and expectorated somewhat; and his voice, to the ear placed upon the supra-spinal fossa, sounded unduly loud and resonant, and the respiration there was evidently tubular.

The patient remained easy, and thought himself better, for some days; but no essential improvement took place. Some remarkable modifications of the auscultatory signs, however, in consequence of the operation, it may be well to notice. The left side, as he sat up, was unnaturally resonant under percussion. There was still no vesicular breathing whatever to be heard in it. Nay, the bronchial breathing and bronchial voice, which existed between the scapula and spine, before the operation, had entirely vanished. How is this to be explained? Thus, as I believe. The bronchial breathing and voice are readily conducted to the ear laid against the side of the chest through a *solid* lung; less readily, yet still, in many cases, actually so conducted, through the *liquid* which fills the pleura and compresses the lung; but not at all, as it would seem, through *air* existing in the pleura.

You do not always, I repeat, hear it when the pleura is full of water. I could distinguish none yesterday in Dr. Hawkins's patient already referred to.

For a similar reason, there was still no vibration to be *felt* when the patient spoke.

But *those* sounds had now supervened which under the circumstances were to be expected. The whole of the fluid was not, perhaps, evacuated; some fresh fluid too, it was probable, had been poured out. I anticipated, therefore, the remarkable sounds which denote the co-existence of air and liquid in the pleural sac. Listening the instant he assumed a sitting posture, I distinctly heard, several times, a tinkle like that of a tin kettle slightly struck by a stick: I make no doubt this was caused by the dripping of liquid from the roof (as he sat) of the cavity. The voice had a strong metallic ring or echo, and so had the cough, especially just at its termination. I noticed also that a *borborygmus*, which took place in his stomach, had the same character, and seemed to the ear, placed against the side, to come from the chest. Also, when the patient jerked his body, I plainly heard the splashing of fluid in the pleura.

The circumstance of the metallic tinkling, and the ringing sound and echo heard with and after the voice or a cough, prove (what however had been proved before, by Dr. Williams, in opposition to the opinion of Laennec,) that a fistulous communication with the bronchi is not necessary to the production of such sounds, nor any communication with the external air: for the wound was closed up, and (as we afterwards saw,) no communication with the air-tubes existed. The sound acquired by the rumbling in the stomach illustrates also Dr. Williams' remark, that the metallic sounds may be conveyed from without, when the sac is closed. He states that he has known the pulsation of the heart cause a tinkling echo in pneumo-thorax.

On the 4th of December, five days from the operation, he became rather suddenly faint and sick, lost his appetite, and vomited his food: and his pulse, which had been about 120, rose to more than 130.

He rallied somewhat after this; but on the morning of the 9th he was attacked with dyspnoea—his countenance became sunk and cadaverous—some crepitation was audible in the right lung—he had “the rattles” in his throat—and at 3 o'clock, on the tenth day after the operation, he expired.

When the body was examined, the intercostal spaces were observed to be still much less distinct on the left than on the right side. One of them being punctured, there was no audible rush of air either inwards or outwards, but the gas which quietly escaped soon made itself sensible by a most disagreeable odour.

Two large oblong openings were made by removing a portion of the parietes of the thorax on each side of the sternum, which was left.

It was then seen that the mediastinum was pushed much over towards the right side, the left margin of the right lung appearing without and beyond the line of junction between the sternum and the cartilages of the ribs; and the heart lying still further over. The right lung was unadherent, but a small portion of it, as big as a French plum, at its very summit, was rendered quite solid by clustered tubercles. In various other parts of the same lung small tubercles were thinly scattered.

In the left pleural cavity, besides air, there was a considerable quantity of an opaque grey sero-purulent liquid, containing flakes and granules of lymph. The lung, with its division into lobes still evident, adhered, like a flat broad cake, to the mediastinum from one extremity to the other, and from sternum to vertebrae.

A large membraniform sheet of lymph

hung loose like a curtain at an equal distance between the ribs and the compressed lung: it was ragged and largely perforated towards the diaphragm. The inner surface of the cavity was universally smeared with pus, or puriform lymph.

The right bronchus was now firmly tied, and air was forcibly blown through the trachea. This raised and swelled out the adherent lung to a considerable extent, cracking in several places the layer of lymph spread over it; but the lung subsided again to nearly its former dimensions when the inflation was intermitted.

The adhesion of the flattened lung to the mediastinum was very firm: when it was divided by a scalpel, the cut surface appeared red, and like the section of a muscle; but it crumbled in a slight degree under pressure; and portions of it, cut off, floated upon water. No tubercles could be detected in it.

Such is the case I was desirous of bringing fully before you, as an instructive example of pleurisy and its consequences, and as a text which admitted of much practical comment. One more circumstance connected with it I may now point out—viz. that whereas, up to the time of the operation, the inflammation had been of the adhesive kind, or stage, it was afterwards converted into the suppurative. This was the effect of the admission of air into the pleura: it is a very common consequence of the access of air to an inflamed surface; we see it in the case of simple incised wounds, and under various other circumstances which I have not leisure to specify.

Did Coggs die sooner than he would have done if the operation had not been performed? I cannot tell. He could not have lived long without it. The operation was followed by no immediate ill consequence, but by some degree of comfort. Yet I think the patient's life may have been slightly abridged by it; but it afforded him a chance, and the only chance, of escape. His condition may be compared to that of a man left by a wreck on a barren rock, near an uninhabited but fertile island, surrounded by a dangerous surf; if he remain on the rock, he is infallibly destroyed by famine; if he plunge into the sea, he incurs the risk of perishing in the breakers, but he has the chance of reaching the shore, and of living.

Certainly the most important question arising out of these cases is the expediency of the operation; and if it be expedient, the time for its performance.

The advocates of the operation, even under other circumstances than those which I have already spoken of as governing my own determination, allege that if it be delayed beyond a certain period

the compressed lung becomes unable to expand, both by internal adhesion of its vesicular texture, and by the firm coating of lymph which is almost always spread over it, and too often binds it inextricably down; whereas, they say, if the liquid that presses the lung into a heap be let out *in time*, the lung will receive air and rise again, even in spite of the soft layer of lymph which may envelop it. If this be not done, and the patient should survive, he recovers (they further argue) with the loss of one lung, and subject, as long as he lives, to the inconvenience, deformity, and hazard, belonging to such a loss. The hazard is of this kind:—the other lung, called upon for a double quantity of work, will, on that account, be more than naturally prone to take on disease; and such disease occurring in it as might be harmless if the patient had both his lungs permeable and efficient, would be inevitably mortal.

If these arguments are valid (and it cannot be denied that they deserve an attentive consideration), the rules to be followed would appear to be these:—During the continuance of the inflammatory action, while there are fever and pain, and the other indications of inflammation still going on, the operation should not be done, unless suffocation, or syncope, are impending. After all signs of inflammation are over, a further short interval should be allowed, to ascertain whether the process of absorption commences. If it does, then the case should be left to nature and physis. If, on the contrary, the practitioner can satisfy himself that no diminution whatever of the effused liquid is taking place, then, while the adhesions and false membranes are yet fresh and tender, the pressure should be taken off the lung by letting out the water.

Such, I say, would seem to be the rules, supposing the advocates for an early operation are right. But I cannot venture to recommend you to adopt these rules, until more statistical evidence than we yet possess shall have been obtained of their propriety. The case now in progress, in Regent's ward, will furnish one datum towards the solution of the problem.

I imagine that after a certain space of time the lung will be quite unable to rise. How long exactly after the disease begins, it would be difficult to say. In Coggs's case, 11 weeks, all but two days, had elapsed. The effused fluid was still serous. It seems probable that the existence of tubercles in the other lung may have produced and kept up a state of the body incompatible with the absorption of the liquid.

That you may not form a more unfavourable estimate of the utility of the operation from this single case, than any sin-

gle case can warrant, I must tell you that we have had two patients in the hospital lately—one last year, one in the beginning of the present—in whom the same operation was completely successful. One of these was a patient of Dr. Wilson's, who has published the case, and a most interesting case it was. For your information I will state the heads of it, as given by him.

It occurred in a lad of nineteen. On his admission there were all the indications of copious effusion into the left pleura; the side enlarged and motionless, and dull on percussion; the intercostal spaces tense and even with the ribs; the heart beating to the right of the sternum; respiration puerile on the right side, inaudible on the left; *urgent dyspnoea*; a tendency to coma, marked by drowsiness, and blueness of the cheeks and lips: in short, the boy was on the brink of being suffocated. He had been ill about a month, and had been bled, and cupped, and brought under the influence of mercury. Dr. Wilson, with great promptitude and judgment, determined on letting out the fluid.

A grooved needle was first passed between the fifth and sixth ribs; and some serum following the puncture, a trocar was then introduced by Mr. Tuson, and nine pints of a clear fluid were drawn off. During the operation he became faintish at different times, and then the orifice of the canula was stopped for a moment by the finger. But the immediate effect of the tapping was most interesting and gratifying. While the liquid was flowing, the heart was observed gradually to move over from beneath the right mamma towards its natural situation, and his difficulty of breathing was greatly relieved. At the commencement of the operation he respired fifty times in a minute; at its conclusion thirty-eight times only. A good deal of air got in while the liquid was escaping, and for some days after the operation a splashing sound was audible on succussion of the chest, and one part of that side was unnaturally resonant, and the other part unnaturally dull, when struck, and whatever was the posture of the patient, the hollow sound was uppermost, and the dull sound was undermost; and when he sat up, or spoke, or coughed, a brazen resonance was heard by the ear applied to the scapular region. This lad got quite well, without the recurrence of a single bad symptom. He has since been here; and I understand that the left side is in a very slight degree smaller than the right.

The fluid evacuated in this case was clear and transparent. It separated, on cooling, into three parts; one of quite watery consistence, one more viscid, and a

third which constituted a soft transparent jelly-like mass of fibrin.

In this instance no injurious consequences arose from the free admission of air.

The other successful case to which I alluded happened in a patient of my own, Frederic Stevenson, thirty-seven years old. It was the more interesting, because the other lung was not healthy. He came in (last April) labouring under dyspnoea, pain in the left side, "under the heart," on coughing or taking a full breath, and inability to lie down. Three weeks before, being perfectly well, the pain seized him, and for a fortnight the orthopnoea had been present. The left side at its lower part was prominent, and one inch larger by measurement than the right. The intercostal spaces were effaced, and the sound was dull on percussion.

There were reasons, which I cannot now stop to give, for thinking that in this case the effusion was probably limited by adhesions. Four days after his admission, the pulse, which previously had been small and frequent (120), became intermittent, and rigors supervened. I was apprehensive that the heart's action might be fairly stopped, and I therefore requested Mr. Arnott to tap the chest; and fifty ounces of a lemon-coloured serum were let out, and then the wound was closed. This fluid separated also into two portions—one thinner and more serous, the other consisting of fibrinous blobs and strings.

No such separation took place in the fluid removed from Coggs' thorax. It had a distinct red tinge, but no red particles subsided on its being allowed to stand.

In Stevenson's case, the operation was done, according to his statement of dates, three weeks and four or five days after the inflammation set in. It succeeded perfectly. In two days the oppressed lung had resumed its place, for at the lower part of the left side of the chest, where no respiration was audible before the operation, large crepitation was now heard; and this gradually gave place to the healthy sound. The intercostal depressions were again visible, and the ribs moved as he breathed.

On the right side, in this man, a wheeze during expiration was heard at the upper part of the lung, and large crepitation in its lower lobe, and he expectorated mucopuriform matter, tinged with blood.

In this case, also, air freely entered and escaped during the operation, and its entrance and exit were marked by the accompaniment of the metallic sounds already spoken of.

Dr. Thomas Davies has published a tabular account of the operations of Paracentesis thoracis which he had then super-

intended. Of sixteen cases of empyema in which the operation was performed, twelve recovered; that is, the operation was successful in three-fourths of the cases—a very encouraging result. In three of the unsuccessful cases the lung could not expand after the evacuation of the fluid, in consequence of the thickness of the false membranes covering it.

The value of Dr. Davies' table would have been still greater, if it had shown in each case the time, after the beginning of the disease, at which the operation was performed; the symptoms which called for its performance; the nature of the fluid evacuated; and whether the effusion was on the right or the left side.

I have now witnessed five cases of paracentesis thoracis—two successful, and one unsuccessful, all noticed in the present lecture. A fourth occurred in a patient under Mr. Mayo's care. The operation was performed fourteen weeks after an attack of pleurisy occasioned by submersion in the Serpentine. Pus was let out in considerable quantity. The man died, exhausted, many weeks afterwards. The operation cannot therefore be called successful, for it was not followed by recovery; but it gave present relief, and prolonged apparently the patient's existence. The fifth case is still *sub judice* *. In all the five the disease was on the left side of the body.

ROYAL INSTITUTION.

Friday, Jan. 19.

Electric Induction.

THE first of the evening meetings of this useful and interesting establishment took place on Friday last, when its distinguished professor, Dr. Faraday, delighted a large assembly by an experimental illustration of the phenomena *electric induction*, and concluded by a brief statement of his new theory, which, although by himself modestly termed "a notion," until confirmed by the researches of others, will probably soon change the whole aspect of electrical science. For the full substantiation of his views, Dr. Faraday referred to his paper lately read to the Royal Society, and now in the course of being printed in its Transactions; and he now brought forward only those experiments which were most susceptible of demonstration before a public assembly. It would be doing injustice to the professor, were we to attempt to give more than

* This patient died subsequently to the delivery of the lecture. I intended to have said a word or two upon the fittest place for puncturing the chest, and upon the question of closing or keeping open the aperture; but I most not trespass any longer upon your time.

an abstract of the more prominent points of a lecture, in which experimental proof kept pace with the flowing words of the eloquent lecturer.

Electric induction is that property by which an electrified body can induce an opposite electric state in that part of other bodies to which it is approximated. Thus when a conductor charged with positive electricity is approached (but not within discharging distance) to one not electrified, the electricity of the latter, before latent, becomes developed; its negative portion being drawn towards the positive conductor, while its positive portion is repelled to the further end. A double electric state is thus induced in the uncharged conductor, without either receiving or giving any to the charged conductor, and remains so as long as the neighbouring conductor continues charged; but the moment that it is discharged or removed, the induction ceases, and the electricity returns to its balanced latent state. Now if we could divide the induced conductor into two, we should find one-half charged with positive, and the other with negative electricity; and the same result may actually be obtained by inducing electricity in two conductors in a line, with their ends in contact, and removing the further one whilst the inducing influence continues. All the common phenomena of electric excitement will be found to involve this principle of induction. Let two examples suffice. When we approach our knuckle to the charged conductor of an electrical machine, the electricity crowds towards it, being drawn there by the opposite electricity which accumulates from our body and contiguous objects into our knuckle, until we bring it within discharging distance, when the whole charge passes across the space at that point. In the Leyden phial or battery, the cumulative property of electric induction is exemplified in a higher degree. Here is an extensive conductor of tinfoil inside, communicating with the machine, separated only by the glass of the jar from an equally extensive conductor outside, in communication with the earth; the electricity excited by the machine passing into the inside of the jar, draws the opposite electricity from the earth to the outside, and the extent of the electrified surfaces and closeness of their approach give to the inductive attraction its greatest force; so that two enormous quantities of opposite electricities become heaped up close to each other, ready to discharge and equalise themselves whenever a conducting medium is presented to them. Dr. Faraday showed that where circumstances prevented induction, there was no development of electricity. Thus the interior of an electrified coal-seattle

showed no evidence of electricity, but its exterior being in inductive relation with surrounding bodies, was obviously electric.

Philosophers and mathematicians have generally sought to explain or calculate electric phenomena or effects under the hypothesis, that they are the result of attractive and repulsive forces, acting in straight lines, inversely as the square of the distance. The profound calculations of *Æpinus* and *Poisson* were founded on this notion. They considered that induction is the same law acting on distant particles, the intervening non conductor being wholly passive in regard to the electric force. Professor Faraday sought to bring this view to an *experimentum crucis*. If the forces are exerted only in right lines, electricity should not be induced in curves or round a corner. By several ingenious experiments, however, he proved that opposite electric states may be induced round a corner, and without any limitation to the law of right lines. This and other facts have brought him to the conviction, that electric induction does not depend on attractions and repulsions exerted between separated particles, but on a particular polarised state which the particles of non-conductors are capable of assuming, and which acts contiguously from particle to particle. We look with great interest to the further development of these views.

The learned professor, at the conclusion of his lecture, congratulated the members on the flourishing state of the Institution, which he added now received them with a *clean face*. He announced that a lady had just placed a thousand pounds to the credit of the Institution, the interest of which is to be applied once in seven years to a prize for the best work *On* (as we understood) *the Evidence of Design in the Works of Creation*.

Wind, N.E. and S.E.

Except the morning of the 18th, and afternoons of the 18th, 20th, and 22d, generally cloudy. Snow fell on the 18th and 19th.

Severity of the Frost.—In our last weekly journal we had to call the attention of the reader to the extreme degree of cold indicated by the thermometer on the morning of Monday the 18th: on the same day that this fact was published in the *MEDICAL GAZETTE*, viz. Saturday, the 20th, we had to record a degree of temperature still lower by six, viz. *five degrees below Zero!* being within 13 degree of the lowest ever, I believe, recorded in Great Britain.

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine,

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE VII.

Apparent Death—Errors as to the fact of Death—Signs of real Death—Cessation of the Circulation and of the Respiration—Uncertain signs—Certain signs: Rigidity, Putrefaction, Loss of Muscular Contractility—Causes of Death: External Violence; Natural Disease—Diseases of the Nervous System as the Causes of Death—Diseases of the Structures of the Cranium—Diseases of the Dura Mater: Idiopathic; connected with Affections of the Ear—Gorged condition of the Blood-vessels of the Dura Mater.

Apparent death.—Suppose you are called to a case of sudden death, and required to investigate the cause of it. Your first object, of course, must be to ascertain whether the death be real or only apparent. Do not, without examination, assume that death has taken place; do not hastily and positively affirm it. You will be placed in an awkward position if, after a positive declaration that the death is real, the person should at last recover.

On a superficial view there may be every appearance of death, and yet it may be merely a case of suspended animation; or a state of the system produced by disease closely resembling that of death. Syncope, apoplexy, catalepsy, concussion, even intoxication, may so perfectly simulate death, that it may be quite impossible

to determine the true nature of the case without close observation.

Errors as to the fact of death.—Nor are the signs of real death by any means so manifest and certain in all cases, as to render attention unnecessary. Authentic cases are on record, which indisputably prove that error as to the fact of death has been committed. Without doubt, in proportion to the progress of medical science and the improvement of medical education, the number of such errors has greatly diminished; and if it be right to judge of the state of medical knowledge in Europe a century ago by a test derived from the correctness of the opinion pronounced on this subject, the state of the science at that period must be deemed even more imperfect than it is commonly supposed to have been. Bruhier, in his treatise on the Uncertainty of the Signs of Death, published in 1740, records 181 cases in which apparent was mistaken for real death. Out of this number of persons, really alive, but supposed to be dead, it is stated that fifty-two were buried alive; that four were opened before death; that fifty-three spontaneously recovered after having been laid out in their grave clothes; and that seventy-two were erroneously reported as dead. It is impossible not to suspect that this statement is exaggerated; but Zacchias, Lancisi, Philippe Peu, Guillaume Fabri, Pechlin, Kirchmann, Kornemann, Winslow, Falconet, Rigodeaux, all cite examples of the commission of the like error. In the present state of medical science this mistake is not very likely to be made; yet the apprehension of its occurrence is by no means entirely removed from the public mind. A friend of my own, a medical man, laboured for years under such a terror of it, that he bound me by a solemn promise, if I should survive him, to take effectual care to prevent his being buried alive, by making such a dissection of his body as should be incompa-

tible with the continuance of life. He died several years ago, and I performed my promise.

Signs of real death.—There are positive and unequivocal signs of real death; and no well informed medical practitioner of the present day can possibly confound this event with the state of the system in apparent death, except from culpable carelessness. I cannot suppose that you will ever experience any real difficulty in arriving at a correct conclusion on the matter, because your instructed and experienced eye will commonly teach you the truth instantaneously and irresistibly; the conviction of which will be derived from a number of sources, which it might take you some time to discriminate. Still you ought to be familiar with the most certain signs of death, and to know where to look instantly and steadily for evidence of the event, in case any doubt should arise in your own minds, or there should be doubt in the minds of others.

The first event to which you should look is the state of the circulation. If there be complete and protracted cessation of the pulse of the heart and arteries, that will afford one evidence of the fact of death,—not, indeed, sufficient, taken alone, but unequivocal and certain if it be connected with another event, the existence of which you should next endeavour to ascertain, namely, the cessation of respiration. We know from direct experiment that the respiration cannot be perfectly and continuously suspended for the space of four minutes, without producing the complete and irrevocable extinction of life; at least so complete and irrevocable, that reanimation can be effected by no means yet discovered. But respiration may appear to be suspended when it is only exceedingly slow and faint, decarbonizing just enough blood to prevent the extinction of the irritability of the heart, but not sufficient to give it any sensible action.

Whenever you are in doubt about this, uncover the thorax and abdomen, and observe intently and for a long time continuously, whether any respiratory movements take place. Accustom your eye to judge accurately of these movements, which are highly characteristic, and to the experienced eye sufficiently obvious, when they may be overlooked by ordinary observers. Certain it is, that no faith whatever can be placed in the methods vulgarly recommended for ascertaining whether the respiration has ceased—namely, by applying a mirror to the mouth, or a downy feather to the nostrils. If the mirror be warmer than the expired breath, no sign can be obtained from it, because the breath will not be condensed upon it; while the mirror may become sullied by the insensi-

ble perspiration of the hand that holds it. As to the feather—

——— “By his gates of breath
There lies a downy feather, which stirs not.
Did he suspire, that light and weightless down
Perchance must move.”

But the Prince, when, trusting to this token, he bore the crown from the pillow of his royal father, was deceived by it; and so will you be, if ever you place the slightest confidence in it.

The certain signs of death.—If in any extraordinary case circumstances should occur to excite doubts in your own minds, or if you should be unable by the ordinary indications of death to remove the doubts of others, then you must wait until you are able to obtain one or more of the certain signs of death. The certain signs of death may be included in three—namely, rigidity, putrefaction, and loss of muscular contractility.

Rigidity.—Rigidity is that general stiffness of the body which comes on in a given time after the extinction of life. Doubts have been entertained whether this phenomenon be an invariable consequent of death; but Louis has set this matter at rest; for with the view of determining it, he made careful observation, in the hospital to which he was attached, on 500 cases of death, and never in a single instance found it absent. Subsequently it has been observed to be constantly present in a wide range of the animal scale—in all the mammalia, in birds, reptiles, fishes, mollusca, crustacea, and insects.

The seat of the general rigidity which follows death is in the muscles, for on the dissection of a limb in which it is fully developed, if the common integuments, aponeuroses, ligaments, and synovial membranes be removed, the stiffness remains; but, on the contrary, if the muscles are taken away, the other tissues remaining entire, the limb becomes perfectly flexible.

Though the rigidity of death always comes on in a definite time after the extinction of life, yet the period varies according to the state of the system, the nature of the death which has proved mortal, the mode in which it has extinguished life, and the condition of the atmosphere around the dead body. In general it appears early, in proportion to the feebleness of the muscles, and the general weakness of the system; hence it comes on rapidly in persons who die of extreme old age—of protracted fevers of the typhoid type—of chronic diseases which greatly impair the nutritive functions, and exhaust the powers of life, as consumption, marasmus, scrofula, &c. On the other hand, it appears much later when death takes place rapidly in the

athletic, in a vigorous state of the system; in accidental death from external injury, as from wounds; in concussion; in the different forms of asphyxia, and more especially in that which is induced by the irrespirable gases. In this latter case it appears so tardily, that Bichat, not continuing his observation long enough, concluded that the phenomenon is not constant and invariable.

The rigidity appears first in the muscles of the trunk and neck; it extends thence to the muscles of the lower, and last of all to those of the upper extremities. It disappears in the same order. The sooner it comes on the shorter is the period of its duration; and conversely, the slower it is to appear, the longer it lasts. It disappears the most rapidly in summer, in warm and damp air, and lasts longest in winter in a cold and dry air. Its mean duration is from twenty-four to thirty-six hours; but in a case of asphyxia, in which it did not come on until sixteen hours after death, Nysten observed it to last for the space of seven days. It is often fully established before the extinction of animal heat; and the most complete paralysis of a limb does not prevent its occurrence.

The limbs, and even the trunk of the body, may become stiff, during life, from several causes; but these are so manifest that I do not suppose you can possibly be in danger of overlooking them, or of confounding the stiffness from the spastic vital contractility of the muscles in syncope, catalepsy, epilepsy, or hysteria, with the rigidity that follows death.

Putrefaction.—Of course if any degree of putrefaction be present, indicated by a blue, green, dark brown, or blackish colour of the integuments, by a softening of the tissues, and the exhalation of the peculiar odour distinctive of the putrefactive process, there can be no question of the certainty of death.

Loss of muscular contractility.—In certain extraordinary cases, in which the cessation of the heart's action, the suspension of respiration, the extinction of animal heat, the general rigidity of the body, and the commencement of the process of putrefaction, are all doubtful, it has been proposed to expose a muscle by a small incision, on a part of a limb where such a wound can do no serious injury, and then either to irritate the muscle mechanically by pricking it with any sharp-pointed body, or to apply to it the stimulus of electricity or galvanism. It is ascertained by numerous and decisive experiments that the muscles retain the power of contractility for a certain time after death. If the stimulus of electricity or galvanism be applied to a muscle a few minutes after death, it causes it to contract with

extreme violence. The forearm of a man who had been executed was bent on the arm; an electric discharge was made on the extensor muscles; several men who held the limb in a bent position were knocked down by the force of the muscular contraction, which extended the limb. From numerous experiments performed both by English and French physiologists, with a view to determine the duration of this power, it would appear that under different circumstances it may be extinguished at any period from two to thirty hours after death. Although, then, the continuance of the contractility of the muscles, on the application of stimuli, be not a certain sign of life, yet the loss of that power is a certain sign of death.

The period immediately subsequent to death may, then, be divided into four epochs. In the first the animal heat remains, and the body continues flexible. In the second the body is rigid, the animal heat sometimes remaining and sometimes not. In the third the rigidity has passed away, the body again becomes flexible, and the animal heat is always extinct. In the fourth, putrefaction commences. The duration of the first period varies under different circumstances from half an hour to twenty hours. The duration of the second period occasionally is only from two to four hours, commonly it lasts from forty-eight to seventy-two hours, and it may be protracted as long as seven days. The third period, in winter, may last from five to eight days; and a case is on record (one of asphyxia from charcoal) in which an interval of fifteen days elapsed before indications of putrefaction were manifest.

You may be required to decide on the certainty of death during any one of these four periods. In the first it may be impossible to ascertain the fact without evidence that the power of muscular contractility is lost, which evidence you cannot obtain unless you lay bare a muscle, and apply to it some powerful stimulus, which, of course, you would not do without a cogent reason. You must therefore pronounce no positive opinion until the second period come on, in which the general stiffening of the body will place the matter beyond doubt. In the third period, when the rigidity has passed away, you will be enabled to pronounce an equally decided opinion, if, together with the coldness of death, there be an extinction of muscular irritability; and in the fourth period, the presence of any degree of putrefaction will place the matter beyond all possibility of doubt.

Causes of death.—Suppose, then, the death to be real. The body has been found in some unusual situation. No history of the case

can be obtained. Or suppose that a person has died suddenly, under circumstances which have excited a suspicion of poisoning. No one is at hand able and willing to give a true account of the circumstances which preceded and accompanied the fatal event. You are called upon to ascertain the real cause of death; you are required to state the evidence on which you ground the opinion you deliver. The only sources from which, under such circumstances, you can derive the information which will enable you to form a decision, are the appearances on the exterior of the body, and the condition of its internal organs.

External violence.—The appearances on the exterior of the body will, in general, enable you to decide whether or not death has been produced by external violence. The indications of external violence of such a kind and degree as may prove mortal, I shall particularly describe when I treat of death occasioned by wounds, bruises, and so on.

Natural disease.—At present I suppose the death in question to be produced by some natural disease having its seat in the interior of the body. When natural disease is the cause of death, where are you to look for evidence of that fact? In the brain, in the spinal cord, in the heart, in the large vessels, in the lungs, in the stomach, and in the intestines. The nervous, the circulating, the respiratory, and the nutritive systems—not one of the organs belonging to either of these systems, but may be the seat of a malady that may prove rapidly mortal. When it does so, how is it to be known? By the lesion of the organ that is the seat of the malady. But does that lesion always exist? Unquestionably always. Is it always manifest after death? For the most part it is. Is the appearance uniform? With few and rare exceptions it is quite uniform. When discovered may it form the basis of a sure and positive decision? In general it may. Is it easily overlooked? Sometimes it is very easily overlooked. Easily mistaken? Yes. Can it be to any one the basis of a sound decision, who does not study it? Never. Can it mislead any one who does study it? Never.

What the knowledge of structure, and the relation of vessel to vessel, and organ to organ, is to the surgeon, that the knowledge of the pathology of natural and more especially of sudden death is to the medical witness. Without this knowledge he must almost always be proceeding in the dark; with it, he has a clear and steady light always shining upon his path; without it, he has nothing certain from which to reason and to which to refer; with it, he has a standard of comparison to which he can bring almost every case upon which

he is called to decide. If you do not know what the diseases are which produce natural, and more especially very rapid death—if you do not know the morbid changes which indicate the presence and operation of such diseases, you cannot possibly distinguish between these and the effects of poison. Before all other things, then, you must study those organic changes which indicate the existence and operation of rapidly fatal but natural diseases.

Diseases of the nervous system as the causes of death.—On the diseases of this class which have their seat in the nervous system, the labours of modern pathologists have shed so clear a light, that it is scarcely possible for any one who avails himself of the knowledge already accumulated, to fall into essential error respecting these important maladies—most of them capable of proving rapidly mortal, all of them, until comparatively a recent period, involved in profound obscurity, very imperfectly distinguished from each other, and hardly more satisfactorily distinguished from the effects of poisons and even of external violence. Independently of their value to you as medical practitioners in the daily exercise of your profession, the pathological facts disclosed and discriminated in the works of Abercrombie, Alison, Brodie, Craigie, Cheyne, Hooper, and Bright, in our own country; and of Laennec, Foville, Lallemand, Magendie, Rostan, Rocheaux, and many others on the Continent, are capable of rendering you inestimable service in the study of forensic medicine—an application of the fruits of their labour which these honoured cultivators of our science could scarcely have had in view. On the present occasion, I cannot bring out of these treasures the riches they contain. I can do little more than direct your attention to them, and show you how you may appropriate them, rather by teaching you the mode in which they were obtained, and in which you must look at and study them, and imitate the labour that produced them, than by attempting to put you in full possession of them. As the precious materials they contain were drawn with much skill and unwearying exertion from the great mine of nature, so in applying them to your own particular purpose, you must work them up with something of the like skill and labour before you can derive real advantage from them.

Diseases of the structures of the cranium.—When about to examine for a judicial purpose the condition of the great central masses of the nervous system, begin by inspecting minutely the appearances about the head, and the state of the external scalp. Blows, lacerations, or wounds, either recently inflicted or of long stand-

ing, may have left external traces of their existence and operation, which may at once disclose to you the condition of the internal organs, and decide the object of your inquiry.

On the other hand you may find, as the result of natural disease in the integuments of the head, and in the muscular and tendinous tissues, inflammation, phlegmonous, erysipelatous, rheumatic, or syphilitic; you may find, intimately connected with the morbid condition of these structures, the pericranium inflamed, thickened, and separated from the bone; the bone itself dead and exfoliating, and extensive deposits of bony matter on the external surface of the skull. It is rare that these changes take place in the structures on the exterior of the head, without being accompanied with corresponding changes in the organs contained within the skull, in the dura mater, in the other investing membranes of the brain, and in the brain itself. You may, therefore, in general, infer with tolerable certainty, the existence of disease of a given character, in the internal organs, from the presence of diseases in the external tissues.

You may find, as the result of natural disease, the bones of the skull preternaturally enlarged, as in hydrocephalus. The extent to which this enlargement sometimes takes place, you see strikingly exemplified in the specimens and drawings before you. On the contrary, you may find the very opposite state, insufficient evolution, from the too early closing of the sutures, the result of which must necessarily be pressure upon the brain, just as when there is too rapid an increase of the cerebral substance. You may find imperfect ossification, either from deficient nutrition, or from preternatural distension of the bony parietes by the accumulation of fluid within the cranium; and the deposition of bony matter may be so imperfect, over a large surface, that the membranes of the brain, and the brain itself, may protrude, forming the congenital hernia cerebri.

You may find, as the result of natural disease, the skull preternaturally thin, when fluid has accumulated to a great extent within the cranium, as in chronic hydrocephalus; when partial or circumscribed accumulations of serum have taken place; when tumors or cysts have grown from the membranes or surface of the brain; when the glandular bodies around the longitudinal sinus are preternaturally large and abundant; and above all, when there has been excessive nutrition and consequent inordinate growth of the brain. If the thinness of the skull be confined to particular spots, beneath those spots you will commonly find some cause of pres-

sure; if the thinness be general or very extensive, you may infer that a general pressure has been applied, either from an excessive development of the brain or from the progressive effusion of fluid within the cranium. Pressure, from any of these causes, in proportion to the extent of it, must of course disturb the functions of the brain; and when it reaches a certain point, must inevitably extinguish life. Instead of deficient, you may find superabundant depositions of bony matter, which may take place to such an extent that the cancellated structure of the diploë may be entirely obliterated, and the structure converted into a substance resembling ivory rather than bone. You may be pretty sure that a cranium thus diseased does not enclose a sound brain. You will commonly find associated with this condition of the bony parietes of the skull, the morbid changes hereafter to be described as peculiarly connected with epilepsy, in fatal cases of which malady the skull is not unusually hard, dense, heavy, and three times its natural thickness.

Instead of a general thickening and induration of the bony structure, you may find irregular deposits of bony matter, occupying different situations and varying in extent, perhaps from minute spicular to masses so large that they greatly diminish the capacity of the skull, and even encroach upon the natural outlets, lessening and nearly blocking up the foramina, through which nerves and vessels pass. Of this morbid condition of the cranium, I show you striking examples in these specimens and drawings. Such preternatural and extensive depositions of bony matter must necessarily produce irritation, and perhaps pressure, and may cause death, either by apoplexy or by epilepsy, most commonly by the latter form of cerebral disease.

Thus even the solid case which encloses the brain, may be the seat of diseases of sufficient magnitude to occasion death; but these diseases are commonly connected with still more formidable maladies in the internal organs.

Diseases of the dura mater.—At particular points, or over large portions of its surface, the dura mater may be preternaturally adherent to the skull,—a circumstance very constantly associated with an inflammatory condition of the membrane and of the other coverings of the brain. On the contrary, a portion of it may be completely separated from the skull. The interspace may be occupied by coagula of blood, by coagulated lymph, or by pus. This morbid condition of the dura mater may be purely the result of natural disease, the consequence of inflammation commencing in this membrane as a primary

and idiopathic affection. Inflammation of the dura mater as an idiopathic affection is certainly rare, but still you may meet with it. In a case recorded by Dr. Abercrombie, a young lady was suddenly seized with severe pain in the left temple; to this succeeded a swelling of the left upper eyelid; her look became oppressed, and her pulse irregular, varying from 96 to 120. She sometimes complained of a good deal of headache, but at other times the pain was entirely absent. Shortly after the appearance of the swelling in the eyelid, she began to have severe shiverings, followed by heat of skin and profuse perspirations, and, in two or three days afterwards, she was seized with convulsions, followed the next day by increased headache, a more oppressed look, and an excessively irregular pulse, which sometimes little above the natural standard, at other times was exceedingly rapid. On the day following the attack of convulsions there was little change, but at midnight she became incoherent, and from this time sinking rapidly into a state of extreme prostration, she died in less than three hours after the appearance of the incoherence. On inspection of the body after death, there was found between the bone and the dura mater a good deal of purulent matter. The space in which this matter had been contained was defined by an irregular elevated margin of adventitious membrane, by which the dura mater had adhered to the bone, the included space being about the size of a crown-piece; it was on the anterior part of the right hemisphere. The dura mater included within this space was depressed; its surface was in some places ulcerated, and in others black; but the membrane was quite entire, and the bone was sound. On raising the dura mater, the inner surface of this portion had the same irregular ulcerated appearance as the outer surface, and when held up to the light, the membrane at the part appeared to be in some places considerably thickened, in others very thin. The right hemisphere of the brain, over all that part of it which is usually exposed in the ordinary way of opening the head, was covered by a thin uniform layer of very thick purulent matter, spread over it with great equality; and this being removed, an extensive stratum of adventitious membrane was found under the arachnoid. It was irregular in thickness, being most remarkable on the anterior part of the hemisphere, and disappearing on the posterior part. It followed the course of the arachnoid, covering the openings of the convolutions, but not dipping between them. The pia mater betwixt the convolutions was highly vascular, but without any deposition.

In this remarkable case the inflammation of the dura mater appears to have been the primary disease, though it was afterwards complicated with extensive inflammation of the arachnoid. But in general the separation of the dura mater, and the effusion of blood, lymph, or pus, between this membrane and the skull, is the effect of external violence. Whenever you meet with this condition of the dura mater, search vigilantly for proof of violence, if the evidence of it should not be apparent. It is often the direct result of fractures, and the secondary effect of blows and injuries inflicted either recently or at some remote period; and sometimes the remoteness of the period is exceedingly great.

But though inflammation of the dura mater, as an idiopathic disease, be rare, yet it is very frequently met with in a different form, in connexion with affections of the ear and the petrous portions of the temporal bone. Caries takes place in this portion of bone, and the dura mater corresponding to it becomes detached, thickened, spongy, or ulcerated. Sometimes the disease of the bone is confined to a small spot; at other times it is very extensive. Between the dura mater and the arachnoid there is a deposition of purulent matter, or of false membrane: this deposition sometimes extends along the tentorium, and purulent matter is also found in the cells of the petrous portion, in the canals of the ear, and in the cavities of the tympanum; and sometimes it extends into the cells of the mastoid process. Oftentimes this inflammation in the bones of the skull and the membranes of the brain, seems to develop latent diseases, and leads to the formation of scrofulous tubercles, or fungoid tumors, according to the constitutional predisposition of the individual. Occasionally a large collection of pus forms under the pericranium, behind the ear, extensively denuding the bone; and while the pericranium is detached on the external surface of the skull, the dura mater is equally detached on the internal surface.

These affections often attack most insidiously; they are highly dangerous in their nature, frightfully rapid in their progress, and constantly surprise the patient with death, when he is thought to be affected merely with common ear-ache. In these cases the discharge from the ear, not relieving the pain as it commonly does, but, on the contrary, the pain increasing in violence, the patient becomes oppressed and drowsy; the drowsiness is rapidly followed by delirium, the delirium by coma, and coma by death. In other cases, a purulent discharge from the ear having subsisted for some time, it suddenly stops;

the cessation of the discharge is followed by pain the ear; this by languor and drowsiness, which in a few days terminate in coma and death. A gentleman, about 70 years of age, complained of dull uneasiness in one ear. The seat of the pain he defined by planting the points of his fingers round the ear, so as to include a space of about three inches in diameter. There was no constitutional disturbance, and not the slightest danger was apprehended: one morning he was found in a state of perfect coma, and died in the afternoon.

A young man who had been liable to suppuration of the ear and deafness, was seized suddenly with deep-seated pain in the right ear, without fever. After a violent paroxysm of pain he sunk rapidly, and died within the space of a few hours.

On examination of the head, the petrous portion of the temporal bone was found black and carious; the dura mater corresponding to it was black, sloughy, and separated from the bone. Under the dura mater was a collection of pus and coagulable lymph, amounting to several ounces, which covered the whole superior surface of the right hemisphere.

A boy, aged 14, who had been affected for two months with headache and discharge of matter from the right ear, was one day attacked with increased pain, accompanied by giddiness and vomiting. Suddenly convulsions supervened, in a paroxysm of which he died. Inspection disclosed extensive caries of the pars petrosa, effusion into the ventricles, and abscess both in the cerebrum and cerebellum.

Occasionally, but much less frequently, inflammation of the lining membrane of the cavities of the nose, of the frontal sinuses, and of the ethmoid cells, seems to communicate disease to the brain, and proves rapidly fatal. Mr. John Pearson records the case of a child who was attacked one day with a slight erysipelatous affection of the nose; the next day he was seized with delirium, and the day following with coma, in which he died. Dr. Bright mentions a case in which, after great discharge from the nose, cerebral symptoms supervened, followed rapidly by death. Suppuration had taken place in the frontal sinuses, and a cyst full of muco-purulent fluid was discovered in one of the anterior lobes of the cerebrum.

The deposition of blood, lymph, or pus, between the dura mater and the skull, as the result of natural disease, may produce death, in consequence of the inflammation which has terminated in this effusion; but in proportion to the quantity of blood effused in this situation, pressure must necessarily be made upon the brain beneath; whence this effusion may occa-

sion death, with all the symptoms, hereafter to be described, of pressure upon the brain, and in the mode in which pressure ordinarily proves fatal.

Gorged condition of the blood-vessels of the dura mater.—But without any effusion, and without any other apparent disease, you may find the vessels of the dura mater preternaturally gorged with blood. This engorgement may take place to such an extent, that on the removal of the calvaria blood may issue from every divided vessel that united the two surfaces. The vessels may be not only turgid with blood, but they may be actually enlarged. Both conditions of the blood-vessels may be purely the result of natural disease—of long-continued inflammation of the substance of the brain for example, or of long-continued obstruction to the natural course of the circulation; conditions which occur in many cases of epilepsy, and in many of apoplexy. Whenever, then, you find the blood-vessels of the dura mater permanently enlarged and turgid with blood, search diligently for the cause of this state of congestion or inflammation. You may find it connected with congestion or inflammation of the brain itself as its primary seat, or you may find it connected with primary disease of some other and perhaps some very distant organ. You may find it connected, more especially, with a state of great congestion in the lungs, as in acute bronchitis, or with a preternatural dilatation of the chambers of the heart, or with a thickening of its valves, or with some other cause which has materially and permanently obstructed the natural course of the blood. But while this condition of the blood-vessels of the dura mater may thus be purely the result of natural disease, yet it is very important to bear in mind that it may also be the consequence of violence. It is sometimes found in death from submersion, as will be fully shown hereafter; and it is often the result of the mechanical obstruction to the return of the blood from the head, by the pressure of the cord in suspension. In this latter case it is not uncommon to observe, on raising the calvaria, both the surface of the dura mater and that of the bones of the calvaria mottled with drops of fluid blood from the torn vessels.

All the morbid appearances which have now been described, in as far as they are the result of natural disease, commonly give abundant indications of their presence during life, and sufficiently prepare the medical attendant and the surrounding friends for the fatal event. But some of them attack most insidiously, and all of them are capable of proving rapidly fatal without having excited alarm, and under circumstances which induce a strong sus-

picion of poisoning, or of the intentional infliction of some sort of violence. The study of the pathological appearances induced by these causes of death, as natural diseases, is therefore highly important with reference to forensic medicine, since it will enable you at once to determine the true nature of the case, and consequently to put an end to vague conjecture, and to remove groundless suspicion.

LECTURES
ON THE
ENTOZOA,
OR
INTERNAL PARASITES OF THE
HUMAN BODY,

Being part of a Course on Morbid Anatomy,
delivered at the London Hospital,

By T. B. CURLING, Esq.

LECTURE IV.

14. *Spiroptera hominis*.

THIS name is applied to a species of worm several of which were voided from the urinary bladder of a female, whose case is described by Mr. Lawrence in the second volume of the Medico-Chirurgical Transactions. A poor woman, living in the parish workhouse of St. Sepulchre, London, had been subject, since she was 24 years of age, to attacks of retentation of urine, accompanied with uneasiness in the bladder, and pains down the thighs. The employment of the catheter was attended with the discharge of large numbers of a vermiform substance, and small granular bodies regarded as ova. In the course of three or four months she passed about 1000 of these bodies, and has since, at various intervals, voided them in great abundance. The worm-like substances were of two kinds; the larger measured from four to six, and even eight inches in length, were attenuated at their extremities, contracted in the middle, and of a triangular form. They were composed of a solid parenchymatous substance without any trace of alimentary or generative organs, and they possessed so little the appearance of organized bodies, that Rudolphi and Bremser were inclined to regard them as portions of coagulable lymph moulded into a cylindrical form; an opinion, however, at variance with the fact that one of the angles or ridges constantly presented a beautiful crenated appearance. Their real nature, therefore, must be regarded as doubtful. But the animals referred by Rudolphi to the genus *Spiroptera* were some small worms transmitted to that naturalist in a separate phial, but

which were voided at the same time with the ova and larger parenchymatous bodies above described. They were of different sexes; slender, white, and highly elastic; the male measuring eight lines in length, the female ten. The head was furnished with small papillæ and a round mouth, and the body attenuated at both extremities. The tail of the male, more slender

than that of the female, emitted from its apex a small tube, probably the sheath of the penis. A dermal aliform production near the caudal extremity determined the reference of this entozoon to the genus *Spiroptera*.

The escape of the worm in this anomalous case was aided by the use of turpentine, both by the mouth, and injected into the bladder.

15. *Strongylus gigas*.

(from στρογγυλος, cylindrical). This is a dark-coloured worm inhabiting the kidney. As its name implies, it is of large size, sometimes attaining the length of three feet, and the thickness of the little finger. In the Hunterian collection at the College of Surgeons there is a specimen nearly of this magnitude which was found coiled up in the capsule of the left kidney, its glandular structure being completely atrophied. The male *strongylus* is less in size than the female, and is slightly attenuated at both extremities. The head is obtuse, the mouth round, and encircled by six hemispherical papillæ. The oesophagus is round, and dilates at about two inches from the mouth into the intestinal canal, a square and straight tube terminating in the anus. The body is slightly im-

pressed with circular striæ, and with two longitudinal impressions. The tail is incurved in the male, and terminates by a dilated pouch, from the base of which the single penis projects. In the female the caudal extremity is less attenuated and straighter, with the anus a little below the apex: the vulva is situated at a short distance from the anterior extremity, and communicates with a slender cylindrical

Anterior extremity of the Strongylus gigas, showing the commencement of the digestive, and the termination of the generative tube.

tube or vagina, about an inch in length, which dilates into the uterus, a canal about three inches long, terminating in the ovary, which is simple, and three or four times the length of the body. A nervous system can be easily and distinctly demonstrated in the *strongylus*. It consists of two slender nervous rings, one encircling the gullet, the other the anus, connected by a single cord running in a straight line along the middle of the ventral aspect.

From the few cases on record, it would seem that the *Strongylus*, both whilst in the kidney, and after it has passed into the bladder, occasions considerable distress and disorder in the urinary organs.—The *Strongylus gigas* is met with in the wolf, dog, horse, bull, and other animals, as well as in man.

Commencement and termination of the nervous system in *Strongylus gigas*.

16. *Ascaris lumbricoides*, *Lumbricus teres*, or Common round worm.

This worm, which is one of the most common infesting man, varies in length from about five or six inches to a foot, its thickness being about two lines. The body is round and elastic, and tapers towards both extremities. At the apex of the anterior is a triangular-shaped mouth, surrounded with three papillæ or tubercles, which characterize the genus. The pos-

c, Oral aperture.

terior extremity, at the apex of which a small black spot may frequently be observed, terminates in the male more acutely than in the female, and is also abruptly curved. The anus is situated, in both sexes, close to the extremity of the tail, in form like a transverse fissure. The tegumentary covering of the *Ascaris lumbricoides* is smooth, unctuous, and transparent, and is transversely furrowed with numerous fine striæ. The body is likewise marked with four longitudinal equidistant lines extending from the head to the tail: two lateral, and larger than the others, widen as they descend, but diminish again towards the caudal extremity. They are supposed by Cloquet, who has written an elaborate monograph on this particular worm, to

denote the situation of the principal vessels of the body. The dorsal and abdominal longitudinal lines are less distinct than the preceding, and correspond to two fine cords running beneath the tegumentary covering, and connected, anteriorly, to a slender white ring, encircling the gullet,

*Digestive and generative tubes of the male
A. lumbricoides.*

the whole constituting the nervous system of the ascaris. In the female the abdominal nerve, as it descends, forms a circle around the vulva. The muscular system is composed of two sets of fibres intimately connected with the integument; one set circular or transverse; the other longitudinal. The longitudinal are attached to the oral tubercles, which they serve to separate, and by this means open the mouth. The oesophagus is muscular, four or five lines in length, and separated by a well-marked constriction from the intestinal canal. The intestinal canal is readily distinguished by its brown or dark greenish colour, occasioned by the matter which it contains. It is a thin transparent membranous tube which proceeds nearly in a straight course to its termination at the anus. To its external surface are attached a great number of soft obtuse processes, the nature and use of which are unknown. They arise chiefly in the dorsal and ventral regions, and are continued from numerous transverse bands which pass across the body from one lateral vessel to the other. Both the obtuse processes and the transverse bands are composed of a homogeneous spongy tissue without any central cavity. This worm is oviparous, and the

f, Soft obtuse processes.

generative apparatus, in both sexes, occupies a great part of the body. In the female the vulva is situated at the junction of the anterior with the middle third of the body, and forms the entrance to a distinct vagina, which is about five or six lines in length. This leads to the uterus, which soon divides into two slender cornua or oviducts of a whitish appearance, which are many times longer than the body, and gradually diminish in size to capillary tubes, regarded as ovaries. These organs form numerous and almost inextricable coils around the alimentary canal, and one of them, unravelled by Hunter, measured more than four feet. In the male worm there is a single seminal tube, which, like the oviduct of the female, is a slender canal of remarkable whiteness,

much longer than the body, being nearly three feet in length, and likewise arranged in a similar tortuous manner. It terminates in a seminal reservoir, which is about an inch in length, and communicates with the base of the penis, a slender conical process, which may be protruded or retracted, according to circumstances, by muscular fibres adapted for the purpose. At the extremity of this organ a minute pore may be observed with the aid of the microscope. The females are more numerous and more frequently met with than the males.—These worms are not only found in man, but infest likewise the horse, the hog, and the ox.

The *Ascarides lumbricoides* inhabit naturally the small intestines, although they often make their way into the large, and are voided by stool. They sometimes even pass into the stomach and œsophagus, and escape by the mouth, or nostrils; and there are some rare instances on record, in which it is stated that they had gained entrance to the larynx and trachea. Laennec, Guersent, and Cruveilhier, have met with these worms in the hepatic ducts and biliary canals. The latter pathologist is inclined to believe that they had migrated into this unusual situation after death, or during the last moments of existence. Dr. Hodgkin alludes to two cases in which they passed out at an artificial anus. Sometimes only one or two are present in the intestines, at other times they exist in considerable numbers. Guersent and Dr. Hodgkin have found between fifty and sixty of these worms in one subject; and Dr. Hooper speaks of a girl, eight years of age, who voided upwards of two hundred in one week. They are far more common in children than in adults, and are rarely found in old age. When present, they excite more or less irritation in the mucous membrane. We have a preparation in the museum, showing considerable hypertrophy of the follicles, both of Peyer and Brunner, in a portion of intestine which contained a good-sized worm. There is generally a copious secretion of mucus, effused, without doubt, for the protection of the lining membrane. The mucus is often thick and viscid, and it existed in such abundance in some cases of fever accompanied with worms, noticed by Pinel, that he was induced to apply the term of "mucous" to the disease. The accounts to be met with in the old authors, of these worms eating through the coats of the intestines, are not worthy of much credit. They sometimes, it is true, occasion ulceration, which may extend until perforation is produced, but even this is a rare occurrence. There are, however, a few cases on record, in which an abscess formed in the parietes of the

abdomen has burst, and given vent to pus, mixed up with gas and feculent matter, and likewise one or more of these worms. It would appear, from those instances in which dissection was performed, that the peritoneal tunic at the site of ulceration had contracted adhesion to the abdominal parietes, and that the subsequent extension of the ulcerative process had caused the formation of an abscess in the subcutaneous cellular tissue, which, bursting externally, made a passage for the discharge of the worm, together with the feculent contents of the canal. The *ascaris lumbricoides* is not, indeed, furnished with any apparatus which would enable it to perforate the living tissues, and is very rarely, if ever, found attached to the mucous membrane, or entangled in the follicles.

The symptoms originating in the development of these worms in the intestines are of the same inconstant and vague nature as was remarked of the other entozoa infesting the alimentary canal. It often happens that digestion is more or less impaired, the breath fetid, the appetite deranged, and that there is a sensation of sinking, or faintness, at the epigastrium; itching at the nose, occasional diarrhœa, colicky pains in the abdomen, and a degree of general emaciation. These are the symptoms most commonly observed, yet I have known individuals who have every now and then passed an *ascaris* during several years, and yet have betrayed no indication of ill health. There are, in fact, no signs or assemblage of symptoms which enable us to determine with certainty the presence of worms in the intestinal canal, unless they have been expelled from the bowels.

17. *Ascaris vermicularis*.

Before speaking of treatment, I must proceed to describe the last species of entozoa remaining to be noticed—viz. the *Ascaris vermicularis*, called by Bremser, *Oxyuris vermicularis*; the common thread-worm. This worm was known to Hippocrates, and received the name of *ασκαρίς* (from *οσκαρίζω*, to leap), on account of its supposed activity. It varies in size according to the sex; the males rarely exceeding two lines in length, and the female measuring about five. The body is proportionally slender, white, round, and highly elastic. The head is obtuse, with a transparent membrane on each side, and, according to Rudolphi, presents the three valvular papillæ characteristic of the genus *ascaris*. Bremser, and other helminthologists, have not succeeded in detecting these papillæ; and, believing that they do not exist, have referred this species of worm to the genus *oxyuris*. The

*Ascaris Vermicularis.*

* Natural size.

tail of the male is spiral and obtuse; that of the female, straight and tubulate. These worms are so exceedingly minute, that their internal organization cannot be very readily observed. It is very similar, however, to that of the *ascaris lumbricoides*.

The *ascaris vermicularis* inhabits the large intestines, especially the folds at the inferior extremity of the rectum, where it is found in large numbers. Bremser states that he has met with it in the cæcum. It is the most troublesome parasite infesting children, though it is found occasionally in adults. Bremser mentions the case of an old man, eighty years of age, who was troubled with these worms until he died. It is stated that they sometimes make their way into the vagina, where they cause intolerable itching, discharges, and even nymphomania. Children affected with them experience an itching at the anus and at the nose, which they frequently rub and scratch until they produce excoriation and bleeding. They have a repeated inclination to go to stool, with tenesmus, and the motions are slimy, and sometimes tinged with blood, and generally contain a few of the worms. Pro-lapsus ani also frequently exists, owing to the straining and forced efforts made by the patients on going to stool. The general symptoms which they give rise to are very various, and occasionally of a threatening nature. Convulsions and other cerebral symptoms, excessive appetite, nausea and vomiting, griping and purging, feverishness, and general emaciation, may likewise be occasioned by ascarides; whilst, in many cases, there is so little

deviation from health, that their existence would never be ascertained, or even suspected, if they were not detected in the stools. But, however slight may be the irritation and disturbance dependent on these and other kinds of the intestinal entozoa, it is always an important object to obtain their expulsion from the system. Their presence may not, perhaps, be indicated by unequivocal symptoms of morbid action; still they operate, often in an imperceptible manner, unfavourably on the constitution, and are the cause of a sort of *malaise*, a condition far removed from high and vigorous health, and expressed by enfeeblement of the powers both of the mind and body; thus constituting an evil, though not of a striking nature, still one which it is very desirable should be removed. Besides, too, any continued irritation, however mild and slight in its effects, tends to bring the constitution into a condition favourable for the reception of morbid impressions, which, in strong and robust health, would not be succeeded by hurtful results. Whenever, then, the existence of any of these parasites has been ascertained, whether the symptoms be mild or grave, an appropriate course of treatment should be pursued for their destruction and expulsion.

The medicines by which these objects are attained are called anthelmintics; but as treatment scarcely comes within the scope of these lectures, I shall only allude to a few of the remedies which enjoy the best reputation amongst practitioners. The expulsion of intestinal worms can be effected by the exhibition of an active purgative. For this purpose you may administer a large dose of calomel and jalap, or croton oil. There are some medicines, however, which appear to be extremely unfavourable to the life of these animals, such as the oil of turpentine, one of the most common remedies employed in these cases, and a very efficacious one, especially as its purgative action obtains the expulsion of these worms after they have been destroyed. Although turpentine had been previously resorted to in worm cases, Dr. Fenwick, of Durham, has the credit of having made its virtues more generally known, by a paper published in 1811, in the second volume of the *Medico-Chirurgical Transactions*. He was led to adopt this remedy in consequence of learning from a friend, that a sea-faring man, suffering severely from the tape-worm, having observed that whenever he drank rather freely of gin he always passed portions of the worm and experienced relief, was induced to take a wine-glass full of the *Oleum Terebinthinæ*, under the impression, that being of the same nature, but stronger than gin, it might effectually cure him;

The consequence was, that about two hours afterwards he passed, with a purgative stool, an entire tape worm; from which time the complaint did not return. Turpentine is useful in all kinds of intestinal worms. It should be given in large doses, as half an ounce or an ounce, in conjunction with or followed up by castor oil. In infants, from half a drachm to a drachm may be safely taken in milk. In cases of the small ascarides, it has been injected into the rectum with great benefit. In cases of tænia, it is generally advisable to repeat the dose of the turpentine two or three times, in order to destroy the ova of the worm, which, being left in the canal, might lead to their reappearance. Chabert's empyreumatic oil, which is strongly recommended by Rudolphi and Bremser, and is much used in Germany, especially in cases of tænia, consists of a mixture of one part of the oil of hartshorn with three of the oil of turpentine, which having stood for three days, three-fourths are distilled off in a glass vessel, by the heat of a sand bath. The bark of the pomegranate root, a remedy for worms known to Celsus, has recently been recommended to the notice of the profession as a valuable anthelmintic for those affected with tape-worms. It is a remedy very generally employed in France, and may be exhibited in the form of decoction or powder. The latter, which is considered the most efficacious, is given in doses of ℥ij. or ℥j. two or three times a day. The fresh bark is found to be more active than the dry. Some caution is necessary in its administration, since an over-dose has the effect of producing giddiness, sickness, convulsions, and purging. The cowhage, *delichos puriens*, or cowitch, a remedy highly recommended some years ago, by a practitioner of the name of Chamberlain, has been a favourite vermifuge in cases of lumbrici and ascarides in children. It is given in the form of an electuary, and is usually followed by a smart purgative. The occasional employment of an injection of cold water, a mode of treatment sanctioned by the authority of Van Swieten, has been found successful in keeping the rectum free from the ascarides vermiculares. Being so readily within reach, these worms have been attacked by other remedies in this way, as mercurial ointments, turpentine clysters, and injections of bitter medicines. There are many secret and quack medicines and recipes which have obtained a considerable reputation as anthelmintics, but they are mostly composed of the substances already mentioned.

It has been common amongst practitioners to refer too many of the diseases of infancy to the presence of worms in the

intestinal canal, and active medicines have been exhibited, under an erroneous supposition of this nature. Powerful anthelmintics, indiscriminately employed, may, however, prove more hurtful to the patient than the evils which they are intended to remove; and without the conclusive evidence afforded by the discovery of worms in the stools, we are scarcely warranted in resorting to the more irritating remedies recommended for our use in these affections. After the exhibition of vomitages, steel medicines, bitters, and other tonics, will often prove of essential service in restoring the tone of the alimentary canal, and in correcting the disposition of the organs which favours the development of these animals. It is stated that they abound in humid situations and unhealthy districts, and are common to those who take their food without salt, or who do not obtain wholesome nutriment. The diet, therefore, and other circumstances favourable to a sound state of health, should likewise be objects of care; and as the production of worms is frequently secondary to derangement of the important organs of digestion, it will often be found, when their functions are improved, and the general health properly attended to, that the parasites will disappear without any other means being employed for their removal.

ON THE FIRST CHANGES

IN THE

OVA OF THE MAMMIFERA

IN CONSEQUENCE OF IMPREGNATION,

And on the Mode of Origin of the Chorion.

By THOMAS WHARTON JONES, ESQ.

Communicated to the Royal Society by Richard Owen, Esq. F.R.S.*

PART I.—On the Changes in the Envelopes.

HAVING previously described the structure of the ovum of mammiferous animals, as it exists in the ovary before impregnation†, I now proceed to relate some facts respecting the changes which it undergoes in consequence of that act.

My observations in reference to this point are the following:—

Observation 1.—On Wednesday, the 16th, and Thursday, the 17th September,

* See Philosophical Transactions, Part II. for 1837, p. 389.

† See Lond. and Edin. Phil. Mag. vol. vii. p. 209.

1835, I examined the internal organs of generation of a rabbit, which had been impregnated on the afternoon of the Saturday preceding, and which was killed on the afternoon of Tuesday. The ovaries of both sides presented corpora lutea.

In the fallopian tube of the right side, near where it enters the horn of the uterus, I found six ova. In the same place on the left side there were only two. They differed very remarkably from the ova as they exist in the ovaries before impregnation, inasmuch as the former presented, in addition to the component parts of the ovum of the ovary, a thick gelatinous matter surrounding it, similar to what is observed in the ovum of the frog. The addition of this gelatinous envelope made the diameter of the whole body about 1-70th of an inch. Fig. 1 represents one of these ova magnified 40 diameters, and fig. 2 the ovum of the frog when recently laid, magnified 2 diameters.

I could not detect the germinal vesicle in the ova in question. The granular matter of the yolk was coherent. The application of weak vinegar to the ova rendered the yolk transparent. Dilute nitric acid made the superadded gelatinous envelope contract, but by the addition of more water it gradually expanded again.

The question which this observation suggests is, "Where do the ova acquire the additional gelatinous envelope; in the fallopian tubes or in the ovaries?" The two following observations give the answer, "In the ovaries."

Obs. 2.—March 6, 1836. Examined a female rabbit to-day, 41 hours and 40 minutes after impregnation. There were *no ova* in the horns of the uterus, nor in the fallopian tubes.

The right ovary presented on its surface a very large and prominent graafian vesicle, quite transparent, except at its most projecting point, where there was a spot of blood. I perceived nothing peculiar in the ovum contained in this vesicle. I did not detect a germinal vesicle in it.

Besides this large and prominent graafian vesicle there were on the surface of the right ovary other five prominent vesicles filled with coagulated blood. At the most projecting point of each of these there was a small whitish mamillary elevation, within which was contained the ovum, surrounded by a

transparent gelatinous substance, the same as that described in the preceding observation; only it is to be remarked, that in the fallopian tubes this gelatinous-looking substance had swelled out and acquired a greater diameter than it presented in the ovary. I did not detect a germinal vesicle in the ova forming the subject of this observation.

In the left ovary I found only one vesicle, containing the coagulated blood and the ovum surrounded by the gelatinous-looking envelope.

Obs. 3.—A rabbit, 48 hours after impregnation, presented appearances much the same as the above.

Is any trace of the gelatinous-looking envelope of the ovum to be observed before impregnation? In the ova of the rabbit, &c., before impregnation, the proligerous disc, in which the ovum is embedded, is observed to be composed of a gelatinous substance, interspersed with grains, but as yet there appears no distinctly circumscribed envelope*.

The gelatinous-looking envelope of the ovum I have just described must not be confounded with the vitellary membrane of the ovum, which was fully considered in my former paper. The former appears to be analogous to the cortical membrane surrounding the ovum of the *Ornithorhynchus paradoxus*, &c. while still in the ovary, described by Mr. Owen†. That it, and not the vitellary membrane, as I formerly imagined, forms the chorion, will be made evident by the following observations:—

I would, however, premise some remarks on the ova of the batrachian reptiles, in order to place in a more striking point of view the circumstances I am about to relate in regard to the ova of the mammifera.

Fig. 2 exhibits the ovum of the frog magnified two diameters. It is composed of a yolk, black on its surface, and whitish inside. The yolk is surrounded by a vitellary membrane, thicker than that of the bird's egg, but thinner in proportion than that of the ova of the mammifera. Outside the vitellary membrane is a gelatinous envelope, which is added in the oviduct, the two preceding

* Dr. Karl Krause, of Hanover, however, in a late number of Müller's Archiv., speaks as if the gelatinous substance really formed a well-defined envelope. From his observations on the ovum before impregnation he has been led to form much the same opinion regarding the origin of the chorion as is recorded in this memoir.

† Philosophical Transactions, 1834, p. 561.

parts being formed in the ovary. When the ova are laid, the gelatinous envelope rapidly absorbs water, and swells out to great thickness.

The ovum of the newt differs from that of the frog, inasmuch as the gelatinous-like matter which surrounds the yolk and its membrane is of an oval form, and is somewhat hardened on the surface, so as to form a kind of shell, inside which is a fluid substance, in which the yolk and its membrane can freely revolve and glide from one end to the other. The vitellary membrane is thinner in the newt than in the frog. Fig. 3 is the ovum of a newt, in which development has commenced, magnified rather more than twice.

But what I wish particularly to insist on, in regard to the ova of the batrachian reptiles, and especially of the newt, is, that when the embryo of the latter has attained a certain size, but still at an early period, the vitellary membrane gives way, and then the embryo is only contained within the cavity of the substance, which is added to the ovum in the oviduct, fig. 4.

In the case of the frog the vitellary membrane does not give way, until about the time the tadpole is ready to burst all its envelopes. With the development of the embryo the cavity circumscribed by the vitellary membrane increases to as much as one-fifth of an inch in diameter, and always retains its spherical form. There is a limpid fluid in the interior of the vitellary membrane which seems to serve the purpose of an amniotic fluid, fig. 5.

Obs. 4.—March 18 and 19, 1836. Examined a female rabbit seven days after impregnation. The right ovary presented four corpora lutea, the left ovary two. I found only one ovum in each horn of the uterus; they were about 1-50th of an inch in diameter*. Fig. 6, magnified 40 diameters.

No vitellary membrane was to be seen. The gelatinous-looking envelope constituted the only covering of the yolk, which now formed a spherical blastoderm. The cavity of the gelatinous-

looking envelope was much larger than the spherical blastoderm. The inner surface of the gelatinous coat presented what I supposed to be fragments of the vitellary membrane adhering to it.

In both ova the spherical blastoderm was irregular on one side, that on which I supposed the embryo was about to be developed. It was beginning to present the separation into layers, and had the same peculiar friable globular structure as the blastoderm of the hen's egg.

Obs. 5.—This observation, which refers to the human ovum, agrees with that just related in regard to the ovum of the rabbit.

In the spring of 1836 I examined a small human ovum sent to me to Cork, where I then was, from Glasgow, by Dr. Mackenzie. In his letter to me, dated November 29, 1835, he describes it thus: "A very small human ovum. It came along with the entire decidua from a patient of mine. It lay in the middle of one of the parietes of the decidua, rather near its upper edge, and was about the size of a marrowfat pea, before being put into spirits. The decidua covering it, towards the hydroperic cavity, was thin and semi-transparent, but the opposite portion of the decidual nidamentum was thick, and marked with foramina, as if from vessels which had penetrated and adhered to it. Having opened the nidamentum and taken out the ovum, I observed what will immediately strike you, that one side of it was bald and the other shaggy with the villi of the chorion. The bald part lay towards the hydroperic cavity. A small puncture was made through the chorion, and perhaps through the amnion, by which some fluid escaped: nothing more was attempted. The fallopian portions of the decidua measured nearly half an inch, and were both entire."

In a subsequent letter Dr. Mackenzie says, in reference to the age of this ovum, "The ovum in question I consider as three or four weeks old. The lady had missed one menstrual period, and thought herself four weeks gone."

On laying open the ovum, by carefully cutting and reversing the bald side of the chorion, the following appearances (delineated, natural size, in fig. 7) presented themselves. The whole cavity of the chorion was filled with a fine

*The reason I found but two ova is, perhaps, that from their great transparency they may have escaped notice. The gelatinous coat was so transparent that I could with difficulty see the outline of it under the glass when it was observed by transmitted light. The spherical blastoderm being opaque was the only circumstance that enabled me to detect the ova at all.

gelatinous cellular tissue, imbedded in which, towards one extremity of the ovum, was a small round body.

It was evidently the spherical blastodermis; on being taken out and examined under the microscope, it presented the same friable globular structure found in the spherical blastodermis of the rabbit in the preceding observation. There was no vitellary membrane to be seen.

From observation 4 it may be inferred, that in the progress of the development of the ovum of the rabbit the vitellary membrane gives way, as in the ova of the newt, and indeed of many of the oviparous animals; that the gelatinous coat acquired by the ovum in the ovary, and more especially circumscribed and defined after impregnation, constitutes the only covering of the spherical blastodermis after the giving way of the vitellary membrane; that this gelatinous-looking coat forms the chorion, which in the rodents at a further stage of development presents itself under the form of a thin and transparent membrane, very like the vitellary membrane of the bird's egg, situated immediately outside the non-vascular and reflected layer of the umbilical vesicle.

The conclusions to be drawn regarding the human ovum, from observation 5, are the same as above. The human ovum, as regards the spherical blastodermis, was in much the same stage as the ova of the rabbit seven days after impregnation; the vitellary membrane had disappeared, or been resolved into the gelatinous cellular tissue filling the interior of the chorion; and the embryo had not yet appeared, though the spherical blastodermis was undergoing the preparatory changes. As regards the chorion, the human ovum was more developed than that of the rabbit, but it is to be remarked that even in an after stage of development the same difference in structure continues to prevail.

PART II.—On the Changes in the Vitellus.

What I have to communicate in this second part of my memoir is of a much less definite character than that which is given in the first part. From the nature of the subject it in many cases necessarily consists of inferences rather than observed facts. It relates chiefly to the ova of the batrachian reptiles, and is added here merely for the pur-

pose of throwing some light on the changes which take place in the yolk of the ova of the mammifera, previously to the commencement of the evolution of the embryo.

In approaching this subject the first question which presents itself is: "When does the germinal vesicle of the ova of the mammifera disappear; before or after impregnation?" It is known that in birds and reptiles the germinal vesicle disappears before impregnation. In the ova of the frog, contained in the oviduct, and also in the more advanced of those contained in the ovary, no trace of the germinal vesicle is to be observed. The black blastodermis surrounds the whole yolk, with the exception of a small spot* on the opposite side to that where the primitive streak appears. In the furthest advanced ova contained in the ovary of the newt, the blastodermis was formed, and I think I perceived the place where the germinal vesicle had been. As to the ova of the mammifera, I have found many in which there was no germinal vesicle, and which certainly had not been impregnated. It is to be remarked that in such ova the vitelline grains were for the most part coherent, and formed the spherical blastodermis.

It being determined that the disappearance of the germinal vesicle is prior to impregnation, and not dependent on it, the next question which arises is, "how does the germinal vesicle disappear?" My observations on the ova of the water-newt are the only ones I have which bear upon this question. From what I have observed in them I think the mode of disappearance is the following:—

The vesicle, at first imbedded in the substance of the yolk, approaches more and more the surface of it, until it comes to lie immediately underneath the vitellary membrane. The coat of the vesicle having now become very soft and weak, gives way, and the contained fluid is

* This small spot of the ova of the frog, which is white, (from the exposure of the white yolk,) always turns to the most depending side. The germinal point is thus always uppermost. I turned a mass of spawn upside down; the white spot was exhibited by all, but in a short time the white spot had turned downwards, and the germinal surface again became uppermost. In this case, does the vitellus alone revolve, or does the vitellus and its membrane turn round together in the gelatinous substance surrounding the ovum? It appeared to me that the latter was the way in which the revolution took place.

effused on the surrounding surface of the yolk. The coat of the vesicle being of extreme tenuity cannot be seen after it has given way. The small depression in which the vesicle was situate now forms the cicatricula.

I think that the fluid contained in the germinal vesicle being effused, gives a degree of consistence to the matter composing the surface of the yolk, and thus promotes the formation of the blastoderma.

If, then, the disappearance of the germinal vesicle is not dependent on impregnation, it may be asked what is the first change which takes place in the ova in consequence of impregnation? Of all the ova, the ova of the frog are those in which such change can be most directly observed. In them *the breaking up of the surface of the yolk into crystalline forms*, described by Prevost and Dumas, is the first change I have seen.

March 17th, 1835. I examined to-day the spawn taken from a frog yesterday, part of which was impregnated and part not; that which was impregnated presented the appearance delineated in fig. 8. The unimpregnated ova presented no change. The surface of the yolk becomes every day still more broken up, the crystalline forms becoming smaller and smaller, until the surface of the black blastoderma appears under a magnifying glass like shagreen.

The blastoderma, consisting of an aggregation of clear globules, different from those of the rest of the yolk, is now fully formed; it has extended itself so as to close in the white spot. Evolution then proceeds.

The change which takes place in the yolk of the bird's egg appears to be limited to the neighbourhood of the cicatricula. In the ovum of the mammifera, there being little more than a blastoderma to be formed, the whole of the vitelline grains undergo a change, and are resolved into a spherical blastoderma, presenting the same peculiar friable and globular texture as the blastoderma of the egg of the newt, frog, bird, &c. The matter contained in the cavity of the yolk of the bird's egg seems to be a substance of the same nature as the blastoderma, and to serve for the extension of it. The blastoderma of the bird's egg being once formed by the effusion of the fluid of the vesicle of Purkinje, and animated by fecundation, probably has the power to assimilate the matter in the cavity of the yolk to its own substance, without the assistance of a fluid such as that of the vesicle of Purkinje, which was first required to promote its formation. There is no central cavity in the ova of the frog and newt, because the blastoderma is formed at once all round the ovum.

Fig. 2. The ovum of the frog when recently laid; magnified two diameters.

Fig. 3. The ovum of a water newt in which development has commenced; magnified rather more than twice.

Fig. 4. A diagram showing the embryo of the newt after the vitellary membrane has given way, contained only within the cavity of the substance which is added to the ovum in the oviduct.

Fig. 5. A diagram showing the embryo of the frog still surrounded by the vitellary membrane, as well as the gelatinous substance which is added to the ovum in the oviduct.

Fig. 6. An ovum found in the horn of the uterus of a rabbit seven days after impregnation; magnified forty diameters.

Fig. 7. A human ovum aborted at the third or fourth week; natural size.

Fig. 8. This exhibits the breaking up into crystalline forms, observed on the surface of the frog's ovum after impregnation; magnified about six diameters.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

BY WILLIAM GRIFFIN, M.D.

Limerick.

Mortality of Cholera.

No. V.

THE inferences from the foregoing reports is so much more favourable to medical science than the aggregate amount of deaths would lead one to anticipate, that doubts might possibly be entertained of their accuracy; but independent of their agreement in demonstrating the vast proportion of cures which may be effected in the early stage, as well as the usual incurability of the cases admitted in collapse, I can directly answer for the general correctness of those kept in the hospitals with which I was connected.

It appears by these reports, that in no hospital was the mortality over 16 in

the 100, or less than 4 in the primary stage. I think it probable that the small proportion of four deaths in the 100, was more dependent upon the admission of a greater number of light cases than upon any essential difference or increased success in the treatment; as both rates of mortality occurred in my own practice, without any important change of remedies or management. When I come to speak of these, however, by and by, it will be necessary to recollect that the results, such as they appear, have been tested in 1665 cases; a number which, I believe, it will be readily admitted must set all question on the subject at rest.

As the number of cases brought into hospital shrunk, cold, and pulseless, is seldom less than one-third, generally amounts to half, and sometimes exceeds two-thirds of the total admissions, the average rate of mortality in collapse, on the whole, as given in those reports, appears frightful. The apparent failure of the treatment made me particularly anxious to compare the results with those in other hospitals throughout the kingdom; but all my inquiries for this purpose ended in disappointment. There was, considering the importance of the subject, a strange deficiency, or disingenuous reserve, observable in a great proportion of the published statements from medical men, or (what was equally injurious to science) a propensity to draw general and absolute conclusions from a very moderate experience. To the latter, indeed, we would in charity attribute many of those individual pretensions to success with remedies, new neither in this nor in other countries. The probable mortality, however, may perhaps be gathered pretty correctly from the following statements:—

Dr. Christison, speaking of thirty-seven cases of collapse treated at Edinburgh and Leith by saline injection of the veins, says that not more than two or three of these would, at all events, have recovered, according to the previous experience of the medical men there; which is estimating the recoveries from collapse, under ordinary treatment, below one in ten. Dr. Colclough, staff-surgeon, in his report to the Army Medical Board, says, he has seen no recovery in any military patient, from collapse *with total loss of pulse*; but believes such recoveries may have taken place, though rarely, in the general cholera

hospitals, which are filled with impoverished, poorly-fed patients, among whom the disease is usually of a milder type.

Mr. Annesley observes, "that most of the fatal cases were nearly moribund on their admission into hospital; on the other hand, all the cases that recovered were brought for assistance *before the circulation had completely ceased*, and when blood could be freely drawn." Surgeon Gordon Satara says, "*after the pulse has failed at the wrist*, and the extremities have become cold, I consider the patient as almost irrecoverable." Surgeon Corbyn, Camp Eritch, states it as his opinion, "that unless remedies are resorted to within six hours after the attack (i.e. before collapse has set in), the case is almost hopeless." In the circular of the London Board of Health, dated August 9th, it is said of the stage of confirmed collapse, "that there is but little reason for hope;" a statement amounting, Dr. Hardwicke Shute conceives, "to an admission, founded on the most extensive observation which the records of the disease in this country afford, that a very great majority of the patients (say 49 in 50, or at least 18 in 20) perish." Dr. Venables says, in a letter from Whittlesea, published in the MEDICAL GAZETTE, "The fully formed collapse, or even the advanced approaches to it, seem as unmanageable here as it has proved in most other places. I have, however, witnessed *one recovery* and *one convalescence*, under these circumstances." Dr. Miller, in a communication to the MEDICAL GAZETTE, asserts, "*that all cases of collapse die*.* A report from a medical gentleman in Liverpool, who was connected with an extensive hospital there, states—"Of *fifty-four cases of collapse*, we have saved but *three*, and even in these there was some little heat of surface." A physician in Dublin, to whose valuable observations on the disease, forwarded to me during its prevalence there, I must always refer with pleasure, says, "I would go so far as to assert, that in the young and robust, if not unusually bad cases, the recoveries from collapse may be rated as *one in three*; while in the old, enfeebled, and dissipated, they may not be *one in twenty*. Suppose the mean—there would be nearly *one in*

twelve, which is not far from what is generally admitted."

Allowing for differences that may exist in the severity of the disease, and in the proportions of the young or the old attacked at any particular place, there appears to be a very general similarity in the results of cases in collapse. If we look to the only accurately detailed reports that could be offered, the mortality varies from about nine to seven in ten; or, in larger numbers, from 90 to 70 in 100. These would appear to be the natural results; and sad as they are, it is a question, with our present experience, whether active medical treatment may not be found to increase rather than diminish the fatality. In Limerick, in proportion as medical men lost confidence in all the various remedies suggested in the treatment of collapse, and trusted more to the efforts of the constitution, the recoveries seemed to increase.

With respect to those differences in the type of cholera which have given it the character of mild or severe at particular periods or places, it is necessary to give some general idea of the extent to which they might possibly influence the rate of mortality. Looking merely to the reports, they may appear to be so great as to render any just comparisons between one mode of treatment and another exceedingly difficult; but a more intimate knowledge of the disease will convince us, that the lighter mortality at all times depends, not so much on the greater curability of cases in collapse, as on the disease becoming more prolonged, and thus allowing more time for treatment, or removal to hospital, previous to the extinction of the pulse. Patients in the advanced or collapsed cases die nearly in the same proportion as before, but a greater number are admitted in the primary stage, and there are consequently less deaths upon the whole. There is no disease so true to itself as cholera—so constant in its characteristic symptoms—so steady in its amount of destructiveness. It is violent and severe at its onset in every place, not simply because it is less under the influence of medicine at any particular stage than afterwards, but that it runs its course so rapidly, there is no opportunity of treating it in any but the last. The malignity or fatality of cholera, in fact, consists principally in

* MED. GAZ. July 31st, p. 543.

the speed with which it has passed through the primary stage, for on this depends the usually hopeless state in which patients are brought into hospital, or fall under treatment. Hence it is, looking to the aggregate mortality merely, we can never form a just estimate of the influence of treatment. A report from one hospital, for instance, may give only 26 deaths in 100, while another gives more than double that number; and yet, on strict investiga-

tion, it may be found that the treatment in the latter has been the more successful of the two. For instance, if in one hospital the cases admitted in collapse amounted to three-fourths of the total amount, and in another only to one-fourth, the former would have double the number of deaths, even though the treatment was precisely twice as successful, as the following statement will show:—

First Hospital.

	Admissions.	Cured.	Died.
In the primary stage	25	24	1, or 4 in 100.
In collapse	75	15	60, or 2 recoveries in 10 cases.
Total	100	39	61, or nearly two-thirds of the whole.

Second Hospital.

	Admissions.	Cured.	Died.
In the primary stage	75	67	8, or 8 in 100.
In collapse	25	2½	22½, only 1 recovery in 10.
Total	100	69½	30½, or nearly one-third of the whole.

There is another source of fallacy in the general reports of hospitals: a number of patients in the premonitory stage of the disease, that is, not in cholera at all, are included in them to a greater or less extent. To point out this, it is not necessary to contrast one hospital with another, but simply to contrast the reports of two different periods in the same hospital. It will scarcely be believed they are records of the same disease, the results sometimes prove so different. In Dublin, during three weeks commencing the 1st of April, there were 121 cases, and 66 deaths; while in the three weeks subsequent to the 16th of May there were 784 cases, and only 69 deaths. In Cork, from July 16th to August 9th, there were 121

cases, and 69 deaths; while from the 11th to the 25th May there were 710 cases, and only 93 deaths. In the Limerick general reports, from June 11th to 18th, there were 435 cases, and 208 deaths; while from July 1st to the 17th, out of 481 cases there were only 121 deaths. In Barrington's Hospital in the same city, from 11th July to August 17th, there were only 79 deaths in 396 cases; while from August 26th to September 27th, 139 died out of 200 admitted; and from September 23d to April 17th, 121 died out of 217. The contrasts will appear still more striking in the daily reports. The following are from the Dublin hospitals in April and May:—

	Cases.	Died.
Dublin, May 19	97	10
20	28	3
21	38	5
22	46	2
23	40	5
24	40	4
25	90	7
Total	379	36

	Cases.	Died.

The medical reader need scarcely be told that of the 379 patients admitted in

the week in May, no more, probably, than 72 could have been in cholera. It

was not always in the power of the medical gentleman in attendance to prevent the admission of patients not in cholera; frequent impositions were practised by the poor for the sake of procuring clothes, which were given gratuitously to the convalescents, and those complaining of mere diarrhœa could not be safely rejected when cholera was very prevalent, or frequently of the rapid type.

This peculiar character of the disease, its rapidity, invariably marks its commencement every where, but seldom lasts more than from three or four days to a week: the complaint then assumes the protracted form; there is a greater opportunity for treatment; more cases are brought into hospital with perceptible pulse, and there are consequently more recoveries. The proportion of patients admitted into hospital in collapse in this country has, as I have already mentioned, never been less than one-third of the whole, and has seldom exceeded two-thirds, except in villages or hamlets where the poor were prejudiced against all medical treatment, and permitted their friends to be removed to hospital in the last stage only for the sake of obtaining coffins. The proportion of deaths in real cholera has been at all times as nearly as possible the same, varying with the variation in the number admitted in collapse. For as, under the best management, in a large number of cases the proportion of those admitted in the primary stage, who ran into collapse and died in despite of the treatment, nearly equalled the recoveries from collapse, the aggregate of the mortality necessarily corresponded with the aggregate of cases admitted in collapse. The greatest mortality which occurred in Limerick during the prevalence of cholera, as I have before stated, took place on its second incursion in Barrington's hospital, on the evening of the 26th of August, when, out of 73 cases admitted on that and the two following nights, 52 expired. These cases were mostly of the rapid type, and I believe more than three-fourths were brought in in deep collapse. In Paris, where the mortality was so terrific, the cases of collapse appear to have been immense; they were for the most part, as M. Magendie called them, "cadaverized cases." On the 28th of March, says the report*,

nine men labouring under intense cholera were admitted into the Hôtel-Dieu. One died in a few hours, seven more the next day, and one only recovered. A woman was next admitted about four in the afternoon, and expired before midnight. On the 29th, 23 new cases, 14 men and 9 women, were lying in the St. Martin and St. Monica wards; 8 of the men and 1 of the women died the same day, and the remaining 6 men on the day after. On the 30th, 40 new cases were received; 10 died the same day, and almost all the rest on the ensuing day. At midnight there were altogether 78 cholera patients lying in the Hôtel-Dieu; and on the evening of the following day only 16 were in life: these expired in the course of the subsequent days. At this period, of 27 females only 19 died; while among 51 men there were 43 deaths. "On the 3rd of April," the report continues, "when it became necessary to distribute the patients in all the wards on the left bank of the Seine, 388 patients had been treated in the wards of St. Martin and St. Monica, and next day 281 deaths were to be divided among the twelve physicians in attendance. Some days after, one-half at least of the residual 107 had expired, and threescore only quitted the hospital recovered."

This terrific mortality occurring under the treatment of the most celebrated physicians and physiologists in Europe, might very well put to shame the ridiculous and silly, or yet worse, the dishonest pretensions, of practitioners in this country. Such results in such circumstances ought rather to have made candid and thinking men distrust the extent of their experience of the disease, even if it led to a more favourable estimate of the influence of remedies. On my own mind, after witnessing the progress of nearly a thousand cases of cholera, the impression now is, that the mortality in Paris would not have been considerably less under any medical treatment which has been suggested or tried in this country; but that it might possibly have been somewhat less if the cases had been left wholly to nature. The patients were almost all brought into hospital in a state in which medicine is almost wholly uninfluential; the bodies corpse-like, the pulse extinct, and the violent and anxious efforts that were made to rescue them, as it were, from the verge of death, must, it is to be

* Archives Générales de Médecine, April 1832.

feared, have often precipitated them into it.

In estimating the mortality under different modes of treatment, besides the considerations to which I have adverted, it is necessary to attend to the ages, habits, and station in life of the patients. The deaths appear to be least at the middle period of life, amount to considerably more in infancy, and to most of all in old age, as the following tables declare:—

ST. MICHAEL'S HOSPITAL, LIMERICK.—*Report for the Month ending June 30th, 1832.*

Admitted at 45 years of age and upwards, 103, of whom 24 recovered and 79 died.
Under 45 years and over 15 years, 186, of whom 100 recovered and 86 died.
Under 15 years, 39, of whom 19 recovered and 20 died.

Report for the Month ending July 31st, 1832.

Admitted at 45 years and upwards, 29, of whom 15 recovered and 14 died.
Under 45 years and over 15 years, 115, of whom 90 recovered and 25 died.
Under 15 years, 21, of whom 17 recovered and 4 died.

ST. JOHN'S CHOLERA HOSPITAL, LIMERICK.—*Report from 28th August to September 10th, 1832.*

Admitted at 45 years and upwards, 19, of whom 8 recovered and 11 died.
Under 45 years and over 15, 54, of whom 37 recovered, and 17 died.
Under 15 years, 37, of whom 18 recovered and 19 died.

It was remarked in Paris, that not only were a greater number of men admitted into the hospital than women, but that a much greater number died in proportion. The observation would not appear to be at all applicable to the disease in this country. At its commencement, indeed, the very reverse was the fact with respect to the admissions—women constituting the great majority. After some length of time, the numbers of males and females in all the hospitals bore some near proportion to one another. The following is a summary of the report of the Nunnery Hospital, in St. Mary's parish, Limerick:—

Total number admitted	282	..	Died	124
————— of Males	102	..	—	56
————— of Females	180	..	—	68

It is evident the cholera varies very much in the selection of its prey at different periods; sometimes striking men

chiefly, sometimes women, sometimes laying society waste by families. In the first irruption in Limerick the sufferers were chiefly the middle-aged; the infants attacked were very few, and those few almost all died. On its second visitation the admissions took place in families; the children were in abundance, and many recovered.

It has been long observed of typhus fever, that although the rich are less liable to be attacked by it than the poor, it is much more mortal among them. This is as strictly true of cholera. The wealthy and well-fed are little liable to be affected; but when once seized with it, very generally die. I have by me a list of nearly 150 respectable persons who died in Limerick, which I should suppose is much more than half the number of that class who suffered with the disease.

Persons in advanced age, or of broken or dissipated habits, seldom recovered from cholera. In drunkards, it almost always assumed the rapid type. The mortality was also greater among those admitted in diarrhoea with little disturbance of stomach or cramps, but with a failing pulse, than where the vomiting was violent and the cramps distressing.

In conclusion, it may be assumed, from the foregoing observations—

1. That, as it appears the disease, if abandoned to nature, almost invariably runs into pulseless collapse, the mortality in all such cases may be rated at the usual average in that state.

2. That in patients in whom the pulse has ceased at the wrist, no known remedy possesses any decided influence in bringing about recovery; the mortality sometimes amounting to nineteen deaths in twenty cases; and under the most successful treatment, furnished in authentic reports of large hospitals, never proving less than seven in ten.

3. That the mortality in cholera cases, under judicious treatment, when commenced before the pulse had ceased at the wrist, varies from 4 to 16 in the 100.

4. That cases of cholera occurring when it is not epidemic, even though presenting all the characters of the Asiatic disease, are more protracted and manageable. They do not always run into collapse, even when neglected; and sometimes recover without assistance when they do.

5. That the severity of the epidemic

itself is very variable, differing materially, not only on different nights, but in different places on the same nights: so that to form just comparisons of the mortality, or of the influence of remedies in different hospitals, or in different wards of the same hospitals, it is essential the cases compared should correspond both as to time and locality. When this cannot be strictly done, the probable errors may be at least partially corrected by increasing the number compared; so that the un-noted varieties in the nature of the cases in the several hospitals may, in some degree, mutually compensate one another.

REMARKS ON PHRENOLOGISTS

AND

DR. ELLIOTSON,

BEING A POSTSCRIPT TO AN INTRODUCTORY LECTURE, BY R. GRAVES, M.D.*

SINCE my introductory lecture was delivered I have had leisure to peruse the second part of Dr. Elliotson's Human Physiology with the attention it deserves: as Dr. Elliotson has devoted so much of the volume to phrenology, I feel it right to add the following remarks:—

It appears certain, if we believe Dr. Elliotson, that Spurzheim's labours, and those of his pupils and followers, have done much to impede the progress of phrenology; of Spurzheim he says—"In his fondness for changing his names, his arrangement, and his numbering of the organs, he introduced confusion without advancing knowledge. To prove his speculative spirit, I may mention that instead of giving the origin of any of his asserted discoveries, as Gall did, and adding a host of examples, he tells us, in regard to the organ of inhabiteness, only that a gentleman much attached to his house had a particular spot of his head much hotter than any other; and, in regard to the organs of hope, marvellousness, conscientiousness, size, weight, order, time, he neither tells us how he discovered them, nor adduces a single proof. He changed even the situation

and extent of organs in his last plate. The space allotted by him to marvellousness was originally between wit, imitation, hope, and ideality; now it is more than twice its former size, and placed between these four, and veneration: covetiveness was placed by Gall, and admitted by Dr. Spurzheim, before cunning and ideality; now it is over cunning, and between ideality and cautiousness. Ideality, in his first edition, was chiefly above covetiveness and before circumspection; now it is above constructiveness, and a large organ stands between it and covetiveness."

Mr. Combe, we are told, drives away his readers in disgust; and Mr. Carmichael is said to be guilty of great mis-statement and great injustice towards Gall! When phrenologists use such bitter terms towards each other, we need not expect from them much courtesy to those who are not of their sect. Is it not refreshing to find a single Elliotson thus attacking a whole phalanx of giants?—"Few anatomists and physiologists have any idea of the errors, as to facts, and of the poverty of argument displayed by Cuvier, Tiedemann, Pinel, Esquirol, Richerand, Carus, Rudolphi, Serres, &c."

Sir David Brewster, too, is summoned before the judgment-seat, and receives from Dr. Elliotson a mild rebuke, calling both his honesty and ability into question. At p. 582 his sentence is thus recorded: "and yet Sir David Brewster would wish to be considered a philosopher in all his intellectual and moral doings." The reader will at once perceive that this philosopher is no phrenologist.

Sometimes Dr. Elliotson indulges in sarcasm against some unnamed person, as where, at p. 397, he says, "though Sydenham resided in Pall-Mall, he was never employed by the court; yet the names of the court physicians of his day are no more known than the names of the court footmen*." Removed as we are in Ireland from the seat of government and of court favour, we can

* The lecture itself shall appear in its proper place hereafter, in Dr. Graves' Course on Clinical Medicine.

* This sarcasm of Dr. Elliotson is not a fortunate one, for it so happens that the court physician of Sydenham's day was the celebrated Talbot, the very man who taught Sydenham the right method of administering bark; Talbot is highly praised in Madame de Sevigné's Letters for his cure of the Dauphin. Ray, in his *Historia Plantarum*, gives him the greatest praise.—Vide *Lancet*, Dec. 23, 1837: Dr. Sigmond's Lecture on Bark.

only guess at Dr. Elliotson's meaning; and we therefore cautiously interpret this sentence as meant to make little of the present court physician, Sir James Clarke. If this surmise be right, it may be well to remark, that Dr. Clarke's book on Climate, and his work on Phthisis, are extremely prized in Dublin, and that all the profession here were pleased to find the management of the Queen's health entrusted to the care of so able a physician; but perhaps Dr. Clarke is not a phrenologist.

As for the late Dr. Fletcher, Dr. Marshall Hall, and Sir C. Bell, they have been spared by Dr. Elliotson; he merely says, "The views of all these gentlemen appear to me equally confined and erroneous" (p. 496.)

In two different parts of this physiological work, Dr. Elliotson presents us with a list of his own discoveries in the practice of physic and pathology. These extraneous matters are very ingeniously introduced, and apparently for the purpose of self-defence; for his hand is against every man, and *he* imagines every man's hand to be against him. In truth, he writes like one who thinks himself an object of peculiar persecution, and one who believes that his merits in the cause of science have been sufficiently great to ensure the enmity of the whole profession. He talks of the inevitable opposition that awaits new truths on the part of mankind in general, but of himself he complacently remarks (p. 686), "I have never yet declared an opinion upon a new truth that I have been obliged to retract." He instances Aristotle, Galileo, Bacon, Newton, and Harvey, as men whose opinions drew on them jealousy, or even hatred—and then he speaks of the stethoscope, prussic acid, quinine, and the glanders!

These discoveries of Dr. Elliotson have drawn down upon his head the ill-will of his brethren, and have excited an opposition *we* should have but little anticipated. Had he acted wisely, or had he not been really fond of opposition and censure, he might have easily diverted contemporary malice into other channels; for in truth he could have found but little difficulty in disclaiming an apparent originality, when he learned that thereby he incurred so much odium. Thus, what could have been easier than to refer to the twelfth volume of the Dublin Medical Journal, in which Dr.

Eck's paper affords ample proof that Dr. Elliotson was anticipated, by at least ten years, with respect to the discovery of *glanders* in the human subject? Dr. Barker, of Dublin, published on, and recommended the quinine, before Dr. Elliotson; and the *stethoscope* was used diligently in the Meath hospital immediately after the publication of Laennec's work; yet no one here ever dreamed of having deserved praise, or having incurred censure, in consequence of using either quinine or the stethoscope.

MENSTRUATION AT AN ADVANCED AGE.

To the Editor of the Medical Gazette.

SIR,

AMONG the selections from foreign journals, in the British and Foreign Quarterly Review of this month, two cases are reported of menstruation occurring in aged females. Should you deem the following worthy of a place in your valuable and extensively circulated journal, you will greatly oblige

Yours respectfully,

ARCHIBALD BROWN, M.D.

21, College-Street, Glasgow,
18th Jan. 1835.

In the summer of 1835 I was consulted by Mrs. S., aged 56: the following are a few of the most prominent symptoms. Great emaciation, expression anxious and disturbed; skin harsh, dry, and jaundiced. Pulse 96, weak and irritable; tongue loaded with a brownish-coloured coating; bowels costive, stools whitish; urine scanty, and tinged with bile; hepatic region full, and slightly tender on pressure; liver is felt to be considerably enlarged; is distressed with occasional severe lumbar pains shooting down the posterior aspect of thigh, and downward and forward embracing the pelvic viscera. Catamenia ceased to flow fourteen years ago. Complaint, of seven months' duration, ascribed to cold and over-exertion.

The treatment adopted consisted of active purgatives; occasional use of the hip-bath; anodyne friction to lumbar region; and friction with nitro-muriatic lotion to the hepatic. This was followed by an alterative combined with a tonic and a light nutritious diet. Three weeks after commencing the alterative, I found

her, on calling, much excited, and on inquiring into the cause of it she told me "that during the night she felt as if something gave way within her, which was followed by a discharge similar to her usual courses." Having satisfied myself as to the appearance of the discharge, I enjoined rest, and stopped the medicaments for a few days. The quantity passed at that time, she mentioned, amounted to about the same as that discharged at the usual periods during the last year of menstruation. After this, there was a marked abatement of all her previous ailments, and a few weeks' continuance of the treatment above mentioned completed her recovery.

Catamenia continued to flow regularly every four weeks, with little variation as to quantity, for eleven months, and again subsided. I visited her the other day: her health continues good, but she has had no return of catamenia.

TRANSPOSITION OF THE VISCERA.

To the Editor of the Medical Gazette.

SIR,

By inserting the following case, in which the heart was situate on the right side, and an immense tumor occupied the anterior mediastinum, you would much oblige

Your obedient servant,

THOMAS FALCON.

Bradford, Jan. 20, 1838.

John Boardman first came under my observation in the spring of 1834, for a pulmonic affection, at which period the respiratory murmur was dull, accompanied by a harassing cough and dyspnoea. From these symptoms he rallied in the summer of 1834, so as to be enabled to follow his usual employment. This reprieve was, however, very temporary. In the beginning of September of the same year, he was seized with symptoms in their nature most appalling. Unable to respire except in a semi-erect position; his pulse weak, irregular, and intermittent; with a dull pain in the dorsal region, and also following the course of the axillary nerves.

The sensation of oppression in the precordial region he compared to the pressure of a sack of flour on the chest; he, however, referred his chief pain to

the epigastric region, which was very tender on pressure. He was unable to retain food upon his stomach, except of a farinaceous nature, and only in very small quantity. The urgency of the symptoms at this period indicated the presence of gastritis of an acute character. Under this conviction he was treated by leeches and counter-irritants to the epigastric region, and the other remedial means which are found serviceable in gastritis. The vomiting and pain were, however, in nowise relieved thereby.

Oct. 15th.—The paroxysms of embarrassment in his breathing are now truly urgent and distressing. The heart's pulsation cannot be felt on any portion of the left side of the chest, neither can the respiratory murmur be heard except upon the posterior part of the chest, near the vertebræ. He now informs me that the heart has always pulsated on the right side of the chest. Upon applying the hand to the part indicated, the heart's impulse is felt feeble and irregular. On applying the ear, the bellows murmur is constant and distinct.

These being the most prominent symptoms of the case, I would add, that the man lingered till April 1835, when he died. Upon opening the cavity of the chest, I found an immense tumor, weighing nine pounds, of a dark brown medullary substance, easily lacerable by the fingers, and surrounded by a fibrous capsule. Having taken its origin in the anterior mediastinum, it appeared gradually to have increased in size to the time of his death. The two-lobed lung was so compressed as not to be more than two inches in thickness; it pressed upon the bronchi above, as also upon the aortic arch, extending considerably into the right lung. The heart had evidently always been situate on the right side, and not pushed to its present situation by the tumor; for the aorta passed downwards on the right side of the vertebral column, the brachio-cephalic artery passed to the left, whilst the single carotid and subclavian passed to the right.

Although the continued gastralgia and vomiting were most probably the result of the pressure of the tumor upon the vagi nerves, yet the stomach was not found inflamed, an effect which experimentalists have produced by dividing these nerves. The lumbar glands

were enlarged. The thoracic and abdominal viscera were transposed.

The man had suffered amputation of the right testicle for fungoid disease, ten years previous to his death. The nature of the tumor in the chest was evidently fungus hæmatodes, affecting the remains of the thymus gland.

TRANSPORT OF THE WOUNDED.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel myself obliged by your giving a place, in the next number of your journal, to the following short article.—I am, sir,

Your very obedient servant,

F. C. CHERRY,
Vet. Surg. 2d Life Guards.

Regent's Park Barracks,
Jan. 29, 1838.

IN the MEDICAL GAZETTE of the 20th January is an article on "Transport of the Wounded," by Mr. J. Rutherford Alcock, wherein my name is brought conspicuously forward.

I have not the honour of knowing Mr. Alcock, but I have attentively read his paper, and am at a loss to know what its real object is.

With the complaint he makes as to difficulties occasioned to medical officers by the regulations of the British service, I have nothing to do whatever; neither with the improvements "beneficial in the extreme," effected among "ward-masters, clerks, orderlies, &c." under the sanction of, not by, the inspector general.

But with regard to transport by wheel carriages, I must beg to say, that the time and attention necessarily devoted to the duties of hospitals and the sick, appear to have laid him open to misinformation and misconception in regard to transport and its organization; and to these carts of mine in particular.

I found my claim to entertain and express opinions on the subject of military transport, from very long experience, under circumstances extremely varied; and on industry in collecting information, under circumstances more favourable than falls to the lot of many to encounter.

These I reduced to a practical working state, and printed the result, more than ten years ago. The book is in the

hands of heads of department, and many others interested in its details, with experience competent to enable them to decide on its merits.

[In compliance with Mr. Cherry's request we have inserted this note. We leave the party attacked to answer it if he thinks proper; but as referring to Mr. Alcock's communication, he professes to be "at a loss to know what its real object is," we beg to inform him that one very distinct object was, to point out certain imperfections in Mr. Cherry's carts for transporting the wounded; and we know that Mr. Alcock (who has done this without any degree of disrespect or ill-nature) has excellent opportunities of judging.]
—ED. GAZ.

IRISH COLLEGE OF SURGEONS AND APOTHECARIES' HALL.

To the Editor of the Medical Gazette.

SIR,

A LETTER signed "A Professor in the School of the Apothecaries' Hall of Ireland," having lately appeared in your columns, I take advantage of your impartial intimation appended to it to offer a very few observations, rather in the way of comment than reply. The condition which you very fairly require of being furnished with my name, I have complied with in the accompanying billet.

The great bulk of the *soi-disant* Professor's letter being purely of a personal nature, does not, in my opinion, demand either notice or reply. When a crisis is at hand involving the interests of a numerous and important profession, and the welfare of the community, I, for one, am little disposed to hair-split the letters of an official oath for the purpose of proving or disproving the claims to the epithet of renegade, of a gentleman who has thought proper to unite himself in intimate relation with the bitter and avowed enemies of a College whose "reputation, honour, and dignity," he has solemnly sworn, "to the utmost of his power, to endeavour to promote." I, for one, would never think of sifting out the two grains of reasonable apology from the two bushels of wordy chaff in which the professor has conveyed his excuses for entering into a servitude which he obviously despises, nor would I have the cruelty to inter-

rupt the prosing lullaby with which he has sought to quiet his conscience, were it not that this same lullaby prosing, as it is, contains a *refrain* which has now become the watch-word of the professor's present taskmasters.

"That we may the better understand the question," says the professor, "I will state the case as it is. The apothecary is compelled, as well by the wants of society, as by the position in which he is placed by others rather than by himself, to act in the double capacity of the prescriber, and the dispenser of medicine." Here, sir, comprised in these few words, you have the real object of the *professor's* lengthy epistle, and now permit me to "state the case as it *really* is." The medical profession in Ireland has been hitherto entirely composed of physicians and surgeons, who are in the habit of practising only as prescribers or consultants, no class equivalent to the general practitioner or apothecary of England having ever been sanctioned by law or custom in this country. To meet the wants of the public, and to serve those physicians and surgeons practising as I have described, a body of apothecaries (in the true acceptance of that name) was created by Act of Parliament, in the year 1791, for the express purpose of preventing "*injury to the fair trader, the dis-appointment of the physician, and the imminent hazard of the lives of his Majesty's faithful and loyal subjects throughout the realm.*" Let it be here expressly remembered that the apothecary was not, either by the spirit or letter of the act, required to learn or authorised to practise medicine as the English apothecary was by the act of 1815; but was simply and purely required to "be well skilled in the preparing and compounding of medicines," and was in all respects identical with the chemist and druggist of England of the present day. That body, which was originally created under the sanction of the physicians and surgeons of Dublin, which was even furnished in its puny infancy with a local habitation by that College of Surgeons against which it is now struggling in ungrateful insubordination, differed in no respect except its incorporation from the druggists and chemists of England. Its members were educated solely with a view to the making them expert and skilful compounders of medicine, being required to serve an apprenticeship to the *mystery* of an apothecary,

and to be examined, at its termination, in the knowledge of the pharmaceutical art. For many years they professedly confined themselves to the duties of their respectable and useful occupation, to the great advantage of the community, and the comfort and satisfaction of the medical profession. That profession, however, having somewhat incautiously permitted their employment about the sick, in what they unwisely considered the menial offices of applying leeches, and administering clysters, &c., advantage was taken of the opportunity, and the apothecaries commenced at first to dabble in practice over their counters, and, at a still more recent period, to insinuate themselves by all arts into the confidence of such patients as they were allowed to approach under the circumstances first alluded to, and of course, *pari passu*, to remove from the same confidence the proper medical adviser. These steps were taken silently, and by slow—very slow gradations; but within the last year or two, having gained, as they supposed, a sufficiently strong position, the apothecaries have thrown off the mask, and having hired into their service, as teachers, certain physicians and surgeons (whose poverty, I hope, not their will, consented,) they have boldly set themselves forward, not merely as general practitioners, but as the sole licensers and instructors of that class of the medical profession.

In this very hasty sketch, sir, you will no doubt recognise an identity between the Irish apothecary and the English chemist and druggist. Let not the name of apothecary, by its different signification in England, blind your readers, nor prevent them from sympathising heartily with their brethren in this neglected country. Their cause is our cause, with this difference, that in England the druggist has not as yet ventured from behind his counter, while, in Ireland, he has already issued forth into practice, and even shews his inclination to be a licenser of medical practitioners. This difference may not long exist; the public in England, as here, know little of the real merits of their medical advisers, the value of education is by them little understood, but low charges, and mean servile and cringing habits, are comprehensible by all, and unhappily acceptable to too many.

This, sir, is "the real state of the case," and it is to relieve themselves from the cruel oppression and hardship

to which such a state of things subjects them, that members of the College of Surgeons in Ireland have determined upon praying the Legislature to remove from them the trammels of the Apothecaries' act, and of their own charter, and enable them to practise their profession with some honest advantage to themselves and safety to the public, by permitting them to supply their own medicines instead of trusting to the tender mercies of rival practitioners. This is what the College asks for; it does so in the conviction that it would be vain to seek the more desirable remedy of obliging the druggists to confine themselves to their proper business of preparing and compounding medicines, and I leave it with confidence to the profession to decide whether, in what the College is doing, it is desirous, as the professor has accused, it of throwing unjust odium upon any class of individuals, or of degrading itself and its members from the station they have hitherto held.

The professor threatens you with future communications respecting the Charter of the College, &c.: should they be merely requiems to his conscience, my time, I hope, will be better employed than in disturbing their anodyne effects; but in case of their containing calumnies against the College, to which I am proud to belong, I shall again trespass upon your kindness for an opportunity of exposing them.

I have the honour to be,

A MEMBER OF THE ROYAL COLLEGE
OF SURGEONS IN IRELAND.

Dublin, Jan. 23, 1838.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégier.”—D'ALEMBERT.

THE DISCOVERIES OF SIR CHARLES BELL.

Idea of a New Anatomy of the Brain.

By C. BELL. 1811.

On the Nerves, &c. &c. By C. BELL.

Transactions of Royal Society. 1821.

Ditto, ditto. 1822.

Journal de Physiologie. Par M. MAGENDIE. 1821 and 1822.

Anatomical and Physiological Commentaries. By HERBERT MAYO. Parts 1 and 2. 1822 and 1823.

In the course of our last volume we had occasion to bring forward the sub-

ject of Sir Charles Bell's observations on the nervous system, in illustration of the degree of confusion which occasionally arises in the history of discoveries in medical science. The question of originality has of late been agitated in a new quarter—between Mr. Whewell, the learned author of the *History of the Inductive Sciences*, on the one hand, and the writer of a critique on that work in the *Edinburgh Review* on the other. We will first present (partly in a chronological form) the principal features of the writings of the several authors who are most interested in the question, and will then show what appear to us to be the just conclusions to be drawn from the evidence they afford.

1811. “*Idea of a new Anatomy of the Brain*, by C. Bell.”—This was a small work which the author did not publish, but merely distributed among his most intimate friends, containing, as he has often said, the fundamental principles of his system. We extract the following as the most important passages:—“In opposition to these opinions (the prevalent ones of the day,) I have to offer reasons for believing that the cerebrum and cerebellum are different in function as in form; that the parts of the cerebrum have different functions, and that the nerves, which we trace in the body, are not simple nerves possessing various powers, but bundles of different nerves whose filaments are united for the convenience of distribution, but which are distinct in office as they are in origin from the brain.—That the external organs of the senses have the matter of the nerves adapted to receive certain impressions, while the corresponding organs of the brain are put in activity by the external excitement; that the idea or perception is according to the part of the brain to which the nerve is attached, and that each organ has a certain limited number of changes to be wrought upon it by the external impression.—That the nerves of sense, the nerves of motion, and the vital nerves, are distinct through their whole course, though they seem sometimes united in one bundle, and that they depend for their attributes on the organs of the brain to which they are severally attached.”

Speaking of the experiments to prove these points, and the impossibility of making them on the brain itself, he says, “I took this view of the subject.

The medulla spinalis has a central division, and also a distinction into anterior and posterior filaments corresponding with the anterior and posterior portions of the brain. Further, we can trace down the crura of the cerebrum into the interior fasciculus of the spinal marrow, and the crura of the cerebellum into the posterior. I thought that I might have an opportunity of touching the cerebellum, as it were, through the posterior portion of the spinal marrow, and the cerebrum by the anterior portion. To this end I made experiments, which, though they were not conclusive, encouraged me in the view I had taken.

I found that injury done to the anterior portion of the spinal marrow convulsed the muscles more certainly than injury of the posterior portion, but I found it difficult to make the experiment without injuring both portions. Next, considering that the spinal nerves have a double root, and being of opinion that the properties of the nerves are derived from their connexion with the nerves of the brain, I thought that I had an opportunity of putting my opinion to the test of experiment, and of proving that nerves of different endowments were in the same cord, and held together by the same sheath. In laying bare the roots of the spinal nerves, I found that I could cut across the posterior fasciculus, which took its origin from the posterior portion of the spinal marrow, without convulsing the muscles of the back; but that on touching the anterior fasciculus with the point of the knife, the muscles of the back were immediately convulsed. Such were my reasons for concluding that the cerebrum and cerebellum were parts distinct in function, and that every nerve possessing a double function obtained that by having a double root."

Then, having pointed out the distribution of different nerves in the same organ for the performance of different functions, as the 1st and 5th in the nose; the 5th and 7th in the head and face; the 3rd and 5th in the orbit; the 5th and 9th in the tongue—"no part is sufficiently supplied by one single nerve, unless that nerve be a nerve of the spinal marrow, and have a double root, a connexion (however remotely) with both the cerebrum and cerebellum." "From the crura cerebri, or their prolongation in the anterior fasciculi of the spinal marrow, go off the nerves

of motion; but with these nerves of motion, which are passing outwards, are nerves going inwards—nerves from the surfaces of the body, nerves of touch, and nerves of peculiar sensibility having their seat in the body and viscera."

1821.—A paper "On the Nerves," &c. read before the Royal Society, July 12, 1821, and published in their Transactions a few months after:—"No organ which possesses only one property or endowment, has more than one nerve, however exquisite the sense or action may be; but if two nerves, coming from different sources, are directed to one part, this is the sign of a double function performed by it. If a part, or organ, have many distinct nerves, we may be certain that, instead of having a mere accumulation of nervous power, it possesses distinct powers, or enters into different combinations, in proportion to the number of its nerves." "When an animal is endowed with mere sensation and loco-motion, where there is no central organ of circulation, and no organ of respiration but what is generally diffused over the frame, the nerves are extremely simple; they consist of two cords running in the length of the body, with branches going off laterally to the several divisions of the frame." "There is the same uniform and symmetrical system of nerves in the human body as in the leech or worm, although obscured by a variety of superadded nerves," which "do not destroy but obscure that system; and accordingly, when we separate certain nerves, the original system of simple constitution is presented even in the human body. The nerves of the spine, the tenth or sub-occipital nerve, and the fifth or trigeminus, of the system of Willis, constitute this original and symmetrical system. All these nerves agree in these essential circumstances: they have all double origins; they have all ganglia on one of their roots; they go out laterally to certain divisions of the body; they do not interfere to unite the divisions of the frame; they are all muscular nerves, ordering the voluntary motions of the frame; they are all exquisitely sensible, and the sources of the common sensibility of the surfaces of the body." Then having spoken of the general characters of the respiratory superadded system of nerves, he passes to the relation of the

well-known experiments on the nerves of the face, from his conclusions on which we extract the following:—“The portio dura is the principal muscular nerve of the face; it supplies the muscles of the cheek, the lips, the nostrils, and the eyelids; that is, it is a nerve which orders all those actions which are in the remotest connexion with the act of respiration.” “These facts regarding the lips are of difficult explanation, until we consider what is necessary to the simple act of feeding. When a horse gathers the oats from the hand, or from the ground, he must feel the food, which is the office of the branches of the fifth; he must move his lips under the direction of that feeling, or he cannot gather it. It was accordingly discovered by experiment, that whether the seventh or the fifth were cut, if the operation were done on both sides of the face, the creature was deprived of the power of feeding, but from different causes; for in the first experiment it was owing to the loss of motion, and in the second to the loss of sensation. I am unable to decide whether or not the muscular branches of the fifth nerve go exclusively to the muscles of the jaws. I have found in an individual, that when the cheeks and lips were twisted by paralysis, he possessed the power of holding with his lips, in a manner that indicated a power independent of the seventh. But that the whole sensibility of the head and face depends on the fifth pair there is every possible proof.” “The fifth nerve, the nerve of mastication and sensation.” “The disease of the bone at one time affecting the fifth nerve, and producing excessive pain without paralysis; at another affecting the seventh nerve, and inducing paralysis without pain, are phenomena now accounted for.”

It is unnecessary to quote further from the paper read before the Royal Society, in May 1822, where Sir C. Bell endeavoured to prove the fact of branches of respiratory nerves being distributed to all the muscles of the trunk concerned in respiration, as he had in the previous one seemed to shew they were sent to the corresponding muscles of the face. He considered all the respiratory nerves, viz. the fourth, the portio dura, the glosso-pharyngeus, the vagus, the accessorius, the phrenic, and the external respiratory, and pro-

bably the intercostal and lumbar in part, to arise from a separate column of the spinal axis, between the anterior and posterior, and to be superadded to the nerves of sensation and voluntary motion, with which the muscles were supplied for common purposes. It is only to be observed, that the object of these papers was solely the illustration of the supposed system of respiratory nerves, and not the exposition of the whole of his system; and that they were the two first of a series which he had intended to present in regular order, when he was somewhat diverted by publications of which we shall now take notice.

1821.—M. Magendie, in his *Journal de Physiologie* for October. “He (Mr. C. Bell) has undertaken to show that the nerves have different functions according as they arise from such or such a part of the brain, or of the spinal marrow.” He then gives an abstract of the paper above quoted from, as *verbally* detailed to him by Mr. John Shaw, who visited Paris at that time, and says, “We have repeated these experiments (on the nerves of the face) at the Veterinary School of Alfort, with MM. Shaw and Dupuy, and the result which we have obtained agrees perfectly with what we have related, with the exception, however, of the influence of the division of the infra-orbital on mastication, an influence which was not evident to me.”—p. 387.

1822, July.—M. Magendie, *Journal de Physiologie*, vol. ii. p. 276. Having detailed very briefly his first experiments on the roots of the spinal marrow, “it is sufficient for me to be able now to advance as positive, that the anterior and posterior roots of the nerves arising from the spinal marrow have different functions; that the posterior appear more particularly destined to sensibility, while the anterior seem more especially connected with motion.” And in October of the same year, in the next number of his journal, having related additional experiments with *nuxvomica*, galvanism, &c.: “These facts are confirmatory, therefore, of those which I have announced, only they seem to establish that sensation is not exclusively in the posterior roots, nor motion in the anterior.” In the period between the publication of these two papers, Mr. John Shaw had sent him Sir C. Bell’s brochure of 1811, and had marked against the passage we have quoted,

about the experiments on the roots of the nerves. He says, "I thought I was the first who had dreamed of cutting the roots of the spinal nerves;" but adds, "we see, by this quotation from a work which I could not have known, since it had never been published, that Mr. Bell, led by his ingenious ideas on the nervous system, was very near discovering the functions of the spinal roots; however, the fact that the anterior are destined to motion, while the posterior belong more particularly to sensation, appears to have escaped him: it is, therefore, to the having established this fact in a positive manner, that I ought to limit my pretensions."

In 1825 M. Magendie expressed the same opinion in the "*Anatomie des Systèmes Nerveux*," by himself and Desmoulins. "We obtain, in fact, contractions by galvanizing each root. But the contractions are generally stronger and more complete with the anterior than with the posterior roots;" "prickings and pinchings (of the anterior roots) produce more strong and convulsive contractions, while there are scarcely any signs of pain. The isolation of the two properties in each of the two orders of roots, is, therefore, not absolute."—Vol. ii. p. 778. And even as late as 1833, when the third edition of his "*Précis Élémentaire de Physiologie*" was published, after Müller's experiments, he speaks, scarcely more positively.

1822, October.—Mr. Mayo, *Anatomical and Physiological Commentaries*, No. 1. "I infer, from the preceding experiments, that in the ass, the portio dura is a simple nerve of voluntary motion; and that the frontal, infra-orbital, and inferior maxillary, are nerves of sensation only, to which office that branch of the fifth which joins the portio-dura probably contributes; and from the preceding anatomical details, that other branches of the third division of the fifth are voluntary nerves to the pterygoid, the masseter, the temporal, and buccinator muscles."—Page 112.

1822, October and December.—Mr. John Shaw, *Medical and Physical Journal*. After pointing out the analogies between the fifth and spinal nerves, in structure, arrangement, and pathology, in a very lucid manner, "I cut a branch of the fifth upon the face; the sensibility of the corresponding side of the lip was destroyed;

but little paralysis ensued, excepting of certain actions of the orbicularis oris. I cut the nerve nearer the brain, and at a point previous to its having given off the branches to the muscles; then the jaw fell, and the muscles of that side were powerless. I varied the experiment by irritating the nerve, where it lies in the spheno-palatine fissure, immediately after an animal was killed; the jaws then came together with much force, indeed, so as to nip my assistant's finger severely."

1823, July.—Mr. Mayo, *Commentaries*, No. 2, corrected his former observation on the motor nerve of the buccinator, finding that "pinching the branch of the fifth, which penetrates that muscle, produces no action in it," page 8; "by this analogy (of the fifth with the spinal) I was led to conjecture that the double roots of the spinal nerves have functions corresponding with those of the fifth." "When I was engaged in experiments to determine the fact, M. Magendie's were published, which establish the justness of my conjecture."—Page 10.

1831.—Müller, in the "*Annales des Sciences Naturelles*," and 1834, "*Physiologie des Menschen*," p. 627. A series of experiments completely determining the entire isolation of motor power in the anterior, and sensitive in the posterior roots, the experiments of Federa, Schoeps, and others, having left the question in the same degree of uncertainty as those of Magendie.

The several passages we have now quoted have been selected as least capable of misinterpretation, and as including in the least space possible the principal features of each work. We have only room for the conclusion, which we believe they fairly lead to, viz. that to Sir Charles Bell is entirely due the honour of having proved (what had been imagined previously on insufficient grounds), that no one nervous filament is capable of performing more than one function; and for having first suggested and established the fact, to use Mr. Whewell's words, "that the two offices of conducting the motive impressions from the central seat of the will to the muscles, and of propagating impressions from the surface of the body and the external organs of sense to the sentient mind, reside in two distinct portions of the nervous sub-

stance." We believe that no one previously ignorant of the subject, but capable of judging of it, could read Sir Charles Bell's works published before any others, without being convinced of these important facts; and that he had carried his investigations almost to completion, is sufficiently proved by the subject being nearly perfected in two years after his first paper was read at the Royal Society.

Of those by whom facts supporting the doctrines were confirmed, improved, and supplied, we would accord the first honour to Mr. Mayo, for his experimental proofs of the facial branches of the fifth being purely sensitive, and his anatomical proofs of the motor power of its non-ganglionic portion; and, when the respiratory system is satisfactorily proved to be imaginary, for his arguments against it. The next place we think belongs to Müller, for the first clear experimental proof of the complete isolation of the motor and sensitive powers in the anterior and posterior roots. Next after Müller, credit is due to Magendie, for his approximations to the experimental proofs of this isolation, and of the absence of motor power in the infra-orbital nerve; nor must we omit our tribute to Mr. John Shaw, for his experimental proof of the motor power of the non-ganglionic portion of the fifth, and the numerous very important dissections and cases which he supplied.

Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."
 CICERO.

LAPSE OF LEGACIES FROM INSANITY.

WE have had, in our recent numbers, to call the attention of our readers to an unfair attempt judicially to place the person and liberty of a fellow-creature under the control of others, and his property, consequently, out of his own management. The attempt, as we have shewn, happily proved abortive; and

we should have been glad if another case we then cited, (and probably many more might have been adduced,) had been equally well adjudged. We shall, at all times, seek to expose these efforts to possess the control of the property of others by such means; for we consider it our province, and our duty, to watch every legal proceeding connected with insanity—indeed, the insane are mainly dependent on the medical profession for their comfort and protection. Insanity is, perhaps, the greatest misfortune to which society is liable, and the most distressing that can befall a family; for should the leading member of it be thus afflicted, all his exertions for its support are paralysed, and he becomes a burden on its resources; an object of incessant care and solicitude; and his children may eventually lose his property, from his inability adequately to dispose of it.

When we offered some remarks in a former number*, and an "Abstract from the recent Will Act," it did not at the time strike us, that the consideration of the Wills of Lunatics constituted no part of that act of legislation. The want of due arrangement for such has occasionally been a source of great injustice with regard to the descendants of lunatics; and we will now point out the relative advantages or situations of the sane and the insane, in reference to the provisions of the new Will Act, and take the liberty to suggest some amendments for the consideration of the legislature, to supply the existing deficiencies.

And we may without impropriety premise these, by some observations of the Commissioners appointed to inquire into the law of Property, who, referring to the subject of *Lapse*, say "the rule that gifts lapse, if the person to whom they

are made dies in the lifetime of the testator, sometimes operates with great hardship, and defeats, in many cases, the intention of the testator." And that the framers of the new Will Act, and the legislature, by whom that act was sanctioned, considered the lapse of a gift by will to a *child*, from the death of that child in the lifetime of the testator, to be, in all cases where such child left a family, a great hardship, and contrary to the probable intention of the testators, is obvious, since that Act provides, "that in all wills executed after the 1st of January, 1838, *no lapse shall take place in such cases; but that the gift shall take effect as if the child had survived the testator, unless a contrary intention shall appear upon the face of the will.*"

Thus far the public generally is protected; and every person not labouring under disability, can, and probably will, re-execute his will after the 1st of January, 1838, so as to take advantage of the Act. But how can the lunatic re-execute *his* will, so that his family, also, may obtain a similar or any advantage from the Act? His will having been made while in a state of sanity, contained dispositions of his property, suitable to the then existing state of his family; but many may, from subsequent circumstances, be deprived of his intended bounty. For instance, where the testator has, by his will, divided his property among his children, giving to each an equal share, his probable intention at the making of the will was, that the share of each child should be a vested interest, and descend to the issue of that child. Should the testator subsequently become insane, and, after this event, should one of his children die during his lifetime, leaving a family, then the intended gift to that child lapses, and the grandchildren lose their parent's share; for the testator, who, when

he made his will, never contemplated the event of his not having, at any time, the power to alter it, is now deprived of that power, and cannot meet the contingency which has occurred. Under such circumstances his probable and implied intentions are frustrated, by a cause which is, of itself, a sufficient affliction to his family, without the addition which the loss of the property necessarily carries with it.

With reference to cases similar to the above, the Commissioners, in the Report before quoted, state, that "it is true that the event of death might always be provided for,"—that is, it might at the time of making the will: "but it is found in practice that such provision is very rarely made. A testator does not contemplate that the immediate objects of his bounty, and especially his children, will die before him; he does not like to encumber his will with provisions which appear to be unnecessary; and he imagines that, if the event should happen, he shall be able to alter his will. His legal advisers think the chance that such an event will happen, without being provided for, is too slight to compensate the trouble of inserting clauses to meet it; and, in truth, it would often be difficult to determine how far such provisions should be carried.

It must be allowed, that a future disability from *insanity* is one that is not likely to occur to the testator at the making of his will, and can hardly be suggested by the legal advisers.

But if the lapse of gifts by will to children, as alluded to, was a hardship requiring the interposition of an act of parliament, to provide a remedy for the injury which might be sustained; even although such injury might arise from procrastination, indifference, or neglect, on the part of the testator; it would appear much more imperative on the legislature, to give relief in

situations which arise from a misfortune, over which no human power has any control. This might, perhaps, be best obtained by some provision to the following effect:—To provide, by an amendment in the new Will Act, or otherwise, as may seem expedient to the legislature, that in all cases where persons of unsound mind, *living on the 1st January, 1838*, shall have duly made and executed their wills, at some period previous to such unsoundness of mind, such wills shall be taken and construed as if they had been duly re-executed on the 1st January, 1838, by testators in full possession of their mental powers; so as to bring those wills also within the provisions of the Act. Without this, should any child of such testators die during their lifetime, leaving a family, the issue of that child will lose their grandfather's bounty, because they have had the misfortune to lose the care and protection of their parent; a much greater hardship by the way than any that the Law Commissioners, in their Report on Wills, have alluded to.

As cases may occur where the provision suggested may not afford sufficient protection, it would appear that a more comprehensive and effectual remedy would be afforded by providing, that where a testator has become insane subsequently to the execution of his will, and has continued so to the time of his death, his will shall be considered as speaking and taking effect from the time of the *commencement of his insanity*; a period always readily determinable by legal inquiry. As from that time the capability of the testator to provide for contingencies ceases, as completely as though he were absolutely no longer in existence, and as he is, in both a moral and legal sense, from that period, *dead*:—the property should be used to administer to his comforts, &c.; and at his actual *death*, his property

should be distributed as though it had been coeval with his moral or legal death. By these means any contingencies occurring subsequently to the latter event, will have been provided for by *himself*. Thus, should a child of an insane person have died (leaving a family) at any time subsequent to the commencement of the insanity of the parent, the legislature having so provided for the due fulfilment of the *sane intentions* of the testator, by amending the new Will Act, or otherwise, the issue of such child will be insured that proportion or share of the testator's property, which he meant by his will should devolve upon them. Provision, however, should be made for such as may come into existence between the events of the legal, and the actual, death. But if the law be left as it is at present, lunacy—the most afflicting misfortune of our common nature—will remain, still, to be very often a doubly dreadful blow to a family; for a portion of the unfortunate sufferer's descendants may thereby be bereft of his intended bounty towards them, and that, from a deficiency of our legal code which might be removed.

It is difficult, and often improper, to legislate retrospectively, and nothing but the necessity of distributing justice impartially to all classes and conditions of the community, perhaps, can warrant it. But to accomplish this, is the object and duty of legislation:—and if so, why are lapses in the wills of *lunatics* permitted still to take place, when, in those of sound minds, the legislature has declared lapses to be unjust, and has accordingly provided that they may not arise? This is not legislating impartially for all conditions of the community—not extending an equal guardianship over the interests of all positions of society.

The law very properly takes the persons and properties of lunatics under

its especial care; but has left the children of lunatics, as far as that property (when a will has been made prior to mental alienation) is concerned, to the common chances of survivorship, and absolutely unprotected by any law whatever; and further, the children have no means of protecting themselves, since the life of a lunatic is not insurable. They have, therefore, no hope for an amendment of their cruel and inequitable position, but from the future wisdom and provisions of the legislature.

It may be said, that we have no proof that these lunatics would have altered or re-executed their wills had they retained their mental powers: on the other hand, we have no better proof that they would not have done so; and both probability and experience teach us that the omission, on the part of the testator, to alter his will on the death of a child, leaving a family, arises almost always from procrastination, neglect, or ignorance, and very rarely from design; and the legislature having decided that it is unjust that such gifts by will to children should lapse by death, it would be an act of inconsistency to leave the issue of the children of one class of persons to their fate—perhaps to ruin, while those of all other classes are taken under the protection of its wisdom and care. This situation of the issue of children of lunatics is one of peculiar hardship as to the construction of the existing law in their case; for the lunatic, as far as regards his inability to alter or re-execute his will, in their favour, is taken to be as incapable as if he had died immediately upon the making of that will, when the objects of his bounty were alive; but as regards the causing a lapse, or forfeiture of their interests under the will, he is taken to have survived them.

We shall only add, in conclusion, that the hardship above alluded to is

not imaginary, but exists in the case of one of our brethren, whose family suffers from the "lapse" we have described*.

INQUEST

INVOLVING "A VERY NICE POINT."

A REMARKABLE inquest was held at Norwood, in Surrey, on the 26th of January, on the body of a boy named Henry Bailey. The gist of the case may be comprised in a small compass. The boy, whose age is not stated, had been in Lambeth Workhouse, where he was flogged by a Mr. Rowe with such severity, that the body, when viewed by the jury, "bore evident marks of blows, the back, thighs, legs, and arms, being nearly covered with black marks: there was also a bruise on the forehead."

Bailey had been removed to the House of Industry at Norwood, for the infant poor of the parish of Lambeth, on the 13th of January, and died there on the 19th. Now as it appeared on post-mortem examination that there was disease of the lungs, it would be difficult to say that this punishment had absolutely caused the death of the child, but it is at any rate obvious that it must have accelerated it. This plain fact did not escape Mr. W. Street, a surgeon of Norwood, whose evidence concludes thus:—

"There were also marks of a buckle on the hip, as if deceased had been struck with a strap that had a buckle at the end of it. The blows, in the state of health in which deceased was, would have caused much constitutional disturbance, but would not of themselves have caused death."

On this the following curious dialogue ensued:—

* There are one or two sentences of the above taken from a little brochure lately sent to us, but which, having been mislaid as this is passing the press, we are unable to designate the quotations in the usual form, by inverted commas.—ED. GAZ.

"The Coroner.—That is not the question. Do you mean to say that those blows would have produced death sooner than it would otherwise have taken place?"

"Mr. Street.—They might have hurried him into fever, and rendered him less able to bear up against the complaint under which he laboured."

"Coroner.—Suppose a person stood before us charged with having inflicted those blows, would you take upon you to say that their effect would be to accelerate the death of the deceased?"

"Mr. Street (after some consideration).—*That is a very nice point, and I would rather not answer it.*"

"The Coroner.—It is a nice point, and it is for that reason that I am anxious to obtain your opinion, as well as that of the other gentleman who examined the body."

"Mr. Street.—I repeat, that it is a very nice and delicate point, and, if pressed, I must say that, under all circumstances, I would prefer answering in the negative."

Surely this is sad stuff. The severe whipping which would cause "much constitutional disturbance" in a child labouring under disease of the lungs, must inevitably hasten death; and the witness, having confessed that the blows would have caused this, was not justified in endeavouring to back out of the necessary consequence. Perhaps he did not know, while giving his evidence, that the chief perpetrator of the deed was beyond all human censure, having died on the very morning of Bailey's removal to the house at Norwood. But though this will account for the witness's finding "a nice and delicate point" in his own imagination, it will not excuse it. The really nice and delicate points to decide would have been—1st, whether such a punishment would not have endangered the life of a healthy child; and, supposing this question to be decided in the negative, 2dly, whether the inflictors knew that the child was seriously ill when they so misused it? If they did, it is clear

that they were guilty of manslaughter, not to say of a graver crime. If they did not, under what kind of inspection, medical or other, are the children in Lambeth Workhouse?

These are really difficult questions; but when Mr. Street thinks it "a very nice point" to decide whether the death of a patient with pulmonary disease is hastened by his being whipped till his back, thighs, legs, and arms, are nearly covered with black marks—till there is a bruise on his forehead, and the mark of a buckle on his hip—we must apply an old adage to him, and say, *notum in scirpo querit*.

Another practitioner was now called, whose evidence, in the brief report before us, appears only to be the echo or faint reflection of Mr. Street's. Like him, he thought the disease of the lungs sufficient to account for death; and, like him, he could not tell whether the blows had accelerated it.

If any one wishes to know the cause of the disease of the lungs under which, with the help of the floggings, the poor child sank, he will not find it a very "nice and delicate point" to determine. The deceased, with his father and brothers, being homeless, had been received into Lambeth Workhouse, but were turned out again to shift as they could, and slept several nights in a stable. Those who do not practise the art mentioned in the adage above quoted, of finding knots in bulrushes, will allow, we suppose, that sleeping in a stable in January, and such a January as that of 1838, might *possibly* produce inflammation of the lungs. The jury said that, after the opinions of the surgeons, they could not go much further; they did not, however, appear quite satisfied. They at length returned a verdict, "that the deceased died of disease of the lungs."

This inquiry, if it can be called one, was badly managed in many particu-

bars. A juror wished to examine the father and brother, who, however, were not called; and the medical evidence will, we fear, be cited by those who are apt to say on points of forensic medicine, that "they manage these things better in France." In such a case as this, it was imperatively required that the professional witnesses should not only be free from all local partiality or bias, but from all suspicion of it; and therefore the services of some distinguished London surgeon should have been procured. Mr. Watmore, indeed, the clerk to the Lambeth Board of Guardians, stated not only that this inquiry was instituted at their particular desire, but that they had directed a post-mortem examination by two most eminent surgeons. Neither their names nor their opinions, however, are to be found in the report.

CLINICAL LECTURE

ON

SYPHILIS.

Delivered at St. Bartholomew's Hospital.

BY WM. LAWRENCE, ESQ. F.R.S. &c.

The Venereal Poison does not always produce the same effects—Case of Acute Phagedæna—Case of Sloughing Chancre—Remarks upon these Diseases—Effect of Intemperance and Licentiousness—Treatment to be employed.

I CALLED your attention, gentlemen, in the last lecture, to four cases of primary syphilitic ulcers, then in the hospital. All the sores possessed strongly marked characters, and no two were alike. We thus learn that the venereal poison, whatever be its nature, does not produce one unvarying set of effects. Further evidence of similar nature might be adduced in corroboration of the same conclusion. Thus, the first effect of the venereal poison may be an ulcer quite superficial, or a mere excoriation without loss of substance. Many consider that such appearances are not syphilitic: I regard them just as much so as the other forms. They occur from promiscuous sexual intercourse, and are not seen in married life where the parties strictly observe the marriage vow, nor in such as live chastely. They give rise to secondary syphilitic symptoms; and thus it happens that we see cases of the latter

where the patient says that he has had no venereal disease. I was consulted, not long since, by a gentleman with an attack of acute syphilitic iritis, of which the characters were so well marked, that I immediately told him he had venereal disease of the eye. He said this could not be, for he had never contracted a venereal affection. On further examination I found that he had had what he called a rash over his body; that it had lasted three or four months, and that there were still some remains to be seen; these were small patches of scaly syphilitic eruption. It appeared further, that some time previously to the rash he had had a slight excoriation in the penis, which did not heal completely for a few weeks. He had consulted a medical practitioner respecting the latter, who told him that it was a mere excoriation without any venereal character, and not requiring any particular treatment. The crisis in this case required active treatment, and the organ was not completely restored until the use of mercury, carried to the extent of affecting the glands, had been persevered in for four weeks. If the character of the primary affection had here been inferred from those of the iritis and eruption, we should have argued that it must have been decidedly syphilitic.

Whether this gentleman would have escaped without secondary symptoms, if the excoriation, as it was called, had been treated with mercury, must be uncertain—I think he would have had a better chance. If, however, he should hereafter experience further secondary symptoms, such as sore throat, affection of the periosteum, disease of the nose, he will not estimate very highly the knowledge and discrimination of the person who pronounced the primary complaint not to be venereal.

[No further symptoms have ensued in this case: at the end of eight months from the treatment of the iritis, the gentleman remains perfectly well.]

I placed before you, in the last lecture, a case of chronic phagedæna; that is, of an eating ulcer which proceeds slowly; which had lasted eight weeks without causing serious or extensive damage. Phagedænic ulceration may proceed more rapidly; it may destroy the glands in eight days. I will present you with an example of acute phagedæna. A gentleman, twenty-two years of age, observed an unpleasant appearance on the glands ten days after a suspicious connexion. For this he consulted a medical practitioner on a Thursday, and did not see him again till the following Sunday, pursuing his ordinary avocations, and living as usual in the meantime, the weather being very hot. I saw him on the following day (Monday), when his medical attendant informed me that

the complaint had consisted on the Thursday of a black spot; that it had increased fearfully by Sunday, when he recommended that I should be immediately consulted. I found a phagedenic excoriation, which had destroyed one-fourth of the glans on its left side, bounded anteriorly by the frenum. This alarming sore had an irregular surface, with sharp ragged edge; it was of a dirty yellowish and grayish colour, intermixed with bloody spots; and it secreted an offensive ichor, with strong and characteristic fetor. The glans was swelled and bright red. The prepuce could be easily withdrawn so as to expose the sore, which was painful. There was slight inflammatory tumefaction of the penis generally, which might be owing partly to the excitement and partly to exertion in hot weather. Eighteen leeches were applied to the penis, and afterwards bread poultice; black wash to the sore. The bowels were cleared by an active aperient, and subsequently he was ordered to rub in a drachm of the strong mercurial ointment every night, and to take two grains of calomel with one-third of a grain of opium every eight hours. He was confined to bed. The circumstances of his domestic position, the painful nature of the complaint, which compelled him to observe perfect rest, and the severe constitutional disturbance, aggravated by high atmospherical temperature, prevented the use of the frictions; the calomel and opium were therefore given every four or six hours. On Wednesday evening he was in a high fever, the small upper apartment which he occupied being as hot as an oven. I bled him largely from the arm, and found it necessary to substitute an evaporating lotion to the penis for the poultice, of which he could not bear the weight. Two days after he was removed to another residence, where he had a cool and commodious apartment. The action of the mercury was slow in this instance; it did not cause swelling of the gums nor ulceration, but it rendered them white, as if they had been covered by a thin adventitious stratum, and it caused moderate pytalism. The progress of the complaint seemed checked in the first twenty-four hours; but it was not decidedly arrested until about the seventh day. In the meantime it extended deeply, by a sloughing process between the glans and the corpus cavernosum penis; it destroyed the frenum, and shewed itself to a small extent on the right side of that fold, but it did not enlarge beyond its original boundary on the left of the glans, and it left the prepuce entire. When the slough separated it had gone so deeply as to open the urethra to the extent of about an inch on its upper and left side. When the surface

had been cleared the sore healed rapidly; and, as the prepuce was entire, while the contraction of the cicatrix lessened the apparent loss of substance in the glans, not only was the part again capable of all its functions, but its form had suffered very little damage. The mercurial influence was kept up until cicatrization was complete—a period of about four weeks. This is an example of primary sore spreading rapidly by destructive ulceration, which would, probably, have destroyed the glans in four or five days from the time I first saw it, if left to itself. The treatment demonstrates, unequivocally, the powerful influence of mercury over such affections.

[No secondary symptoms have followed in this case; the patient has continued perfectly well.]

I proceed to explain to you the nature and treatment of another form of primary syphilis—*sloughing chancre*; an affection in some respects more formidable than the preceding, the acute phagedenic sore. A lad of sixteen, who had recently left the country, contracted syphilis soon after he arrived in town. He immediately consulted a general practitioner, who observed nothing alarming in the case. This was on a Tuesday, and he was seen again on the following Saturday. In the meantime he had been going into the city daily, from a distance of three miles, and returning, had been actively employed in business during the day, and living in his usual manner, in the family with which he resided; the weather being very warm. The penis was now swelled, red, and painful; the orifice of the prepuce contracted, and there was a degree of feverish disturbance, rendering him incapable of further exertion. Depletion by resection and leeching, with rest in the horizontal position, and other corresponding antiphlogistic measures, were immediately resorted to, and followed up effectively. The local mischief, however, seemed to advance, and loss of the penis was feared. I saw the patient on Wednesday, when he was in a state of the greatest discomfort, from severe bodily and mental suffering. The penis was swollen generally, the prepuce more particularly, while a thin, bloody, and offensive discharge, with the peculiar fetor characterizing these sloughing sores, issued abundantly from the contracted orifice of the latter. The part was so extremely painful that he could not bear the slightest touch. He was enfeebled by the depletion he had undergone, and by the entire want of rest, caused partly by constant pain, partly by mental anxiety and depression, with apprehension that he might lose the member entirely. I divided the prepuce in its whole length

along the upper surface of the penis, finding that the most marked relief is experienced in such cases when the inflamed and ulcerated glans is liberated from the pressure which is caused by the swollen prepuce. Free bleeding ensued, as it usually does, from the edges of the incision. The relief thus afforded by unloading the vessels immediately engaged in the inflammatory mischief, is an important source of additional benefit in this mode of proceeding. One half of the glans had perished, and was converted into a dark greyish slough, separated from the living parts by a distinct line. Poppy fomentation and soft bread poultice constituted the local treatment, and the muriate of morphine was given at night to procure rest. On the following day he was much better; the division of the prepuce had been followed by immediate and effectual relief to the part, and the opiate had procured a good night. The slough was separating. In two days' time the separation had advanced considerably, leaving a rather foul and ragged surface, to which lint, dipped in the balsam of Peru, was applied. In two days more, the surface had become quite clean, and the balsam was left off, as its application caused pain. Soon after, the mortified part became entirely detached; although the slough extended deeply between the glans and the body of the penis, the urethra escaped. The sore now healed rapidly. The measures of general treatment, after the prepuce had been divided, consisted in a nutritious diet, with porter and wine, and the sulphate of quinine, in two-grain doses, three times a day.

[No secondary symptoms have ensued in this case.]

This and other analogous cases show that the venereal poison may cause, not only inflammation, increased and altered discharge, thickening and various modifications of ulceration, but also loss of vitality more or less considerable. The mortified part is separated by the same process as in other cases, the surface left after such separation being perfectly healthy, and usually granulating and cicatrizing rapidly. An ingenious person has written a book to prove "the non-existence of the venereal virus." We will not dispute about words; but we may be permitted to ask, if there is no venereal poison, how it happened that the first and sole amour of a healthy youth, aged sixteen, should have caused the serious mutilation of which I have given you the history?

In respect to the division of the prepuce—a strikingly beneficial part of the treatment in these and other similar conditions of the glans and prepuce—fear has been entertained that the discharges from the

diseased surfaces might contaminate the edges of the incision. This apprehension is altogether unfounded; in a large number of cases, where the proceeding has been adopted in this hospital, no such result has ever been noticed.

I have seen lately a greater number than usual of these serious phagedenic and sloughing diseases; some having occurred in private practice, where they are met with more rarely than in the wards of an hospital. These private cases are particularly interesting in elucidating the natural history of the disease; we can trace out the history more satisfactorily, and can ascertain that the distinguishing features of the complaint are not produced by causes which may be supposed to exert an influence in many hospital cases—such as intemperance, neglect, and perseverance in profligate licentiousness, after disease has been contracted.

I was consulted not long ago by a patient, 64 years of age, who said that he wished to have my opinion respecting an appearance on the penis. As he was preparing to shew the complaint, I anticipated the nature of the affection from a most offensive smell proceeding from the part. He drew back the prepuce without difficulty, and exposed a slough of the glans as large as a shilling, partly yellowish, partly black, discharging a thin fetid ichor. He did not relate how the affair had occurred, and it was not expedient to question him on the subject. I found that he had shewn it in the morning to his medical attendant in the country, and had been induced by his report to come to town, where I saw him in the evening. There was little or no swelling of the penis, and not much pain. I directed him to return home immediately; to go to bed, and remain there; to apply as many leeches as he could place on the penis; to use poppy fomentation and bread poultice, and take opening medicine. I told him that swelling and pain might be expected, and that a division of the prepuce would then be necessary. I did not see him again till the end of two days, when he was considerably worse. The penis and prepuce were swelled, but not considerably; the latter could only be withdrawn with difficulty. He had been in great pain for the last twenty-four hours, and had not slept during the preceding night. I divided the prepuce in its whole length. There was free bleeding, especially from one artery; and twenty ounces of blood flowed from the incision. Half the glans had mortified. The parts were now covered with the charcoal poultice, which is an excellent application, both for correcting fetor, and improving the condition of sloughing sores. The division of the pre-

puce at once relieved the pain, and it arrested the sloughing process. The latter effect has always ensued, within my observation, when the glans has been completely denuded in this way. The debility and the mental depression necessarily attendant on such an affection, and the treatment, required a nutritious and generous diet, with tonics and restoratives; these means restored and maintained strength. The slough, which was dense and hard, separated slowly; a month elapsed before it had completely come away, while in the preceding instance of a younger subject, the mortified part was loose and soft, and completely detached, in a fourth part of the time. Here, too, as I have generally observed, the slough extended deeply under the glans; it also destroyed a portion of the urethra.

[No farther unpleasant effect has occurred in this case; several months have now elapsed since the cicatrization was completed.]

I attended another case of sloughing chancre some years ago. A gentleman, 22 years of age, had connexion with a female on Oct. 24. He had had none for a considerable time previously, and none subsequently before I saw him. On November 4, he observed a small whitish place on the glans, and consulted a surgeon, who touched it with caustic, and prescribed opening medicine, and three blue pills a day. On the 5th the sore place was larger, very painful, and produced a foul discharge. He was worse on the 6th, when three grains of calomel, and half a grain of opium, were ordered every six hours. He consulted me on the 7th, having taken four of the doses last mentioned, and feeling much worse. As soon as he opened his clothes to shew the complaint, I recognized the peculiar factor of sloughing sores. The prepuce was bright red, and slightly œdematous; the glans, equally red, protruded about half way at the orifice of the prepuce. The latter could be withdrawn with a little difficulty, so as to expose a slough equal in extent of surface to a shilling, of which about two-thirds were on the glans, the remaining one-third on the root of the prepuce. The slough was black at one point; yellowish and dark red in other parts; it had the pulpy glutinous appearance of sloughing phagedæna, and it projected above the level of the sound parts; it discharged a thin, red, and extremely offensive ichor. The neighbouring internal surface of the prepuce was highly inflamed. The whole pain was very painful. The mouth was not affected by the mercury.

The mercury to be left off; leeches to the penis, followed by poppy fomen-

tation and bread poultice; the fomentation to be injected under the foreskin. Aperient medicine. To keep in bed.

In the evening, the leeches having drawn much blood with considerable relief, the pain was relieved, the discharge less red and offensive, and thicker. The bowels had been freely opened; the pulse full, and rather hard. I took away sixteen ounces of blood from the arm, and ordered a saline draught, with thirty drops of tinctura opii, if there should be such pain as to prevent rest.

8th.—The blood presented a thin buffy coat; passed a good night without the opiate. The discharge is no longer fetid; the prepuce is still inflamed and swollen; the glans and penis very tender to the touch, and occasionally painful.

Twelve leeches (which occasioned free bleeding); an opiate draught at night.

9th.—The penis less swelled and painful; the discharge no longer sanious nor fetid, but a thin pus.

An opening draught, and afterwards a saline draught every six hours; an opiate at night.

10th.—Occasional severe pain during the night, with intervals of ease; the penis still red, and very tender to the touch. I slit open the prepuce, of which the internal surface was inflamed and partially ulcerated; the sore of the penis was larger, presenting an excavation that would hold a filbert; a loose black slough lay in it; the discharge puriform, not discoloured, but very fetid.

Frequent tepid ablation; poultice of bread and water.

11th.—Much easier since the division of the prepuce; the lining of the latter and the glans present several ulcerations, with ash-coloured surface. As these did not exist originally, they must be referred to the active inflammation of the affected parts, excited by the primary affection. In the same way a syphilitic sore behind the corona glandis not unfrequently causes inflammation, excoriation, and fetid puriform discharge of the glans and prepuce. The original sore is large and deep, the slough having separated.

14th.—The process of granulation is advancing, and the ulcerative excavation is lessened. The secondary ulcerations, and the incision of the prepuce, are healing; all swelling has subsided, and the pain is at an end.

18th.—The sore is cicatrizing rapidly.

Poultice discontinued; dry lint; a draught of infusion of cascarrilla, with

dilute sulphuric acid, three times daily.

Dec. 12th.—The sore healed soon after the last date, and the patient went out of town. The parts are now in a perfectly sound state, the loss of substance in the glans appearing much less than at the time; and the general health and strength are perfect.

This case occurred several years ago. I have seen the subject of it from time to time, and know that no constitutional symptoms ensued.

The cases now related shew you that the venereal poison may cause mortification—either simple loss of vitality, or the state called sloughing phagedena—as its primary effect; and that high inflammation of the surrounding parts, particularly the glans and prepuce, follows more or less quickly as a secondary consequence. The treatment consists in depletion, general or local, or both, with other antiphlogistic means; and in division of the prepuce when it has become inflamed. The propriety of the latter measure is indicated by general swelling, redness, and severe pain of the penis, with fetid ichorous or sanious discharge from the orifice of the prepuce. The latter part will soon slough, if local relief is not procured in the manner now indicated. The division of the prepuce, however, is of great advantage in checking the progress of sloughing chancre on the glans, even where the part is not considerably swelled, nor in the state of phymosis, as you see from the foregoing cases. In this rapidly destructive and formidable complaint, mercury is unnecessary; its free exhibition would probably be most injurious. I do not think it necessary to detain you on the minor points of treatment, such as the occasional use of anodynes, the variations of local treatment according to the state of the ulcer, the diet, the administration of tonics and restoratives when the progress of disease has been checked; the particular indications in each case will direct your conduct in these matters.

ON THE MICROSCOPIC STRUCTURE OF THE BRAIN,

AND OF THE TISSUES INTERMIXED WITH IT.

By DR. LUIGI CALORI.

AFTER describing the three principal forms of the ultimate structure of the brain observed by anatomists, viz. the tubular of Ehrenberg, the fibrous or cylin-

driical of Alex. Monro and Fontana, and the globular of Della Torre, he mentions his own observations, which have led him to conclude that all these forms may be produced and rendered apparent by attention to certain particulars. The most uniform appearance is the globular; but the shape varies much with the mode of preparing the brain for examination, and with the degree of illumination to which it is subjected under the microscope, as well as with the magnifying power; nevertheless, the globular is most probably the real form of the nervous matter.

The tissues that are intermingled with the nervous substance and give it support, are very fine and transparent cellular substance, and the blood-vessels pointed out by Prochaska, of which Calori asserts that no one has hitherto given a full and perfect description. That the vessels of the medullary and cortical portions are not identical, is clear from their difference of calibre and distribution, and hence Gall was wrong in asserting that the latter was the source of the former. These vessels form a remarkably fine network, quite disproportionate to the size of the primary vessel, and similar to the distribution of the vessels on the surface of the allantoïd membrane. The nervous matter is united to these vessels, within whose ramifications it is collected; and, if really globular, it approaches most closely to the adipose tissue of Malpighi in its general appearance.—*Bullettino delle Scienze Med. de Bologna*; and *Brit. and For. Med. Rev.*

CASE OF LIVER ABSCESS.

MR. J. C. S. was seized on the 6th of August, in Canton, with inflammatory symptoms, for which he was leeches on the 10th or 12th, and bled from the arm on the 14th or 15th, and had this treatment afterwards followed up by a succession of leeching and blistering, and the administration of calomel every night, until the severity of the symptoms gave way. The disease was so far got under before his leaving Canton, that he was considered out of danger by his medical attendants, and was recommended by them to go to Macao for the benefit of a purer atmosphere, where he arrived on the 1st of September, labouring under a relapse of all his former symptoms, but of an aggravated and more strongly marked character. He complained of much acute tenderness over the whole region of the liver; so much so, as to be scarcely able to bear any degree of pressure of the hand upon any part of it. An attempt even to take a deep inspiration caused very severe pain in the right side. His respiration was short, quick,

and attended with cough; tongue coated, mouth parched; quick and sharp pulse; anxiety of countenance, and great general prostration; symptoms clearly indicating that the inflammatory process had exceeded the bounds which admit of a termination of active disease by resolution.

The application of leeches to the seat of pain, which was had recourse to repeatedly, and carried as far each time as his reduced state would admit of, afforded only temporary relief. His bowels were carefully attended to and kept open by means of emollient clysters, with occasional small doses of calomel, and rhubarb and castor-oil. Counter-irritation by means of blisters and the tartar emetic ointment was kept up; the nitro-muriatic bath was tried, and persevered in for some time; notwithstanding all which, no decided benefit was produced.

The above treatment was pursued until the 13th, when a sudden change for the better, in the character of the symptoms, took place. He felt himself all at once relieved, and was sensible of something having given way within him. On examining his motions next day, a very considerable quantity of purulent matter was discerned in them, and in those he passed for several days after, which sufficiently warranted the opinion that had been held, of an abscess having formed in the liver. For ten or twelve days after this, he improved considerably, when another return of the symptoms took place. The same remedies were employed as before, together with anodyne fomentations, with the same want of success; he got daily worse; and serious apprehensions regarding his recovery were entertained, when, on the 4th of October, he experienced another sudden change for the better. But this abscess being higher situated in the organ than the former one, burst into the *thorax* instead of the *colon*, and the matter was discharged by expectoration. Ever since he has continued to get better; and nothing further was required than a careful attention to the state of the bowels, keeping them open by mild aperients and emollient clysters, improving the strength generally by demulcent tonics and a strictly regulated diet, and allaying nervous irritability and procuring sleep by means of night-draughts containing the acetate of morphia.

A few days ago he felt some uneasiness in the right side: the cupping glasses were had recourse to, but as he could not endure them, leeches were applied in their stead, and with a very good effect. He is now recovering rapidly*.

ROYAL INSTITUTION.

Friday, Jan. 26, 1838.

THIS evening a lecture was delivered by Dr. FARADAY,

On the Nature of Fatty Bodies, and the Application of Stearine to the Manufacture of Candles.

The lecturer began by stating that all fats, whether animal or vegetable, are composed of the ultimate elements—carbon, hydrogen, and oxygen—though in somewhat different proportions; in all, however, the carbon greatly predominates. But their proximate principles are oleine and stearine; the oleine, or oil, being separable by pressure from the stearine, which is a solid. The lecturer then went on to give a very brief outline of the way in which soap is made—by the application of an alkali (as potass, or soda) to fat, or oil. Before Chevreul, who, in 1813, directed his attention to the subject, it was generally believed that, by the application of an acid, the fatty body thus converted into soap would be restored to its former condition: but his experiments have shown that the qualities are then essentially different from what they were before the alkali was applied.

He next directed the attention of his audience to the process of candle-making; where, instead of potass, or soda (which would be too expensive), quick-lime is employed, and when mixed and stirred with the fat, produces exactly the same effect as an alkali. He explained each step of the process with great clearness, illustrated his remarks as he proceeded by numerous specimens of the materials in their different states, and concluded by displaying two sets of moulds, showing how the wicks are fastened, and how the tallow is used when finally prepared. He stated, that wicks should be soaked in acid for some time before they are used; but the acid used must not be sulphuric, which rots them. Great care must be taken to pour the tallow into the moulds at a proper temperature; for if it is too hot, it is very difficult (in some cases impossible) to extract the candles unbroken; and even if they come out whole, they are inferior in appearance to others. For the sake of facilitating the process of extracting the candles from the moulds, different substances have been employed in small quantities: of these Dr. F. confined his remarks to arsenic, which was first employed by a Parisian; and though the art was attempted to be concealed, it found its way into England a few years ago, where

* Dr. Colledge, in the Quarterly Journal of the Calcutta Med. and Phys. Society, April 1837.

it has since been almost universally employed. At first it was used only in the proportion of 1 10th of a grain, which, however, has since increased to (it is said) $4\frac{1}{2}$ grains per candle. As the arsenic is not dissolved in the tallow, it sinks down in the mould when the liquid is poured in, so that much the greatest quantity is to be found at the top of the candle. Dr. F. showed specimens of candles containing different quantities of this matter, and said that he had been unable to light one of them, in consequence of the quantity contained at the top; but upon cutting it off, the lower part of the candle was lighted with perfect ease. Where it exists in any quantity, if the candle is blown out, a very disagreeable smell is easily perceived. He stated, that one of the best methods of ascertaining the presence of arsenic is to melt the tallow, put a few pieces of it into a retort, along with some pieces of zinc, and pour in a small quantity of sulphuric acid. If the hydrogen thus generated be collected and lighted, the colour of the flame will betray the presence of the arsenic; or (as all may not be familiar with its natural colour) let a white plate be held over the flame for a few minutes, and a deposit of the arsenic will soon be perceptible. It is, however, satisfactory to know, that owing to the late inquiries of the Westminster Medical Society, the practice has been discontinued.

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Surgeon, Mr. ANDREWS.

Assistant-Surgeon, Mr. ADAMS.

Jan.	Sex.	Age.	Case.
2.	M.	28	Injured spine.

(a.) The subject of this case was a sailor, who had fallen on board a ship from a considerable height, and was taken up insensible, in which state he was brought to the hospital. At the time of his admission he was labouring under the apparent symptoms of an extreme degree of concussion of the brain, and a large quantity of blood had escaped from the right ear. His insensibility continued almost complete up to the period of his death, which occurred on the fifth day after the accident. On the third day after his admission a transient gleam of returning sensibility manifested itself, as he spoke to the nurse, asking for food, and took some milk and bread which stood near him; but he soon relapsed into his former insensible state. He was, however, at intervals restless, drawing his arms forcibly away when any examination of his pulse was attempted. The pulse was small and weak; the pupils, almost insensible to light, neither contracted nor dilated; his urine and feces flowed involuntarily from him; he had no apparent paralysis of the extremities. The only external appearance of injury was a slight tumefaction over the right temple, and this scarcely perceptible; but as the symptoms indicated rather a general injury to the brain, no incision was made. The treatment adopted was antiphlogistic; and mercury was exhibited by the mouth and by inunction. He sank gradually.

Post-mortem.—A fissure on the right side of the skull, across a branch of the spinous artery, extending down over the petrous portion of the temporal bone; blood effused on the dura mater on this side. Extensive laceration of the substance of the left middle lobe of the brain, at the basis.

(b.) This patient was admitted with a violent purulent inflammation of the left eye, which he attributed to some lime having been blown into it as he walked. It was, however, soon apparent that the disease was not attributable to this supposed cause, and that the case was to be regarded as one of violent gonorrhœal ophthalmia. He had been the subject of gonorrhœa three weeks. All the symptoms it is unnecessary to detail; but it may be observed, that sloughing of the cornea had occurred at the upper portion, and the iris had protruded. A slight haziness of the cornea subsequently took place. The case is alluded to as a proof of the efficacy of a combination of the antiphlogistic and stimulating plan of treatment, as the dis-

ease is completely arrested. The treatment consisted in the exhibition of mercury, so as to affect the mouth—in the free scarification and excision of the chemosed conjunctiva—and the injection into the eye every hour of a solution of nitrate of silver, in the proportion of three grains to the ounce.

PLASTER CASTS IN FRACTURES.

To the Editor of the Medical Gazette.

SIR,

Nothing could be further from my intention and wishes than to despoil a professional brother of that reputation to which his skill and industry entitle him; and had I seen or heard of Mr. Beaumont's pamphlet, should have felt equal pleasure in acknowledging that I had been led to employ the plaster casts in consequence of

his suggestions, as I had in referring to the paper published by Messrs. Bond and Gale in the *Lancet*, which was to me a satisfactory authority, as I know the former gentleman to be an ingenious man and good practical surgeon.

It is probable that Messrs. Bond and Gale had seen the ill-timed and injudicious critique on Mr. Beaumont's pamphlet in the journal edited by Dr. Ryan, as they refer to a notice which they "recollect reading some time before in one of the medical periodicals, wherein the method" of treating fractures by means of plaster casts was "condemned as impracticable and injurious."

Messrs. Bond and Gale's paper is dated July 1831, and in the following month a letter from Dr. John Browne, of Dublin, appeared in the same journal, saying, that Professor Kirby had employed successfully the plaster casts ten years before the appearance of the paper sent forth by those gentlemen, but it does not appear that Professor Kirby has at any time published an account of the method.

With whom this method of treating fractures originated, it would be difficult at this time to decide. I have been informed within a few days that an account of it was published many years ago in the *Medical Repository*, and it is long since that M. Lallemand introduced it from Montpelier into the Parisian hospitals. There can be no doubt that the practice has been handed down by tradition from a very remote period, but Mr. Beaumont is perhaps the first gentleman who has written a pamphlet expressly on the subject, for which our thanks are due to him. For my own part, I disclaim all title to originality in this matter, and can only express my grateful acknowledgments to the inventors and revivers of the method in question, which I am sure will be found in the fullest manner to answer the expectations of those practitioners who may be induced to employ it; that it will eventually supersede the ordinary splint and bandage, and be found, though rough in its exterior, to be the really "soft and easy method of treating fractures."

I am, sir,

Your obedient servant,

W. SWEETING.

Bridport, 13th Jan. 1838.

In the paper I transmitted to you on the 24th ult. reference is made to a case then under treatment. In the present week the plaster cast has been removed, and perfect union of the fractured bones found to have taken place. The case was in the beginning very unpromising, in consequence of the bones having been a long time without an approach to union, but it has turned out extremely well.

ATMOSPHERIC TEMPERATURE.

WEEKLY ACCOUNT OF BURIALS,

To the Editor of the Medical Gazette.

SIR,

On Friday night, the 19th ultimo, and during the following day, the thermometer indicated the lowest degree of temperature which has probably been recollected in England for many years past. At ten o'clock on the evening in question the mercury stood at 3° below zero, and brandy exposed to the air froze, in the course of the night, into a solid amorphous mass. Some spirit of ammonia, confined in a common phial, deposited a large quantity of crystalline flakes, which were afterwards perfectly insoluble in the same medium. But the most remarkable fact is perhaps connected with the great change of temperature which the atmosphere suddenly underwent. On Saturday, at nine o'clock in the morning, Fahrenheit's thermometer, placed in a northern aspect, sank 4° below 0, and on the Sunday morning following, at the same hour and in the same situation, the mercury had risen to 3° above freezing, thus indicating, in the space of four-and-twenty hours, a variation of atmospheric temperature amounting to thirty nine degrees.

It may be observed, that the thermometer with which these observations were made was graduated (as I believe Fahrenheit's usually are) four degrees only below zero; but the mercury, in the latter instance of intense frigidity which I have recorded, had retreated a small distance into the bulb; and I presume, had the instrument been capable of exhibiting it with accuracy, that it would have indicated a considerably greater degree of cold than that above mentioned.—I am, sir,

Your obedient servant,

R. H. ALLNATT, M.D.

LECTURES

ON THE

PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE XIII.

Diseases of the Air Tubes (continued)—Chronic Bronchitis: Pathology; Course and Signs; Treatment—Croup: Pathology and Signs; Treatment—Whooping-cough: Signs and Treatment. Diseases of Secretion—Pituitous Catarrh: Pathology and Signs; Treatment—Dry Catarrh: Pathology and Signs; Treatment: Alkaline Attenuants—Bronchial Hæmorrhage.

CHRONIC bronchitis is not separated by any distinct line from the acute disease; but in many cases it presents very distinguishing characters. The two forms of inflammation pass by insensible gradations into each other, and are often conjoined; for although acute bronchitis frequently exists alone, chronic bronchitis is rarely free from occasional admixture of acute inflammation, and neither is the long duration of the disease always a proof that it is not acute, for I have known several cases of acute bronchitis in which attack succeeded to attack for many weeks, and never lost the acute character. The expectorated matter gives us some proofs of the state of the membrane from which it comes; and by the heterogeneous charac-

ter often presented by that in chronic bronchitis, we may form a notion of the various pathological conditions simultaneously affecting different parts of bronchial tubes. I think that we may say, however, that there is generally some opaque matter in the expectoration of chronic bronchitis, and that the tendency of chronic inflammation is to make the mucous membrane secrete, instead of glairy mucus, more or less of the opaque matter, which we have classed generally under the head Albuminous Sputa, whether that be muco-purulent, purulent, fibrinous, or caseous; whether these occur separately, or, as is more usual, variously combined, of various degrees of consistence and colour, and variously mixed with a thinner and more transparent fluid of a mucous or serous quality.

Chronic bronchitis presents itself in many forms and modes of origin. We cannot stay to enumerate these; but let us see how it arises out of the acute disease. An acute attack of bronchitis has lasted long enough to injure the membrane; or its effects have not been controlled by treatment; or stimulating causes have kept up a general or local irritation at the stage in which the inflamed bronchial membrane was relieving itself by an unusual secretion: in either of these cases, although the sputa have become partially opaque and *concocted*, and the usual mitigation of the fever and other symptoms have accompanied this change, yet the complaint then becomes stationary, with a lower febrile and inflammatory character, but with unsubdued and more paroxysmal cough, often with dyspnoea, soreness and wandering pains in the chest, and more or less general ill health, and continuing disorder in other functions. The sputa become diffuent, and mixed with some masses, *concocted* and opaque, of a yellowish or greenish colour, often obviously purulent, sometimes of a dirty grey or

brown colour, and in some parts still thin and transparent. More rarely, an albuminous matter, moulded by the shape of the bronchial ramifications, is expectorated by a violent and suffocating cough. When the expectoration is purulent, there is usually a great deal of prostration, and some loss of flesh; occasionally we find evening hectic, night sweats, and other of the common symptoms of tubercular consumption; but the physical signs are wanting.

The chest, in simple chronic bronchitis, still expands equally, and sounds well on percussion. The respiration and cough are heard with various rhonchi, mucous, sonorous, sibilant, and clicking, which are continually shifting and changing. There is no bronchial or cavernous respiration; no permanent absence of respiration in a part; no unusual resonance of the voice; and in spite of the continuance of the copious and puriform expectoration, on listening, day after day, we still find no signs of a cavity, no cavernous rhonchus or pectoriloquy. Under these circumstances, whatever be the general symptoms, we may pretty confidently pronounce that the disease is not tuberculous consumption, but simple chronic bronchitis. It is not, however, always very easy to get this perfect degree of negative evidence, and it requires much experience in auscultation, or repeated examinations, to enable one to report it with confidence. In such, and all doubtful cases, we should take into consideration also, the history of the attack, the constitution of the patient, and such of the general symptoms as may serve to throw light on the prevailing tendencies of the system. The more profuse the expectoration, especially if it be very purulent, or otherwise albuminous, the less likely is the case to be one of phthisis, if no physical signs of this disease are found, and it may be the more readily inferred that the sputa only proceed from a diseased membrane. But there are other difficulties to be considered on this point of diagnosis, which we had better postpone till we treat of phthisis.

Chronic bronchitis is often a very obstinate disease. In its milder kinds it constitutes the winter cough of old people, and may continue for many years without much injuring the constitution of the patient; but in its severer forms, when the expectoration continues to be profuse, or of a purulent nature; or when the membranes are extensively affected, and dyspnoea is the result; or when the cough is very harassing, or has a convulsive character, then the health and the strength of the patient may suffer much; in fact, those of weakly frames often fall victims to it, and this either from the disease

itself only, or also from the alterations which it causes in the structures of the air-tubes and lungs. Of these we shall speak hereafter.

The treatment of chronic bronchitis must vary much, according to the nature of the case, as indicated by the cough, expectoration, and state of the circulation. Bloodletting is not often necessary, unless to relieve a temporary exacerbation or congestion, when leeches under the clavicles, or to the top of the sternum, or cupping between the shoulders, will generally suffice. The most generally useful class of remedies are, counter-irritants, conjoined with mild alterative tonics. Friction of the chest with an oily liniment containing various proportions of tartar emetic, tincture of campharides, the essential oils, ammonia, acetic acid, or a diluted mineral acid, according to the degree of effect desired; or a succession of mild blisters; or, in less severe cases, wearing an ample pitch or mercurial plaster, with a small proportion of blistering fly in it, will furnish a choice of means of counter-irritation, applicable to every case. The methods by friction are preferable to the use of plasters, for they promote in some measure the respiratory movements, whereas plasters, unless they are supple and carefully applied, may somewhat restrain the expansion of the chest. To avoid this the patient should be desired to take long deep inspirations when the plaster is first applied; and if its material be rigid, it should have long cuts in it from middle to margin, corresponding with the intercostal spaces from the sternum to the sides. When we come to speak of the alterations of structure induced by inflammatory affections, you will perceive the importance of promoting in every way the free and equal expansion of the chest. With the plan of external counter-irritation it is generally expedient to join such internal remedies as may seem best calculated to improve the condition of the diseased membrane and of the functions generally. These will vary surprisingly in different cases, and although all these cases may suffer from the same local disease—chronic bronchitis—yet they may be best relieved by the most opposite remedies. Mild tonics, such as calumba and cascarrilla, with nitric acid, sarsaparilla, taraxacum, are very commonly useful to improve the condition of the secretions and other functions; and where the expectoration is profuse, and even purulent, without much vascular excitement, the mineral acids and metallic astringents in some cases, in others myrrh, copaiba, the balsam of Peru, benzoic acid, and the like, prove occasionally useful. Many of these are safe and beneficial only

when combined with external counter-irritation; which, like a safety-valve, lets off in another way any undue stimulation which they may cause. I have found that even steel medicines, particularly that most valuable one the iodide of iron, have been borne, and have sometimes proved very salutary in improving the general health and strength. Of late years much has been said for and against the direct application of remedies, particularly the vapour of iodine and chlorine, by inhalation. I have not much experience of this kind of treatment, but in several cases in which I have seen it tried, an unfavourable effect seemed to arise from the effort necessary in using the inhaling apparatus, the tubes being too small, and the patients complaining of the operation fatiguing them. I should suggest, as a substitute for this plan, the diffusion of iodine, or chlorine, combined with watery vapour, either in the apartment of the patient, or, what would be more practicable, in a small room, or closet, cleared for the purpose, in which he could spend from half an hour to an hour twice a day. Iodine, or chlorine, may be readily dispersed in any quantity through the room, by placing a few grains of the former, or a solution of the chloride of soda, or lime, in a saucer floating on hot water. The quantity should be determined by the effect on the patient; always keeping it below that which causes much coughing or acceleration of the pulse.

When all these means fail, a change of air (especially to a warm sea-coast residence, where the patient can use moderate but regular exercise in the open air) often proves beneficial; and to convalescents, repeated changes, such as those obtained in a sea-voyage or gentle land travelling, in warm weather, sometimes prove very salutary. Besides the several symptoms of improvement which I need not enumerate, and the recovery of looks and strength, we should watch for the physical signs, in the more perfect expansion of the chest, the diminution of the rhonchi, the equal respiratory murmur, and the restoration of the expectoration to a simple scanty mucus.

We must just notice some specific affections of the air-passages, in which inflammation is a prominent part, although the accompanying phenomena, or effects, differ from those of common inflammation.

Croup, and membraniferous or plastic inflammation of the air-passages, are characterized by the solid albuminous matter which they throw out; and their dangerous nature arises from the obstruction which this effusion opposes to the passage of the air. There are two very distinct affections of this kind; one decidedly

inflammatory, of a very acute character, and tending rapidly to the formation of a tough fibrinous matter, which resembles the lymph effused by inflamed serous membranes, but does not appear even to become organized: this is the true croup; a complaint almost exclusively affecting children. The other affection is more of the character of a cynanche, is less acute, and is more tardily accompanied by the effusion of a soft pellicle, like those which form on the tonsils in a kindred affection; indeed the tonsils are generally simultaneously affected in the same way. This is the *diphtherite* of Brétonneau; it is a much more chronic affection than croup: it prevails epidemically, is by some considered to be contagious, and affects adults more than children. I do not think that I have ever seen more than two or three instances of this complaint, so that what I have to say will refer chiefly to croup.

This *croup*, stridulous character of the sound of the air in passing the trachea, particularly in inspiration, which is the most forcible act, the indistinctness of the pulmonary murmur, owing to the little air that enters the chest, which nevertheless sounds well on percussion, and the concave state of the intercostal spaces at each inspiration, showing that there would be room in the chest if the air could get in; these are distinctive signs of unmixed croup. But it very commonly happens that there is wheezing in the chest also, from the simultaneous affection of the bronchi with either the plastic or common inflammation. The sonorous inspiration of croup is audible through the stethoscope, or ear, applied to the throat or upper part of the chest, before it can be heard by the ear unapplied: we should, therefore, use this mode of examination with children liable to croup, whenever they show any signs of indisposition. Spasmodic croup is a distinct affection; but there is probably a good deal of spasm accompanying this disease, both in the early stage, where the inflammation must greatly augment the irritability of the muscular fibres of the air-tubes, and in the subsequent period, when the albuminous coating, becoming detached, acts as a foreign body, continually irritating them. The temporary aggravations of the dyspnoea favour this view. It was remarked by Dr. Cheyne that the solid effusion found in the trachea and bronchi after death, is never sufficient nearly to close these tubes; it fact it is commonly in a hollow or tubular form, with a pretty large opening within; it has therefore been suggested as probable that a spasm added to the constriction.

I have nothing new to offer you on the subject of the treatment of croup. At its

earliest onset, when the croupy breathing is only audible to the ear applied, bleeding and the warm bath, or an emetic, followed by a brisk mercurial cathartic, may sometimes arrest the disease; but when the disease has established itself in its well-known form, that is, after the albuminous exudation has taken place, these remedies lose their effect, and are ill borne. Then the chief resource is mercury in large doses, or tartar emetic watched closely in its effects; and the success of these measures will depend on there being strength enough to battle against the stifling influence of the disease until their operation reaches the system, and causes the absorption or removal of the effused matter. Sometimes violent and almost suffocating fits of coughing are excited by the retained pellicle. An emetic will sometimes assist in its expulsion. In the less inflammatory affection, diphtheritis, the removal of the albuminous concretions is sometimes accelerated, and a healthy action promoted, by touching the fauces and epiglottis with diluted muriatic acid, or a pretty strong solution of nitrate of silver; and stimulant inhalations have been recommended with the same view. Dr. Cheyne, Mr. Porter, and other of the best authorities, agree that bronchotomy offers little chance of relief in croup, for the disease generally involves the bronchi as well as the trachea.

The peculiarity of *Pertussis*, or *Whooping-cough*, lies in the nervous, or rather the muscular, relations of respiration. The affection is at first distinctly inflammatory, and the cough is not unlike that of common bronchitis; but it soon assumes a convulsive character, the fits of coughing being very violent, uncontrollable, shaking the whole frame, and often ending with retching. There may be a *whooping* sound in the inspiration during the cough, but not necessarily; and this, as we have before noticed, depends on an undue irritability of the bronchial and contractile laryngeal muscles, so that they do not relax as usual during the act of taking breath. During this *whoop*, or sonorous back draught, the ear applied to the chest hears little or no natural respiratory murmur; but, during the intervals of the cough, this murmur may be as distinct as usual. This does not necessarily imply, however, as Laennec supposed, that there is a spasm in the bronchi; the upper part of the tube being narrowed, is sufficient to weaken much the sound of vesicular respiration, as it is observed in oedema or spasm of the glottis, and where aneurisms or other tumors press on the windpipe.

I have little to say on the treatment of

pertussis in addition to what you already know, or may find in modern works. In the first stage it is almost purely inflammatory; a bronchitis, in fact, but generally combined with more headache and general disorder than usual. In the second stage it is inflammatory or congestive, and nervous; and at last it becomes entirely nervous; but even in this stage it is often complicated with alterations in the membrane, and even in the structure of the lungs, which the previous inflammation, conjoined with the mechanical violence of long-continued fits of coughing, has produced. Moderate depletions and other antiphlogistics, in the first stage; counter-irritants, occasional emetics, and sedatives to the muscular mobility, in the second; and antispasmodics and nervous tonics in the third, are the chief heads of the treatment. Stimulant and opiate embrocations rubbed over the chest twice a day, are often very useful in allaying the violence of the cough; and I believe that they effect this partly by diminishing the excitability of the respiratory muscles. Of internal medicines for this purpose, I know of none so effectual as belladonna; but, to have its due effect, it should be administered in larger doses than those usually recommended. I have often given a quarter of a grain of the extract three times a day, to a child of two years, half a grain to one of four, and a whole grain to one of eight years of age; and increased these quantities to double, and more when they ceased to relieve. These doses generally cause some dilatation of the pupil; and I conceive that the remedial agency of the drug depends on the same power to diminish irritability in the bronchial and laryngeal muscles, which is here evinced with regard to the iris. In some cases there have been some feeling of heat and dryness in the throat, giddiness and pain over the eyes; but these symptoms lead to no bad consequences, and soon pass off when the medicine is discontinued. In fact, I have known more than one instance of a large quantity of the extract of belladonna being swallowed in mistake (in one case upwards of a drachm), without any other bad effects than the temporary production of the symptoms described as those of *poisoning* by belladonna, and which entirely passed away in a day or two. Sir Benjamin Brodie has informed me that he has repeatedly given large doses to animals; and although they manifested for a time many ugly symptoms of nervous disturbance, they all ultimately recovered. I tell you this, that you may not be alarmed should untoward symptoms sometimes manifest themselves during the exhibition

of belladonna. They occasionally occur when it is given in very moderate doses, and even during the application of a belladonna plaster externally; but they do no further harm. In many cases I have found the belladonna to diminish signally the violence and number of the paroxysms of whooping-cough; but as it loses some of its efficacy by continuance, I have found it best to intermit its use for a few days, and then to resume it again. In the more violent cases we are obliged to resort to opium, which, if more powerful as a narcotic, also may do more harm than belladonna. The preparations of morphia are perhaps the best form of opiate, and they should be combined with ipecacuanha. In the latter stages a change of air is almost a specific; any kind of change, and although only to the distance of a few miles, will sometimes entirely remove a cough that has baffled all medicines.

In the convulsive coughs of adults, which resemble whooping-cough, I have several times found the pilula aloës et asafetide twice a day, with a galbanum or pitch plaster to the chest, cause most effectual relief. Where the complaint is more obstinate, and the nervous system takes up the habit (as in chorea and other convulsive diseases), the metallic salts, subnitrate of bismuth, nitrate of silver, or ammoniacet of copper, will sometimes succeed in restoring the balance; and they may generally be aided by the shower bath, country air, and exercise, and other means which diminish the mobility of the nervous system.

We have seen how remarkably inflammation alters the secretion of the bronchial membrane; but it may also be altered without there being any distinct signs of inflammation. Thus in cases of what in this country is generally called humoral asthma, the attack and its removal are too sudden to be ascribed to inflammation; and after death there are not found any appearances that betoken an inflammatory character; nay, the membranes are often paler and thinner than usual. Although such affections may originate in, or be occasionally complicated with, bronchitis in some of its forms, yet they are not essentially so, and may with more propriety be called diseases of secretion. The most remarkable of these are the *pituitous* and *dry catarrhs* of Laennec.

Pituitous catarrh, bronchorrhœa, or bronchial flux, is remarkable for the quantity of thin liquid that is discharged by expectoration. This liquid does not appear to differ materially from the natural secretion, but in being thinner, and it is probably this, diluted with a considerable ad-

dition of the most watery part of the blood. This suggests that a laxity of the bronchial vessels may be its immediate pathological cause; and this view is confirmed by the fact that we find it to occur chiefly in those of a relaxed habit of body, who usually drink much liquid, and perspire profusely. I have seen several cases in which a discharge of this kind was plainly vicarious with the exhalation from the skin, sudden changes of temperature, irregularities of diet, disorder of the digestive functions, which depressed the cutaneous circulation, being sufficient to excite it. It is often combined or alternated with a similar discharge or phlegmorrhæa from the nasal membrane, a sort of chronic cold in the head. Sometimes it is connected with organic disease of the heart, which causes congestion in the lungs. It generally comes on without fever, with sneezing, cough, and asthmatic or wheezing breathing. On applying our ear to the chest, we hear all sorts of sonorous and whistling rhonchi, which, as the attack proceeds, become mucous or bubbling; and very little of the natural respiratory murmur is heard. The sound on percussion is generally pretty good; but in severe cases this is also impaired by the profuse quantity of liquid, which from the submucous and subcrepitant rhonchi may be known to extend even to the smaller bronchial tubes. Coming on, as the attack does, suddenly, the dyspnoea is sometimes extreme; but the strength of the respiratory forces being also unimpaired, they generally, by dint of violent coughing, get rid of the fluid as fast as it is secreted, and it comes up clear and frothy, sometimes to the amount of a pint or more.

Although not generally dangerous, this complaint often causes much suffering and discomfort; and if it occur frequently it causes much weakness and exhaustion. This affection is sometimes very obstinate in regard to treatment, especially when it has become established in the habit. The most powerful means are those of diet and regimen. A well-regulated, nourishing, but not stimulating diet, with a limited quantity of liquid; a bracing, but not too cold air; and above all, regular and pretty active exercise, with clothing always sufficient to protect the surface from transitions of temperature, and to favour an equable moderate perspiration, will often do more than medicine. Of remedial agents, mild tonics, the mineral acids, or some metallic salts, such as the sulphate of zinc, in small doses, and the milder preparations of steel, are sometimes beneficial. In other cases some of those medicines supposed to act especially on the mucous membranes prove serviceable, such as ipecacuanha, the balsams of copaiba and Peru. During

the paroxysm, as well as in the stage of effusion in humid bronchitis, I have known the ethereal tincture of the *lobelia inflata* very materially relieve the dyspnoea, and shorten its duration. It is, however, a very uncertain medicine, sometimes causing vertigo and nausea in the dose of ten minims, in others giving relief only in the dose of a drachm. There are many other remedies that now and then appear to do good, such as emetics, opium, blisters, &c., but I have no time to enter into further details on the empirical part of the subject.

The other affection which exemplifies the altered secretion of the bronchial membrane without distinct inflammation, is the *dry catarrh* of Laennec. This term, *dry catarrh*, is a very bad one; and but that the word *catarrh* is now used almost synonymously with cough, it would be totally inapplicable. *Catarrh* means a *flowing down*; and what can be greater nonsense than *dry flowing*? The symptoms of this affection are those rather of asthma than of bronchitis. They vary according to the extent of the affection. In its slightest degrees, it is presented by those individuals who, every morning on waking, feel their breath rather short until they have coughed up a little tough semi-transparent mucus. In its severer degrees, that is, when more of the bronchial membrane is affected, the shortness of breathing may amount to a regular fit of asthma, accompanied by cough; and this may last, more or less, for hours, and even days, and be at last relieved by the expectoration of the scanty tough expectoration just mentioned. There is little or no fever or sign of inflammation present; only sometimes a sense of constriction and heat, or rather of stuffing in the chest; but there is often much gastric disorder; the tongue slightly furred; the uvula relaxed; the tonsils congested; digestion imperfect; the liver inactive; the bowels torpid, or liable to extremes; the hæmorrhoidal veins swelled; and the urine turbid. Excesses in diet, the sudden removal of cutaneous eruptions, suppressed gout, and sudden checks given to perspiration, or any other free secretion, occasionally excite this affection. These causes operating on systems not much disposed to inflammatory reaction, such as those of a torpid habit of body, destroy the balance of the capillary system, and occasion an undue distension or congestion of certain parts of it. This congestion is accompanied by a disorder of the functions of the part, and in the bronchial membrane, especially by a derangement of its secretion. The same kind of passive congestion is sometimes more directly occasioned by organic diseases of the heart, particularly those in

which there is some obstruction in the left ventricle; and here we frequently have the symptoms of dry catarrh.

The physical sign of this disease is a more or less complete suspension of the respiratory sound in the part affected, whilst the chest, at that point, still sounds quite well on percussion. This suspension is caused by the tumefaction of the bronchial membrane, which either of itself, or assisted by the scanty thick mucus before named, obstructs the passage of air in ordinary respiration. Sometimes, during coughing, or violent efforts of respiration, a wheezing or sibilant sound announces that the obstruction is not quite complete; and there will generally be some of the tubes which will give these sounds during common breathing. These signs, and the tough scanty expectoration, characterise this affection; to which I would give the more pathological name, *bronchial congestion*. Coming on, as the attack sometimes does, suddenly, continuing for a few hours or longer, and then as suddenly ceasing, it bears none of the characters of inflammation; but the swelled state of the membrane and its dark colour without other change, which I have seen exhibited after death, imply a full state of the blood-vessels referable to the class of congestions, which may be produced and endure for an indefinite time, and have not the same tendency to definite terminations that inflammatory injections have. It may, doubtless, originate sometimes in inflammatory affections of the same part; but according to my experience it is more commonly the result of disorders of the digestive or other organs which tend to injure the tone of some, or other part of the capillary system. Thus, these will, in some persons, locate this congestion in the capillaries of the face, harming nothing but their beauty; in others the encephalic vessels suffer, whence habitual headaches of an obstinate character arise; in others some part of the alimentary canal is the seat, whence indigestion, hæmorrhoids, or some disorder of the alvine function, ensues. So, too, the urinary or the genital systems may become the place of this congestion; or it may fall on the bronchial membrane, and induce the affection under consideration; and the local determination of the morbid vascular condition is, in individual cases, fixed on particular parts or organs in consequence of prior weaknesses or tendencies, or other circumstances which we cannot now stop to enumerate.

Occasionally bronchial congestion is conjoined with what might seem to be its opposite, pituitous catarrh; but according to the view which we have taken of that affection, the pathological causes of the

two do not differ very widely, the same circumstances causing a loss of tone in the capillaries, being capable of producing a relaxation of their exhalant properties, or a dilatation of their caliber. Or what is more usually the case, some parts of the membrane are affected with one, and some with the other; and the result is the expectoration of much thin glairy fluid, with the little pellets of tough mucus in it. So, too, by a modification in the properties of the congested vessels, they may be excited or relaxed, and relieve themselves by the exhalation of their watery contents; and we accordingly, sometimes, find an attack of catarrh or asthma, at first quite dry, and devoid of any but the tough expectoration, suddenly relieved by a copious discharge of thin frothy fluid. This happens more commonly where the congestion results, mechanically, from disease of the heart.

Depending, as this affection generally does, on constitutional causes, it will require measures which may act on the system, as well as those which may improve the condition of the affected membrane. A due management of the diet, avoiding all acid, rich and irritating articles of food; regulating the secretions by mild aperients and alteratives; and subsequently employing tonics, which, by maintaining the balance, may increase the general tone of the circulation, generally constitute the most important part of the treatment. With regard to the measures addressed to the congested membrane, it is not found that the ordinary remedies for bronchitis are of much avail. Blood-letting produces little impression. Dry cupping, and other means of derivation, may be of more use. Stimulating and bracing applications to the whole surface of the chest, pitch plasters, flying blisters, and stimulating embrocations, are occasionally of temporary advantage.

There are, however, means of increasing the flow of the bronchial secretion, which, as temporary remedies, are of more avail than any hitherto named. We have before noticed the property which alkalies have of determining to the bronchial surface, and we have now to notice in addition their attenuant or dissolving power, which diminishes its tenacity, augments its quantity, and thus facilitates its expulsion. These remedies thus not only remove the obstructing mucus already secreted, but by favouring its looser flow, they tend to unload and reduce the congested membrane, and thus to relieve the dyspnoea that arises from its tumefaction. For the knowledge of these remedies I am indebted to Lænnec, who seemed, however, at a loss to account for their efficacy. I am far from wishing to extol chemical medicines in

general; but I cannot but think that we may bring chemistry to our aid in the present instance, to explain the action of alkaline attenuants. We know that we can, by the administration of alkaline medicines, render the urine alkaline, and increase the alkaline qualities of the blood. Now there is no solvent of mucus more effectual than alkalies, and it is easy to perceive that an alkaline state of the bronchial secretion can scarcely be compatible with the formation of tough solid mucus. I have found these remedies very effectual, and I am in the habit of giving either the liquor potassæ (℥ xx. to xxx.), carbonate of soda (gr. xv. to xxx.) or carbonate of ammonia (gr. iij. to vj.), according to the character of the case, three or four times a day, with squill, ipecacuanha, or colchicum, and some narcotic, according to the general state of the system and the prevalence of particular symptoms.

I need not detain you about some other bronchial discharges of rare occurrence. Bronchial hæmorrhage may occur to a considerable amount, independent of any permanent disease; and the fluid blood in the tubes will occasion a mucous rhonchus. In character it resembles epistaxis, hæmorrhoidal flux, and other bloody discharges from mucous membranes; but in this case, besides the weakness resulting from loss of blood, when this is considerable, there may be some danger from the interruption which it might cause to the function of respiration. The treatment, as in other hæmorrhages, will depend on whether the hæmorrhage is sthenic or asthenic—active or passive. These points are fully treated of by authors.

PRACTICAL OBSERVATIONS

ON

DELIRIUM CUM TREMORE.

By WILLIAM MUNK, M.D., Lugd. Bat.,
Physician to the Farringdon General Dispensary
and Lying-in Charity.

“*Scire vere est scire per causas.*”

It ought, in the present advanced state of medical science, to be altogether unnecessary to insist on the immense importance, as directing our therapeutic means, of an accurate knowledge of the causes by which any given train of symptoms is produced, or of the lesions wherewith particular diseases may be complicated. Yet that it is not unnecessary is but too evident when we observe how many there be who seem

altogether ignorant of the fact, that precisely similar phenomena may result from the most opposite causes, and that the accompanying lesions are not unfrequently of a totally different nature from that of the primary disease, and consequently require a most dissimilar treatment.

These observations are, we believe, but too clearly illustrated in the disease termed *delirium tremens*, or *delirium cum tremore*. The opinion entertained by many, that it is invariably an asthenic condition of the system, and consequently admits, and even requires, in all cases and stages, a liberal and almost indiscriminate employment of stimulants and narcotics, but too surely bears us out in this assertion.

As long as we view the phenomena constituting this disease as indicative only of one and a peculiar condition of the nervous system and general habit, as occurring only in individuals who have done an abiding injury to their system by the *habitual* abuse of intoxicating liquids, and as caused only by the want of an accustomed stimulus, or by some sudden shock, so long will our views be complicated and incorrect.

It is necessary to analyze that we may distinguish, and if we prove, as is our object in this paper, that *delirium tremens* results from very different causes, that it is frequently complicated with, or even caused by inflammatory affections, that in very many cases the disease is curable by antiphlogistic means only, and that in some of these instances narcotics and stimulants are not only unnecessary but at the same time injurious, then shall we have taken a step in effectually distinguishing that which ought never to have been confounded.

Certainly, the most usual form under which *delirium tremens* appears is, as occurring to individuals prone to the abuse of spirituous liquors, and in whom, from the absence of their accustomed stimulus, or from some grave or sudden shock, the nervous system is thrown into a morbid condition, whereby the vital manifestations of the system are disordered, giving rise to those phenomena to which, collectively, nosologists have assigned a peculiar designation. In such cases we usually observe, after death, no appearances to which we can legitimately refer the phenomena manifested during life; or, if any peculiari-

ties do exist, they are neither constant in their occurrence nor analogous in different cases; such cases may be termed pure or simple; they are mostly curable by narcotics and stimulants, and being sufficiently recognised and understood will not be again referred to.

Those, however, which it is our purpose here to examine differ from the preceding, not only in occurring occasionally in individuals of the most abstemious habits, but likewise (and this is the point on which we would particularly insist) in invariably presenting symptoms during life, and appearances after death, which unequivocally denote a well known, because appreciable, organic lesion—that lesion being either gastritis, enteritis, or both conjoined.

To complete this cursory view of the disease, it is requisite here to mention those cases in which there exists an evident degree of cerebral inflammation, and which usually require, for their successful treatment, antiphlogistic means, either general or local, conjoined or not, as the case may be, with the simultaneous employment of narcotics and stimulants.

CASE I.—A gentleman, a member of the University of Oxford, aged 28, of extremely temperate habits and of nervous disposition, received, during a temporary stay in London, some distressing intelligence. He repaired to the house of a friend who, seeing his depression, after much trouble, prevailed on him to take some wine. His spirits rallied considerably, he continued drinking for some hours, and left in a state of severe intoxication: he reached home about three o'clock in the morning, and was put to bed by his servant: he got no sleep, was exceedingly ill during the night and throughout the following day, being restless and delirious. He was seen the following morning, the second of his illness: his countenance was expressive of deep distress; there was considerable tremor of the extremities, the tongue could be with difficulty protruded, its centre was covered with a dirty and creamy mucus, its sides and tip being of a dark red. He is constantly getting out of bed and walking about the room, yet can be easily led back again; he talks loudly of an imagined wrong done him by his brother, and if interrogated upon any point at first hesitates, but answers after a

few minutes. He complains of intense thirst, heat of mouth and throat, with nausea; there is some fulness about the epigastrium, with great tenderness; the bowels have not been evacuated since yesterday morning. There is considerable headache, the eyes are suffused, the pupil contracted, and the ball of the eye rolls rapidly about in the orbit; pulse 110, as nearly as it can be counted.

Fifteen leeches to be applied to the epigastrium. An enema of Sulph. Magnes. et Infus. Sennæ. To take nothing but cold water.

In the evening he was much the same; tremors still considerable, and the same agitated manner; has had no sleep; the epigastric tenderness appears but slightly diminished. He experiences much relief from the cold water, which is taken in small quantities, but at very short intervals. The heat and clamminess of the mouth make him very irritable; pieces of ice, of about the size of a walnut, were therefore ordered to be put in fine muslin and held to the mouth until dissolved.

Third day.—Has slept two or three hours; the tremors are lessened, as are likewise the cerebral symptoms; he still complains of pain and heat in the stomach, if long without the ice; the epigastric tenderness is still considerable; pulse 106.

Applicetur hirudines octo epigastrio.
Injiciatur enema commune.

Fourth day.—In every respect better; has slept well; the tremors are much diminished, as are also the symptoms of gastric irritation; the bowels twice opened; the headache is nearly gone; he is more collected, and thirst is but little felt. He was now ordered slightly acidulated lemonade to be taken *ad libitum*, and a purgative enema.

On the fifth day he took some cold chicken broth, and from this time went on gradually improving without the employment of stimulant or narcotic. The bowels, however, for many days subsequently, remained very inactive, and the secretions being manifestly disordered, he was recommended to take, every third night:

Pil. Hydrarg. Ext. Taraxaci et Ext. Coloc. comp.; following it the ensuing morning with Magn. Sulph. Pot. Sulph. Pulv. Rhei. Inf. Sennæ et Inf. Gent. c.

CASE II.—G. B. aged 17. Oct. 27,

1837. This patient presented all the symptoms of delirium tremens, want of sleep, restlessness, trembling of all the limbs, suffused eye, creamy sort of mucus covering the centre of the tongue, the sides and tip of which were red; has been unruly all last night and during the whole morning, is very thirsty, the epigastrium is exceedingly tender, and the bowels are constipated; pulse 118, weak, with some wiriness; pupils contracted. On inquiring into the history of this case, we were informed that about a week previously he had been apprenticed, and on that occasion had had several friends with him; they drank freely, he became much intoxicated, and, as his mother believed, for the first time. Since that period the present symptoms have been gradually coming on; his nights have been without sleep; his actions have all become unsteady, so much so that he cannot now carry a tea-cup to his mouth without spilling its contents; and his temper is very irritable.

Applicetur hirudines duodecim epigastrio. Ol. Ricini f. 3vi. statim. To take iced lemonade or cold water.

27th.—Much the same; bowels not yet relieved.

Injiciatur enema Ex. Magn. Sulph. Infuso Sennæ et syr. Rhamni.

28th.—Bowels freely opened, somewhat better, not so unruly, has yet slept but very little, the epigastric tenderness only slightly diminished.

Applicetur hirudines octo parti maxime dolenti.

30th.—Obtained much relief from the leeches, the symptoms are all diminishing, he has slept freely, bowels open, epigastric tenderness nearly gone, and the tremors are only observed in the hands, when held out at a distance from the body. To take a pint of cold chicken or veal broth daily.

On Nov. 5 he was so much better as to render our further attendance unnecessary. Having since met him in the street, he informs us that he is perfectly well, and has suffered no relapse.

CASE III.—Jan. 2, 1838. H. N., carpenter, residing in Stanhope-street, Clare-market, a man usually of temperate habits. On Christmas-day he got intoxicated, and suffered so much on the two succeeding days from its effects, that he again had recourse to beer and stimulants, in the hope of removing the disagreeable feelings under which he

laboured. In this course he proceeded until Saturday evening. On Sunday he kept his bed, was much agitated in his manner, and very restless; slept but little on Sunday night; he got up on Monday (Jan. 1) and proceeded to his work-shop; he trembled so much as to render him incapable of work, and his employer sent him home.

The following day (Tuesday), we visited him, and found him sitting up in his bed; his extremities, tongue, and, indeed, the whole body, being at the same time in a constant state of tremor. He is vigilant and suspicious, watching every movement around him—his temper is very irritable, and he is constantly finding fault with and abusing his wife and children. The skin is warm, and covered with a clammy perspiration, but his cheeks are pale, and his eyes bright, though inexpressive. He frequently gets out of bed and walks about the room, but, with a little reasoning, at length goes back again. He has had no sleep since Sunday; the pulse is small, rapid, and irritable, 120; the tongue smooth and moist—tremulous and somewhat pointed. He complains of thirst and slight pain in the epigastric region, increased by pressure, and on taking any warm drinks. Finding from his wife that he was not addicted to the daily employment of intoxicating drinks, and that these symptoms supervened upon an unaccustomed debauch—bearing in mind, at the same time, the insidious latency of gastric affections in many cases, and the existence in this individual of symptoms denoting disorder of the stomach—we were induced to attribute the symptoms to gastritis, and treat it accordingly. The following was the prescription:—

Hirudines x. et postea cat. sinapis epigastrio. *Ol. Ricini* ʒvi. statim.
Enema c. Sulph. Magn. Infuso Sennæ et Syr. Rhamni.

R. Hydrargyri c. Cretâ gr. iv.; *Pulveris Rhei*, gr. v. *M. ft. pulv. 6tis horis exhibendus.*

Jan. 3d.—Slept a little after the removal of the mustard poultice; the tremors are but slightly, if at all diminished; bowels freely open; and the epigastric tenderness and thirst diminished. To take cold barley water, apple tea, or lemonade; repeat the castor oil to-morrow morning, and continue the powders.

4th.—In every respect better.

6th.—Tremors greatly diminished;

sleeps comfortably, appetite returning; but he experiences slight pain, a feeling of tension and heaviness in the epigastrium after eating; bowels confined.

R. Hydrarg. Chloridi gr. v. nocte: et haustus ex Infuso Sennæ Magn. Sulph. and Jalapa. Cras mane.

9th.—Tremors entirely gone; indeed he appears perfectly recovered from his original attack, but still complains of gastric uneasiness; bowels still constipated.

R. Bismuthi Oxydi gr. v. bis. die.

Pil. Hydrarg. ʒi.; *Ext. Coloc. Comp. ʒiij.*; *Ext. Hyocyami* gr. viii. *M. et divide in pil. xvi. Capiat duas omni nocte.*

20th.—The bowels are becoming more regular, his tongue is cleaner, but he still complains of severe pain after eating; has had no return of sleeplessness or trembling.

R. Morphiæ Muriat. gr. i.; *Pulv. Tragac. comp. ʒss. tere bene simul et per-misce.* *Fiat. pil. xii. Sumat unam ter die.*

Has been seen this day (25th); the morphia has acted most beneficially, and the gastric uneasiness has nearly vanished.

REMARKS.—The three cases above mentioned will be amply sufficient for the purpose which we have in view, that of affording a specimen of delirium cum tremore, originating in gastritis; or, in other words, of delirium tremens, as symptomatic of, and secondary to, gastritis. In this mode, then, we view gastric inflammation as the proximate cause; an opinion by no means new, inasmuch as the founder of the so-called "physiological school" insisted strongly, many years since, upon this connexion. Here, however, as in many other instances, has Broussais been led astray by his favourite theory—by his love of generalization; he has looked on this relation as of more frequent occurrence than we observe in nature. What he considers the rule, we must look on as the exception. It may be difficult to determine what is the precise numerical relation of such cases with others of a different character; but the following may be taken as a general approximation. Delirium tremens usually presents itself as a disease of debility, and is benefited by stimulants and narcotics. Next to these, in point of frequency of occurrence, are cases complicated with

cerebral inflammation; then follow those cases of the disease of an asthenic nature, but accompanied or complicated with gastric inflammation; and, lowest on the scale, that is to say, of least frequent occurrence, are cases such as narrated, and presenting the connexion on which Broussais insists. A somewhat similar view to that which we have just expressed has been taken by Dr. W. Stokes, of Dublin, and it gives us great pleasure in stating that our attention was first directed to this interesting point by a perusal of that gentleman's excellent lectures on the theory and practice of medicine: "A patient," says he, "who is in the habit of taking wine or spirituous liquors every day in considerable quantities, meets with an accident, or gets an attack of fever; he is confined to bed, put on an antiphlogistic diet, and in place of wine and whiskey punch, gets whey and barley water: an attack of delirium tremens comes on, and symptoms of high cerebral excitement appear. Another person, not in the habit of frequent intoxication, takes to what is called a fit of drinking, and is attacked with delirium tremens. In the first case the delirium arises from a want of the customary stimulus; in the second, from excess. In each the cause of the disease is different, and, consequently, with this view of the subject, it would be a manifest departure from sound practice to treat both cases in the same way."

How are we to discriminate between these different cases. What are the sources of our diagnosis? First, *the history*. If we learn that the patient is of temperate habits, that he is unused to the daily employment of wine, spirits, porter, or the intoxicating beverages,—if he be not an habitual opium eater,—and if the symptoms have supervened on a solitary and unaccustomed debauch, or on what is called a fit of drinking,—then there is a strong presumption that the stomach, from these circumstances, has been over excited, and that its increased physiological action has passed into a true pathological state—that of inflammation, which has been productive of the symptoms constituting the disease. The second source of diagnosis are the *symptoms*. If, in addition to the phenomena necessary to constitute our idea of delirium tremens, we have superadded many of those which indicate an excited state of the stomach,

as nausea, vomiting, heat of throat and stomach, great thirst, desire for cold drinks, fullness of the epigastrium, tenderness on pressure, costiveness, with red and pointed tongue, then our supposition becomes more and more confirmed. Here, however, it is necessary to guard against an error of judgment. Many or all of the symptoms indicative of gastric inflammation may be obscure, or altogether wanting, and yet the disease itself be present. The latency of these affections is well known, and their obscurity is, moreover, much increased; or, in other words, they are, as it were, kept in abeyance by the more prominent symptoms of disturbance in the nervous system. It behoves us, therefore, in all cases when the history has raised suspicions, to be minutely careful in our investigation of symptoms. The third means on which we should rely for a correct diagnosis are the effects of remedies. If both the history and symptoms are insufficient for our decision, then should we cautiously employ different remedies; according as stimulants increase or diminish the symptoms, or as leeches, cold water, &c., produce the same effects, so should our judgment be decided. These are all the means applicable to our particular patient: the morbid anatomy comes in only for the "confirmation or connexion of our previous opinions," after all the efforts of our art have proved unavailing*.

A very few words will suffice for the treatment; reference to the detail of each case will be sufficient to indicate the course which we consider necessary. A point in practice may, however, be agitated; we refer to the employment of morphia in these cases. Morphia appears to us injurious when given in intense inflammation of the stomach. The symptoms will be best alleviated by the usual antiphlogistic means—leeching, cold water, ice, &c., but after the violence of the inflammatory symptoms has abated, when it has arrived at the subacute degree, then we know of no remedy possessing equal power with that now under consideration.

It is our intention, at an early period, to forward some cases and remarks illustrative of delirium tremens, as occurring in confirmed drunkards, but united with gastritis as a complication.

CASE OF FUNGOID DISEASE OF
THE KIDNEY,

WITH THE POST-MORTEM EXAMINATION.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel greatly obliged by the insertion of the following case and dissection in your valuable journal.

I am, sir,

Your most obedient servant,

JOHN GORHAM, M.R.C.S.L.

225, High Street,
Monday, 29th Jan. 1835.

On the 23d June, 1836, Alfred Trendall, aged seven months, was brought to Guy's Hospital as an out-patient, on account of a large tumor in the abdomen. The mother had always suckled him. The two central inferior incisors were cut when he was six months' old.

A month since he had a bowel complaint, which lasted about ten days; the motions were at this time watery and greenish; he vomited also a yellowish matter three or four times a day; and when his digestive organs were thus deranged his mother observed that he looked yellow. He has had no other disorder incident to infancy.

A week since, the mother observed, while washing him, a swelling in the abdomen, for which an emetic and a warm bath were prescribed by a medical man.

On examining the abdomen, I find a large tumor occupying all the regions, but situated rather to the right side, extending from the ribs above to the iliac fossæ below. A depression exists between the margin of the ribs and the tumor, which is more evident when pressure is made with the fingers; this depression renders the origin of the tumor from the liver doubtful.

The abdomen feels hard, there is no fluctuation, the veins are turgid, and the general aspect of this cavity is ascitic. He passes less urine than usual. Since the swelling was first observed it has increased rapidly. Slight cough; skin hotter than natural.

Hyd. Cretâ, gr. iij. o. n. Liq. Am. Acet.
et Sp. Æth. Nit. t. d.

June 10th.—Abdomen 22 inches in circumference; no sickness; motions in large quantity, and of a dark green

colour; countenance pale, dirty colour; slight cough; resp. 80; pulse 188. Therm. Fah. 99.—Pergat.

July 7th.—Abdomen 22½ inches; vomiting; motions in large quantity; resp. 60; pulse 148; ther. Fah. 95; some emaciation; frequent moaning.

11th. Abdomen 22½ inches; frequent moaning.—Pergat.

As the mother supposed that little could be done for the infant, I saw him no more till August 11th, when I was informed that he had died the day before, and I was requested to examine the body.

Post-mortem, 24 hours after death.—Considerable general emaciation.

Head not examined.

Chest.—Thoracic cavity very much encroached on by the abdominal tumor; the summit of the diaphragm rising to an imaginary line, extending from the under edge of the third ribs, where they join with their cartilages.

Right lung.—Pale, anteriorly crepitant over whole extent; reddish posteriorly, from cadaveric infiltration, and it was emphysematous.

Left lung presented, on the posterior part of its apex, a small whitish elevation of the size of a silver penny, which, when cut into, allowed a cheesy matter to escape. On making an incision into the substance of this lung, I could not discover any more traces of tubercular disease: it was emphysematous.

Abdomen.—Greatest circumference 23 inches, the length of the entire body being 27 inches: when its cavity was laid open, about two ounces of a serous fluid escaped. On turning down the flaps, I found the peritoneum inflamed and adherent for the space of one square inch to the tumor. The following parts now presented themselves to view:—

The lower portion of the ileum first attracted attention. It was distended with flatus, and traversed the fore part of the tumor obliquely, from the left side below to the right above, and terminated immediately under the right lobe of the liver in the cæcum; from this point the ascending colon passed transversely, taking the place of the transverse colon, which latter was lost amongst the small intestines, and these were lying to the left of the tumor. The only part remaining exposed to view, before displacing the viscera, was a large tumor situated rather to the right of the abdomen, extending from the liver to the pelvis, displacing the

large and small intestines. It was of various colours externally, being in some places livid, bluish, and streaked with beautiful red vessels; in others it had a paler or yellowish hue. On the left side it was lobulated and nearly white. It seemed to originate in the right kidney, as no traces of this gland, as it exists normally, could be found. It weighed about $4\frac{1}{2}$ lbs. The left kidney was in its natural position.

For all that follows I am indebted to Thomas King, Esq., curator of the Museum of Guy's Hospital.

The tumor was as large as an adult woman's head. The ureter was seen slightly dilated above, and much contracted below, coursing over the inner part of the tumor; the capsula renalis was normal. The tunica propria of the enlarged kidney was very extensively separated from the gland, at different parts, by a sanguineous, serous, and inflammatory effusion. The external surface of the membrane, at the upper part, seemed to have produced a large cake, like a six months' placenta; the texture of which was firm, medullary, fibrous, and cystiform. There were some traces of venal substance pretty generally beneath the proper tunica, pale, compressed, and rather dense; but, for the most part, a section of the kidney presented a complete fungoid degeneration.

The pelvis was dilated, and filled with various more or less vascular excrescences of different sizes; in the interior of these, the formation of compound cysts was evident enough. The other parts were more sensibly medullary in appearance, and contained portions in different stages of dissolution.

There appeared to be a few simple renal cells.

ANOMALOUS CASE OF HYSTERIA. —MESMERISM.

To the Editor of the Medical Gazette.

SIR,

If you will have the kindness to give insertion to the following letter and case, you will much oblige

Your obedient servant,

S. SANDYS,
Surgeon.

4, Francis Terrace, Kentish Town,
Feb. 5, 1838.

To the Baron Du Potet de Sennevoy.

SIR,

I FEEL it but due to you to acknowledge publicly the source from whence I derived such a knowledge of the science of mesmerism as has enabled me to pursue the course of inquiry, and to obtain the results, detailed in the following case.

Surprised at the phenomena exhibited by those patients whom you treated at the University College Hospital, where, through the kindness of Dr. Elliotson, I was invited to attend, I could not hope that so shortly afterwards I should thus, in my own practice, see the beneficial results of mesmerism.

I have only to add, that my attention was not directed to the respiration (as was that of an eminent physician, who has already given us the results of his experiments), nor indeed had I any other object in view than that of simply imitating, as far as I could, the method of manipulation practised by yourself.

I am, sir, with much respect,

Yours &c.,

S. SANDYS,
Surgeon.

4, Francis Terrace, Kentish Town,
Feb. 5, 1838.

A. S., aged about 42, a female of quiet and sedentary habits, her occupation being that of a sempstress, has for several years been subject to dyspepsia, with a remarkable though variable state of the tongue; the whole or a part of the skin falling off about once in ten days, leaving the exposed surface raw and painfully sensitive; in 24 to 36 hours it appears as usual again. For this she has been under constant treatment, of which daily exercise in the open air formed a part. About the middle of November she was affected with a constant vomiting, partially relieved by creosote (the effervescing saline having failed), and completely removed by hydrocyanic acid. This was accompanied by pain and weakness in the back and loins. About a month afterwards she was affected with retention of urine, requiring the constant use of the catheter. Six or seven days after this she was observed one evening to rise from her bed (about nine p.m.) in a state bordering on somnambulism; she put her shawl over her shoulders, saying that she must go out and take a walk; this she was with difficulty restrained from doing, as her

strength was much augmented at the time, and she declared vehemently "she would go out, as Mr. Sandys had ordered her." After a few minutes she began to tremble violently, clinging for support to any one standing near her: her strength gradually decreased, and she suffered herself to be laid upon the bed, when she shortly awoke sensible. This attack did not fail to come on every evening, at first for a few days spontaneously, afterwards in some way dependent upon the use of the catheter, as it always supervened immediately after that operation, though the time was purposely varied at uncertain intervals, between half-past eight and half-past ten, beyond which time, if the operation be delayed, the attack appears to come on spontaneously.

During the attack she exhibits a most pointed aversion to all females, not shewing any friendly recognition of her sister, or any of her friends or acquaintances, positively denying their identity, and declaring that they are all in league to keep her in confinement.

This paroxysm daily increased in violence and induration*. Persuasion, fear, and the cold "douche," having failed to quiet it, recourse was had to Battley's sedative solution, in half-drachm doses, given shortly before the expected time of the attack; the strait waistcoat was applied, and she was tied in bed. The attack came on as usual, but gradually gave way under the influence of the opiate; she slept about three hours. Her state, during the next and three following days, was, however, such as to forbid a perseverance in its use; she vomited her food constantly; her head was in racking pain; she felt worse than usual, and, to use her own expression, "perfectly wretched."

The duration of the attack at this time, if left uncontrolled, was usually two and a half to three hours, when she gradually became quieter, though she still continued muttering, and at length became sensible, without, however, having once closed her eyes.

* So violent had she now become, and so malicious were her expressed intentions during the attack, both as regarded the destruction of herself and sister, the burning of the house, the frequent attempts she made to jump out of the window, and to dash her head against the wall, that more active means of restraint were thought necessary.

I now felt that as mesmerism had the sanction of so eminent a physician as Dr. Elliotson in these cases, I was quite justified in trying it.

On the evening, therefore, of December 27th, the usual passes were made, and continued for about fifty minutes, beginning soon after the commencement of the attack. From that day to this, a period of more than a month, the manipulations have been followed by one uniform result—a state of coma (if I may so call it), or profound mesmerie sleep, coming on gradually after a certain length of time (requiring fifteen or twenty minutes before any effect is observed, and about thirty-five to produce the full effect), the respiration becoming slower, and so gentle as to be quite inaudible. At length a deep-drawn sigh, followed in about five minutes by a second, after which we find the extremities generally so rigid, that moving one leg moves the whole body. There is also always a great diminution, if not a total absence, of sensibility in the skin, as evinced by the following tests: pinching, pricking, scratching, and tickling, particularly the soles of the feet, which at other times she cannot endure.

Her sense of hearing seems equally dull, shewing no sign of perception when her own name is shouted in her ear; not the slightest movement even of the eyelids being visible when a watchman's rattle is suddenly sprung at her bedside. Yet it has appeared to me several times that, when in this state, certainly when in progress towards it, she is sensible of any exertion of the voluntary muscles, even of resistance without motion, and this after all the ordinary sensibility of the skin appears extinct.

She shews no consciousness when violently shaken, and the use of the scarificator (having been cupped on the loins when in this state) produced a short expression of uneasiness rather than of pain; and she immediately relapsed into her comatose condition, not having in the morning the slightest recollection of what had passed.

The catheter, if introduced while she remains in this state, has the effect of partially rousing her, requiring a few more passes of the hand to quiet her.

She was left for two successive nights

without the mesmerism; the attack each night came on as usual, lasted about three hours, and left her low, exhausted, faint, and sleepless; each morning she expressed herself as not being nearly so well. Next day the mesmerism was resumed, and she was quieted as usual.

About ten days afterwards the attack was one evening allowed to remain for forty-five minutes, at which time (her violence being undiminished) the usual passes were made, and were soon followed by their ordinary effect.

From this mesmeric sleep she commonly awakes in about three hours, quite sensible. I should here say, that the above phenomena have as frequently been produced by my pupil, Mr. W. Whitehouse, as by myself; indeed it was he who first, by persevering for about fifty minutes, produced the marked effects above described, though I had several times previously observed a slight and transient drowsiness or quietude result from a few passes.

The introduction of the catheter in the morning has once or twice been followed by a short and slight attack, similar to that of the evening; this has likewise sometimes preceded the operation.

There has throughout been a remarkable temporary loss of power in the lower extremities. In the day-time she can walk firmly; whereas at night, during the attack, when she sets her feet on the floor, the knees sink under her, and she falls instantaneously, without staggering, and without attempting to save herself.

The same results have uniformly followed the mesmerism if practised in the day time, independently of the attack or of catheterism—the same succession of symptoms—the same insensibility to external impressions. It, however, requires less time to effect this, twenty to twenty-five minutes being sufficient. From this day-sleep she awakes in about three hours, much refreshed.

In conclusion I have only to add, that should any member of our profession wish to convince himself, and to be an eye-witness of the results obtained, I shall be happy to shew him the case at any time.

PHARMACY LAWS.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

To the Editor of the Medical Gazette.

SIR,

THE subject of the change proposed to be made in the character and functions of the College of Surgeons in Ireland, and of its members, has been now for some time before the public; and being a matter of much importance to the public itself, as well as to the profession, it has excited a degree of general interest which contrasts strongly with the indifference usually displayed towards questions of medical policy, but certainly not greater than it merits. The question is one of deep interest to the members of the College of Surgeons, and it is the duty of every member who feels that either the welfare of the public or the character of his College is at stake, to adopt the course which appears to him best calculated to protect both. Hitherto I have looked on; because it did not appear to me that the time had arrived when interference was likely to prove seasonable or effectual. As yet, in this, as in most other instances in which the interests and views of numbers are involved, the tide has flowed in one direction: the minds of the public, and of the profession at large, have been carried away by the representations which have been industriously put forth by one side, and the claims of reason and dispassionate inquiry have been lost sight of in the ardour of pursuit; but since the first impulse has now spent its force, and in some degree subsided, the minds of all parties must be in fitter mood for calm and impartial investigation. The intentions and plans of the advocates of the change have been in part made public, and the time has at last come when their value and title to support may be at once strictly and temperately weighed, and the public mind disabused of those erroneous impressions (if any) which may have been made upon it.

You are aware, sir, that there exist, in Ireland, three medical corporations, invested severally with distinct, appropriate, and independent rights, functions, and powers, all conferred and guaranteed either by royal charter or by act of parliament. Hitherto the Col-

lege of Surgeons has been, and still is, a corporation devoted exclusively to surgery, holding, as by its charter it is bound to do, the practice of pharmacy to be a distinct branch, foreign to it, and belonging by law to another body. Now, however, it is sought to alter its original intention and character, and to convert it into a pharmaco-chirurgical corporation for licensing general practitioners, who shall practise both as surgeons and apothecaries, and deal in and vend medicine.

The laws which it is proposed, in the name of the College of Surgeons, to establish and impose upon the College and the apothecary branch of the profession, so far as they have yet transpired, have been published in late numbers of certain newspapers, in articles headed "Royal College of Surgeons" — "Pharmacy Laws." Put forth, as this has been, under the name of the College, the public are, of course, led to suppose that it has been published by its order, and with its sanction. This, however, is not the case, and it would behave the College to see to it; unless it would be sponsor for every one who has the boldness to make an unauthorized and surreptitious use of its name.

I observe that you have been favoured with a copy of the articles; it will, therefore, suffice to refer those who may wish to know its contents, to your number of the 20th inst. The other provisions which it is intended that the act of parliament shall contain, have not been made public: that, however, there are others, of a most important character, I can positively state, and which will require the most serious consideration. But against the code here propounded for the regulation of pharmacy, I protest in the strongest terms, for reasons which I will presently state. Meantime I must advert to a matter which requires notice, before I proceed further.

It has been stated in the announcement of the proposed laws that it is "not for the purpose of deriving income from the sale of them" that practitioners are to dispense medicines. The interpretation put upon this by those ignorant of the real intentions of the parties is, that the members of the College of Surgeons intend not to charge for the medicines which they shall dispense to their patients; but this is as great a mistake on the part of the public, as I

fear the assertion was deceitful on the part of the writer; for, 1. The report of the committee contained no such statement. 2. The intention of the proposers avowedly is that the members and licentiates of the College shall have power to charge for the medicine they dispense, as well as power to dispense it. 3. It is notorious that the prospect of making the money which is now made by the apothecaries, and even in the same manner, is one of the considerations by which it has been attempted to induce members and licentiates to consent to the measure. Now let me ask is it to be believed that practitioners shall have power to charge for their medicine, and yet give it for nothing; or that charging for it, they will not charge as much as consistently with their interest they can do! If the public think so, it will soon be undeceived. It is not in nature that a man wanting money, and having a legal opportunity by which to make it, shall refrain from taking advantage of that opportunity when it may offer. But though the intention of not making money on the sale of their medicine were seriously entertained, it must prove, under the proposed system, impracticable; and either the one or the other must be abandoned. Under this system the practitioner alone could practise; and if he be not remunerated by fee for his service, he must indemnify and remunerate himself through his medicine. Now there is a large portion of the community which is altogether unable to fee a practitioner even to the most moderate amount, and pay also for medicine, and which can remunerate him only by what he may make upon it. All this portion, which really comprehends the greater part of the population of this country, the committee propose to prevent henceforth from applying to the regular apothecary, and to compel to have recourse to their practitioner for relief. How, I ask, is the practitioner to deal with patients of this class? They cannot fee him; and if he make not money by his medicine, how is he to be remunerated? Will any one believe that he will, or expect that he shall, keep a pharmacy for the supply and service of patients from whom he is not to receive a return, or that he will be either generous or fool enough not to take advantage of the powers with which he is to be invested, and remunerate himself by

taxing the medicine which he shall dispense? Doubtless he will; or if he do not, he will refuse to attend such patients, who would then be, by the wisdom of the committee, deprived of all resource.

Having shown that it is intended that the practitioner of the new system shall charge for his medicine, and indeed that he must do so, as well to protect the public as himself, I proceed to state my objections to the entire proposition. First—The College of Surgeons have no right, authority, or sanction, to take upon itself to regulate or propose laws for the regulation of the practice of pharmacy. Its authority is expressly defined by its charter, and does not extend beyond the regulation of the profession of surgery. The regulation of the practice of pharmacy and of the profession of the apothecary, belongs, and is by law conferred upon and entrusted to, the Apothecaries' Hall, and it is not less an encroachment upon the rights of the Hall, by the College to assume authority to interfere in these matters, than it would be of those of the College, if the Hall took upon itself to promulgate laws for the regulation of the profession of surgery. Nor ought it be countenanced for a moment. Let the members of the body, whether individually or collectively, lay before parliament the grievances or disabilities, if any, under which they labour, and seek from the legislature a remedy; but the College have no right to take upon themselves, in their corporate capacity, to make or propose laws for the regulation of a branch of the profession with which the legislature have not given them authority to interfere. If such a proceeding be once sanctioned, where or when is it to stop? Not until all the institutions of the country have changed places, or have been all concentrated in the College of Surgeons. Secondly—The members and licentiates of the College are bound by oath "to the utmost of their power to endeavour to promote the dignity of the College," and "that they will not at any time *hereafter* practise the business or profession of an apothecary, or sell drugs or medicines within the city of Dublin, or at any place within ten miles thereof, so help them God."

It is not necessary to dwell upon the obligations of this oath. No one, not even the advocate of the change, attempts to deny that the dignity of the

College, and the station of its members, would be compromised by their dispensing and selling medicine, and by its conversion from a college of pure surgeons into one of apothecary-surgeons. And if oaths are to bind at all, I know not how any member or licentiate who has taken that just cited can dispense or sell medicine within the prescribed limit, and not account himself a perjured man. The oath is express, positive, and unconditional. It is taken voluntarily and advisedly, and no opening for evasion is left. If gentlemen find the obligations which they have taken upon themselves inconvenient or irksome, they should, when they propose to throw off one part of the compact, put off the other also. Let them cease to be members of a body the functions and privileges of which do not suit their views and wishes, but to which they pledged themselves when they entered it, and let them go to another better adapted to the purpose they have in view. When to the preceding considerations we add the fact, that the College imposed the oath in question upon themselves; that their first charter did not contain it; that it was introduced at their own desire, and that but a few years ago into their new one; what justification have they now for seeking to get rid of it?

Thirdly—The proposed change has not received due consideration or sufficient sanction from the College or the profession. Here, doubtless, I shall be told that "it was passed at an unusually large meeting without a division," and "that the committee had received communications from all parts of the country, expressing satisfaction," &c. But let us examine this matter more particularly, for I like not such general statements. The College contains between one hundred and thirty and one hundred and forty members; and on no occasion has one-third of the number ever voted upon the question. Is it thus, sir, that such a question is to be decided—a question involving the nature, the functions, and the station of a public body? My opponents will say, Why did they not attend? I answer, There are sufficient reasons why they did not; but it should not have been left to option. There should have been "a call of the House." The members should have been specially summoned, and, if necessary, under fines. If this had been

done there would have been a different result, or I am mistaken. Next, sir, for the communications from the country:—The committee, according to their own statement, received nearly one hundred communications from members and licentiates in the country: some adverse; the majority favourable. Now there are about thirty members, and upwards of two hundred licentiates, resident in the country, so that making due allowance for the word “nearly,” and for the adverse communications, the proportion of those favourable to the change, does not exceed a third of the entire. But the strongest proof of my objection is, that the licentiates of Dublin have actually protested against the measure. The public have been told nothing of this, but it is nevertheless true. They have been convened within the College walls. They are upwards of one hundred in number. They have conferred with the committee; and yet, while they complain of their condition, and desire a remedy, they have protested against the proposed measure of dispensing and selling medicine, as unjust to the apothecary, derogatory to the profession, and one which nothing but extreme necessity could induce them to adopt. What is to be thought, sir, of this proceeding? Less than a third of the body take upon themselves to drive on a measure subversive of the nature and functions of the institution, and this in despite of the protest of the very persons whose interests are most deeply concerned. Sir, I have many times known the consideration of a far less important question postponed until a sufficient number of the body should be present to give the decision sufficient sanction. And why was it not so in this case? Will not, must not, the public conclude that those who have acted so precipitately have some object in view which the body at large would not approve? Why has the protest of the licentiates been withheld even from the College? Why have the committee not even alluded to it in their report, though they boasted of the many letters of approbation which they had received? Let them answer. Let them answer also this question: What moral epithet does such a proceeding deserve? or of what kind must be the cause which requires it?

My fourth objection to the proposed laws is, that they are, for the most part,

either highly objectionable, or impracticable.

Fifthly—They are not necessary for the purpose which they profess to seek.

Sixthly—They appear to me to be only a mask for another, as yet not avowed, design. The three last objections will require the space of another letter, and therefore, for the present, I subscribe myself,

Your obedient servant,
A MEMBER OF THE COLLEGE
OF SURGEONS IN IRELAND.

MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”
CICERO.

CONVICTION FOR MALAPRAXIS IN MIDWIFERY.

IN the whole range of forensic medicine no subject can be more interesting, or more difficult, than *malap Praxis*. To lay down the limits of blameable inertness on the one hand, and still more culpable rashness on the other, and to show how large is the intervening space where difference of opinion may have full play, would require no ordinary tact; and we are not surprised, therefore, that some writers have altogether omitted this subject. In the obstetrical branch of our art, at any rate, we should imagine that all prudent persons would join with Dr. Blundell in reprobating what he calls “a meddlesome midwifery”; and, consequently, that no practitioner should be reprov'd for inertness, in abstaining from manual or instrumental interference, unless the case clearly required it, beyond all reasonable doubt. It may not be without interest to our readers to learn how they manage such things abroad; we therefore subjoin rather a curious case in illustration, which we

have taken from one of the German journals*.

On the 2d of January, 183—, Mr. K., an accoucheur, was called between seven and eight in the evening, as he stated in his first examination, to Mrs. X. She was 32 years of age, had borne several children, and was now in the eighth month of pregnancy. For twelve or fourteen days she had been suffering from hæmorrhage, which did not occur every day, but when it did, sometimes amounted to two or three pints. He said that at this, his first visit, the woman was weak and exhausted, the pulse slow, but not too weak, and that there was no hæmorrhage, and no nervous symptoms. On examination, he found the os uteri high, and no part of the child presenting; there were neither labour pains nor pains in the back, but in the body only. The accoucheur was of opinion that the placenta had been partially separated, and was lying upon the os uteri, and that the patient was in danger, but he did not attempt anything, as she was weak, and in want of repose. He therefore contented himself with prescribing an emulsion containing extract of hyoscyamus and ether, and introduced a piece of sponge moistened with alum, strong acetic acid, oxymel, and water, into the vagina.

On the 3d of January, between five and six in the morning, the accoucheur, and Mrs. C. the midwife, were at the patient's bedside together. Fresh hæmorrhage had set in towards the morning, and nearly destroyed the patient; her lips were pale, her eyes dim; she had a weak pulse and cold sweat, but spoke connectedly, and complained of no pain. Mr. K. found that the vagina was puffed, and preternaturally soft, and that the os uteri was high and closed, but remarked no labour-pains. Under these circumstances, and particularly on account of the great weakness of the woman, he did not think it advisable to proceed to delivery, as he feared a renewal of the hæmorrhage and other bad consequences. About nine o'clock he left Mrs. X., and directed the midwife gradually to dilate the os uteri. An hour afterwards he found the patient breathing her last, and she died in his presence. He did not try to resuscitate her, as he thought it superfluous. The child he declared to be

dead, as the mother had not felt any movements for three days. He mentioned the extraction of the child from the mother to the husband, who did not consent to it; but the Cæsarean operation was not expressly named. Mr. K. was opposed to delivery by the natural passage, as he thought that, under the given circumstances, it was too dangerous for the child.

Such was the history of the case, founded on the accoucheur's deposition; but it was contradicted in many material points. The husband of the deceased affirmed that Mr. K. did not return until eleven o'clock, when his patient had already expired; that, after repeatedly touching the body, he declared that the child was dead; and that no mention was made of the Cæsarean operation, which he (the husband) would certainly have allowed.

Mrs. C., the midwife, confirmed this; but added, that the accoucheur, on going away, had said to her that he would return in the afternoon to perform the Cæsarean operation. She also deposed that, by frequent examinations, she had convinced herself of the position of the placenta, but that the accoucheur considered this only as a conjecture; which, however, he altogether denies. She also added, that when Mr. K. directed her to dilate the os uteri till his return, she replied, that the patient would then grow weaker and weaker, and she was of opinion that delivery was indicated. This, too, was denied by Mr. K.; but Mrs. C. persisted in it when confronted with him. Moreover, on the 3d of January she found the os uteri low down, and dilated to the size of a *groschen* (a silver penny), and told this to Mr. K., who, however, says he never found it so. She endeavoured to dilate the os uteri as she was directed, but the floodings followed one another too quickly to allow her to repeat her attempts. Mrs. X. died half an hour before Mr. K.'s return.

Mr. K.'s second examination con-

* Schmid's Jahrbücher. 1837. Band 16. No. X. Heft 1. from Siebold's Journal.

tained still more inconsistencies. He said that he did not attempt artificial delivery, because it was impossible to reach the os uteri; and this, although he had repeatedly declared that the os uteri was closed; and, on the other hand, had confessed, when the protocol of the proceedings was read, that it would easily have admitted a finger. He stated that at first he had suspected a presentation of the placenta, but afterwards thought that the hæmorrhage proceeded from the vessels of the vagina, for which reason he plugged it. Lastly, he declared that he clearly foresaw the death of the patient, and did not wish to torment her uselessly, nor to be exposed to censure in case of her dying while under his hands.

The Board declared, that from the deficiency of information, from the contradictions between the testimony of Mr. K. and Mrs. C., and from there having been no post-mortem examination, they were unable to decide whether the death of the patient was caused by hæmorrhage or apoplexy; and whether it was to be attributed to Mr. K.'s not having delivered the woman, for it might also have taken place during the operation. They declared, however, that the accoucheur's conduct was blameable for the following reasons:—

1st. He had neglected to use proper remedies. They blamed him for having added the strong acetic acid to the solution of alum, declaring its action, when externally applied, to be very different from that of vinegar, and rather tending to increase hæmorrhage.

2dly. He had used plugs for the vaginal hæmorrhage, although, according to his first view of the case, the symptoms required a different treatment.

3dly. Notwithstanding the reasons which discouraged him from attempting artificial delivery, he ought not to have quitted the patient, nor to have left the dilatation of the os uteri to the midwife;

but he ought to have used proper remedies, and to have waited for a favourable moment for delivery, so as to be ready to meet the danger of renewed hæmorrhage, and, if possible, save the life of the mother and the child.

4thly. That he had neglected to try to resuscitate the patient, and had held the child to be dead, without any proof.

5thly. That he had by no means properly recognized the presentation of the placenta.

In consequence, the Board adjudged—1st, that Mrs. X. would perhaps have died under any other method of treatment, and that it could not be shown that Mr. K.'s conduct had unconditionally caused her death; 2dly, that Mr. K. had been guilty of several manifest offences against the rules of medical treatment, so that he could no longer be permitted to practise midwifery, unless he should show, by successfully going through a strict examination, that he had been led astray in the case in question by an accidental confusion of thought.

To this judgment Mr. K. replied, that from the os uteri being high and closed, neither internal nor external examination could prove that the placenta presented, particularly as the insertion of the finger produced no hæmorrhage. That occasional hæmorrhage, indeed, had taken place for a week, but that it had been but slight, according to the account both of the patient and the midwife; and being accompanied by bearing down, and pain in the sacrum, seemed to show that premature delivery was at hand. He endeavoured to answer the several reasons for the judgment (with the exception of No. 2) in the following manner:—

That he had prescribed the best remedies; for the accusation as to the strong acetic acid was founded on an error of the pen (in one of the written pleadings, we suppose), and he referred

to his prescription of the 2d of January, to show that he had ordered vinegar. That on the following morning things had altered, and, after a violent flooding, he had convinced himself of the presentation of the placenta; but that the patient was very weak and near her end, and the dilatation of the os uteri would have required from an hour to an hour and a half, and would therefore have infallibly killed her.

That the duty of a physician, as defined in his oath, is to leave no patient without aid, but that he is not obliged by any law to remain with a dying person till the last sigh. That artificial delivery could not be practised in this case, and as midwives are not forbidden to dilate the os uteri, that it was just the same whether he or the midwife did it. Cordial medicines would have been hurtful by exciting hæmorrhage.

That *apparent* death is not to be presumed when a pregnant woman dies of hæmorrhage from separation of the placenta, but only when death has been suddenly produced by nervous attacks, spasms, apoplexy, or the like. Nor was it possible for the child to live with a separated placenta, and its death was confirmed by the symptoms of putrefaction. It was the fault of the police that he had not performed the Cæsarean operation after the death of the mother; for, when the husband hesitated, they would not afford him the necessary assistance.

That in a woman who has borne many children the os uteri is closed at the end of pregnancy, even although it were possible to press the finger in, which in this case could not be done, from the uterus lying so high. He added, that in a woman in the eighth month of pregnancy, in whom the os uteri was closed and lying high, and where hæmorrhage had come on in consequence of the separation of the placenta,

and the accoucheur was not called in till after the lapse of twelve hours, no practitioner could save the life of the patient. He concluded by attacking the midwife, who, he said, had caused the calamity, by not calling him in three days sooner, when he would have had time to dilate the os uteri.

On this, the board promulgated a second judgment to the following effect*: —Mr. K. is mistaken in saying that no better remedies could have been used to check the hæmorrhage, for experience has sanctioned the internal application of alum and the mineral acids. He was also to blame in refraining from artificial delivery on account of the fainting or weakness of the patient, as such a state is often relieved by the stimulus resulting from dilatation of the os uteri.

The practitioner should certainly never quit his patient when a remedy is to be used with the intention of warding off immediate dissolution. This is especially necessary in artificial delivery, as partial dilatations of the os uteri are injurious, and the patient is exposed to dangerous hæmorrhage, unless with due circumspection and presence of mind the delivery is concluded as quickly as possible after the artificial dilatation of the os uteri.

Mr. K. is quite opposed to experience when he asserts that under these circumstances death is never merely apparent, and that the children are always born dead. His ignorance, too, is shown in other inconsistencies; thus he rejected delivery by the natural passage, because it would have been too dangerous for the child, and yet he says it was dead, because it had not moved for three days.

Mr. K.'s want of knowledge is further shown by his theory as to the closure or openness of the os uteri at the conclusion of pregnancy; for he makes no distinction between the external and

* As Mr. K. had omitted No. 2 in his answer, the board omit it in their reply.

internal os uteri. No fault is to be alleged against the midwife. Following the instructions of her manual, she called in an accoucheur on the appearance of frequent hæmorrhage; and Mr. K. says himself, that he found the pulse slow, but not weak, and that neither hæmorrhage nor nervous attacks were present. Mr. K., however, showed the greatest want of knowledge in entrusting the midwife with the dilatation of the os uteri during his absence.

For these reasons, the board confirmed their former sentence.

This case hardly requires any comment. Mr. K. was certainly censurable for leaving his patient at the period when he did so, especially if we judge by the event; yet if this is thought sufficient to justify so severe a sentence, the accoucheurs of his district must have attained absolute perfection; if his fellow-practitioners occasionally err likewise, then is Mr. K. the most ill used of men. Surely a censure from a public board would have been punishment enough, without suspending him from the practice of midwifery.

COLLEGE OF PHYSICIANS.

THE evening meetings for the season commenced on Monday, on which occasion the rooms were crowded to excess. Among those present we observed his Royal Highness the Duke of Cambridge, the Archbishop of Canterbury, the Duke of Wellington, Sir Robert Peel, and many distinguished members of the church, the bar, and the senate.

The paper, which was listened to with great attention, and excited general interest, was—

On some of the Results of the successful Practice of Physic. By SIR HENRY HALFORD, Bart., President of the College of Physicians, &c. &c.

After acknowledging the favourable manner in which his former papers had been received, the learned President proceeded to enlarge upon the facility with which the physician obtained

a moral influence over his patient in the hour of suffering, and on the advantage which might be taken of this for the best and noblest purposes. The attachment of the sick, and the respect of their friends towards the physician, were strongly sketched by Sir Henry; who, however, did not dwell upon this part of the subject.—

I will rather, said he, turn to history for instances in verification of my position, yet I will not go back to antiquity; though I might find passages in Homer strongly expressive of the attachment and respect of the Grecian heroes to their medical attendants, and several instances in the life of Hippocrates demonstrative of the regard and admiration of his countrymen. Our own times furnish me with a striking example of the deference paid to a physician by the highest potentates. When Dr. Jenner first promulgated the protective influence of vaccination against the danger of small-pox, the king of Spain fitted out an expedition to carry the vaccine matter to every part of his transmarine dominions; and after having left the valuable material at the Canary Islands, the Caraccas, and all the provinces of South America, the director of the expedition resolved to carry the preservative to the remotest part of Asia; and having stopped at Acapulco and the Philippine Islands, he introduced vaccination into China. The Emperor of Russia, too, after he had established the practice of vaccination throughout all his European dominions, sent Dr. Bontaltz to traverse his Asiatic possessions for the same benevolent purpose. The mission, therefore, when it had reached the capital of Siberia, proceeded to Ocholtz; from whence he sent it to Kamschatska, and the islands situated between Asia and America. Fresh matter was transmitted also into China; so that the Spanish and Russian expeditions reached different points of the celestial empire nearly at the same time.

In the Island of Java certain portions of land have been set apart for the support of vaccination; and as a mark of respect and veneration for the author of this valuable discovery, these lands have been designated Jennerian lands.

This detail may be considered, perhaps, as affording evidence rather of the confidence of these sovereigns in the merit of the new invaluable resource, than of their personal respect and de-

ference to Dr. Jenner. But it is true that Bonaparte, in the plenitude of his power, accorded their freedom from bondage to no less than nine captives severally, at the request of Dr. Jenner—a homage to the benevolent author of so important a discovery; and that the Emperor of Austria and the King of Spain paid equal attention to Dr. Jenner's intercession in behalf of individuals who were detained in their dominions.

But the anecdote most flattering to the medical profession, which I would recal to your remembrance, is the occasion of the first establishment of the East India Company's power on the coast of Coromandel, which was procured by the favour of the Great Mogul to one of our profession (Gabriel Boughton, of the ship *Hopeful*), in gratitude for his efficient help in a case of great distress, to the monarch. It seems that in the year 1636 (a very early period of our direct intercourse with India, after the Portuguese had discovered the passage thither by the Cape of Good Hope) one of the princesses of the Great Mogul's family had been burnt dreadfully by accident, and that a messenger was sent to Surat, where foreign traders resorted, to desire the assistance of one of the English surgeons there, for they had acquired a great reputation amongst the natives for their skill in the cure of diseases. Gabriel Boughton proceeded forthwith to Delhi, and was successful in performing a cure, on which the Great Mogul's minister asked him what his master could do for him to manifest his gratitude for so important a service. Gabriel answered with a disinterestedness, a generosity, a patriotism beyond my praise, "Let my nation trade with yours." Be it so. A portion of the coast was marked out for the future resort of English ships, and all duties were compromised for a small sum of money. A better station, it is true, was selected at the mouth of the Hoogley River some twenty years afterwards, and Calcutta was built; but *here* was the first establishment of our power—here did the civilization of that vast continent begin. From hence the blessed light of the Gospel may have been first promulgated amongst 100 millions of native idolaters, since subjected to the control of British power, and made partakers of our enlightened comforts.

This happy result of the successful

interposition of one of our medical brethren suggests a question to my mind of the expediency of educating missionaries who are to be sent to the rude uninformed population of distant countries to propagate the Gospel, in the medical art, as the earliest object of their studies, in order that they may make themselves more acceptable than if they presented themselves professedly to teach a new religion. I propound this question with great diffidence, particularly in the presence of that part of my audience with whom it may rest to direct the preliminary education of this useful body of men; but I know that the candour of these venerable characters is equal to their high dignity, and that they will receive my suggestions in good part, and feel assured that I mean that these missionaries should carry the Gospel in their heads and in their hearts, and govern their conduct by its precepts; though I conceive it might further their purpose to withhold the sacred volume until after they had acquired the goodwill and confidence of their hearers, by the service they had done them in healing their sickness. We know what the Jesuits have accomplished in the pursuit of this concurrent object, wherever they have found admittance, and I am sanguine enough to believe that even that proud and exclusive people, the Chinese, would receive those who entered their country with these views without that suspicion and distrust which they never fail to manifest when they surmise that trade is the object of the stranger's visit, or some covert intention to interfere with their institutions; and that this might be made the occasion of giving the comfort of the Gospel to 300 millions more of the inhabitants of our globe, in process of time.

The Chinese received vaccination kindly; and when a small English tract, written expressly to recommend that process, had been translated into their language, though strenuously opposed to every innovation on all occasions, they not only submitted to receive this new practice, but actually raised a considerable subscription to assist in diffusing it throughout their vast empire; and since that time they have allowed missionaries from America to establish an ophthalmic institution, and also a general dispensary for the supply of European medicines and advice to their poor. I will read a part of a

letter from Canton, dated the 2d of April, 1837, from the Rev. Mr. Gutzlaff, a member of the American Medical Missionary Society there, in which he says, "I humbly hope that the Association will prove a great blessing to this country. Dr. Parker continues to operate most astonishing cures, and other physicians have already arrived at Singapore. By endeavouring to benefit both the body and the soul, some favourable impression, it is to be expected, will be made on the minds of this people."

Undoubtedly the Chinese practice of physic is so meagre, and inadequate to meet and control the ills which flesh is heir to, as to give an easy superiority to the commonest pretensions of European knowledge. You will agree with me in this opinion when I tell you what their physiology and pathology is, and what are their resources under disease, which I am enabled to do by the kindness of the Right Hon. Sir Alexander Johnstone, who put into my hands a MS., since printed in the *Asiatic Journal*, giving, from the best authority, a full account of the practice of physic of China.

It seems that they know nothing of the doctrine of the circulation of the blood. They believe that the human body is composed of five elements—water, fire, wood, metal, and earth; that as long as the equilibrium between these elements is maintained, people enjoy health; as soon as one predominates, sickness ensues; that all diseases arise from disturbing the equilibrium of these parts, and that the art of healing consists in restoring their mutual relation. They know nothing whatever of chemistry. There is not even a name for it in their language. Their medicines are almost all vegetable, and the Ginseng root their panacea. Detesting the sight of blood, the abstraction of it, by whatever means, is almost or altogether unknown amongst them; and their utter aversion to any surgical operation reduces them to the necessity of depending upon the inefficiency of internal remedies in surgical cases. The employment of the moxa and acupuncture can hardly be considered as exceptions to this general interdict.

So long as the erroneous opinion prevails with them that every thing ancient is excellent, and superior to recent in-

ventions, they must necessarily remain in their present state of ignorance, and the most useful sciences will be rejected. Not that we can expect the Chinese to grasp with eagerness at our improvements, yet the cure of diseases set down at once as fatal in their experience, must be likely to facilitate the introduction of our knowledge, and add most humanely to their comfort and civilization; and not to their temporal happiness only, but to their future felicity, by the introduction of the Holy Scriptures amongst them by this avenue.

With those who practise upon such a system of physic as I have detailed, if system it can be called, is it possible that the acquired knowledge of his profession, in an English medical practitioner, should come into competition without the greatest advantage in his favour? Is it possible that his knowledge of anatomy, by which he is enabled to detect the seat of disease; his acquaintance with chemistry, and all other resources of his art, by which he administers effectually to maladies within the reach of human skill, should not give his patients, and those who surround them, a greater confidence in his judgment than in that of a feeble native practitioner? Be it understood, however, that I do not claim your acknowledgment of his superiority for an Englishman of superficial knowledge only. In our profession a little knowledge may be a dangerous possession; and it is on this conviction that I humbly propose that those who are to be educated to become missionaries, after having had their minds thoroughly imbued with moral and religious principles in their first scholastic discipline, shall then attend to anatomy and chemistry, and other courses of medical lectures, and for a certain time frequent some one of the great hospitals, so as to qualify themselves to practise physic and surgery, as if they were to prosecute our profession as their means of living.

With minds so exercised, men are surely not ill prepared to receive, and weigh well, and deeply study, the sacred truths; and having the sanction of holy ordination, to go forth amongst the heathen to expound them. The Americans seem disposed, according to the accounts from Canton, to keep separate the civil and the clerical characters, and have no other missionary there

professedly educated for the practice of physic and surgery but Dr. Parker; yet it is acknowledged that he is most in credit for the good which he does. Now confidence is not transferable, and it does not follow that the impression of gratitude and attachment which the physician shall have made by his successful ministration to disease, will be given necessarily and of course to a stranger introduced to explain what is required for the salvation of the soul. I hold it, therefore, far preferable that the two characters should be united in those whose zeal for the benefit of mankind may carry them to remote parts of the world. Of this union we all know numerous and respectable instances at home; and it cannot fail to be remembered within these walls, that our founder, Linaere, the first President of the College, took orders in the latter period of his life, and died in the exercise of those sacred functions.

But (said Sir Henry, in conclusion) I am afraid I become tedious. Let me make haste, then, to thank you for your patient attention, and to add, in evidence of the sincerity with which I have represented the frequent occasions of the purest mental gratification which the physician finds in the exercise of his calling, independently of any other consideration, and contrary to the maxim in Horace—

“Nemo, quam sibi sortem
Sui ratio dederit, seu fors objecerit, illi
Contentus vivat, laudet diversa sequentes;”

if I were to begin my life again, I would adopt the profession of physic.

Amongst these gratifications, I should be ungrateful to you if I did not enumerate the repeated pleasure of meeting and co-operating with you for the improvement of medicine, and for the promotion of the respectability of our profession, in these evening assemblies at the College; and when it shall please the Great Creator to remove me to another world, which must necessarily be at no very distant day, some of you who now listen to me may bear in mind these my unfeigned sentiments and attachment to our common profession, and not be surprised if they should bear that—

“Occidit et dulces moriens reminiscitur Argos.”

LATE IMPROVEMENTS IN MEDICINE AND SURGERY.

THE diseases of the bones have, of late years, engaged the earnest attention of professional men; and a *concours*, proposed by the Academy of Sciences, on the subject of spinal deformities, could not fail to be an inducement to additional study. After waiting five years, the great prize was carried off by a brother journalist, M. J. Guérin, and the second one by M. Bouvier.

Orthopedy seems to have arrived at a point where it is no longer a mechanical and illu-vory art, but the whole of medicine applied to a branch which may be considered as new, since our predecessors knew nothing but its name.

Medical gymnastics, directed according to the data furnished by the last researches into pathological anatomy, now form one of the most essential parts of the treatment of deformities. Gymnastics, when employed as they are at the present day, constitute an important branch of therapeutics, and are really a science practically applied, but one with which the majority of practitioners have but a very slight acquaintance.

An equally brilliant improvement, which is exclusively of modern date, has been made in the treatment of club foot, and angular ankylosis of the knee. Some years ago, it would hardly have been thought possible that a few weeks should suffice to cure completely, and almost without pain, deformities which were recently thought by great masters of our art to be incurable, particularly in adults; but facts are stubborn things, and we must submit to evidence. Several dozens of children operated upon by M. Duval, in our presence, were perfectly cured of their club-feet in a fortnight or twenty days; and many other patients, aged from twenty to fifty, received the same benefit under the hands of the same practitioner, in a space varying from one to two months after the tendo Achillis had been cut. Our readers are already acquainted with the first results obtained by the operation of cutting the tendons of the popliteal region for the cure of angular ankylosis of the knee; and we shall soon be able to publish several other cases of the same kind, which have been operated on in the institution for club feet, at Paris. An important circumstance to be noted in all these operations is, that if the tendon is not completely divided, they fail entirely in their object. In fact, if a very small strip of tendon has escaped division, the limb cannot be made perfectly straight. This has occurred at the Hôtel Dieu, and

even in private practice, in the case of one of the principal editors of a great political journal, and the deformity returned from this circumstance alone. This want of success proceeds merely from the method of operating employed; for the operation never fails when the tendon is cut according to Stromeyer's method, as improved by M. Duval. It is obvious, indeed, that by cutting in the contrary direction to the one which he follows, that is, if we cut from the skin inwards, the tendon is pushed back, and we are liable to leave some of the tendinous fibres untouched, or else to injure parts which ought not to be meddled with*.

The treatment of fractures of the limbs has undergone important modifications. M. Seutin, chief surgeon to the Belgian army, has successfully altered and generalised the fixed apparatus; he employs a solution of starch as a plastic material for the straps, and uses pasteboard splints instead of wooden ones; at the same time he has adopted the principle of making the patients walk as soon as the bandage is dry.

The results obtained by M. Seutin with the starch apparatus, have received the approbation of the Society of Medicine, and the Academy of Sciences, at Paris, particularly in fractures of the leg. We shall return more in detail to this method of treatment when we give an account of the work which M. Seutin has just published. Let us mention, meanwhile, that several patients with fractures of the leg, who are now in the Charité, and are being treated in this manner, are suffering from considerable eschars.

The pathology of the urinary passages is understood better and better. Strictures of the urethra are no longer treated by any dilatation, except that which is merely momentary; for experience having shown that permanent bougies irritate the canal, delay the effects of dilatation, and predispose the patient to relapses, the practice has been adopted of dilating the urethra for a short time only every day. Bougies are employed of a gradually increasing size, and they are left in the urethra for a few minutes, or at most half an hour, each time. Patients treated in this way experience no bad symptoms, can attend to business, and get well more quickly and certainly than by the old method. The bees'-wax bougies found in

our shops are now generally preferred to those of elastic gum. This method, though sanctioned by the experience obtained in private practice, is not yet employed in our public hospitals.

But whenever a stricture of the urethra seems insurmountable by ordinary means, practitioners do not now hesitate to make use of the bistoury. Experience seems to have shown that in such cases the small incision made at the very point where the stricture is, dissolves the diseased tissues, or rather discharges them by the suppuration which follows, thus ultimately allowing the dilatation of the canal of the urethra.

Lithotripsy continues to extend its domain, and lithotomy has really become an exception. The *percuteur à marteau* gives pitiless raps both to the *pince à trois branches* and to the adversaries of this beautiful operation. Meanwhile, M. Souberbielle is still considered the most successful of lithotomists.

The radical cure of hernia is actively pursued by several professional men. We have seen patients who had been cured by M. Lafond; and M. Bonnet, of Lyons, has made other cases known. Much remains to be done in this important department of surgery.

Hydrocele has of late been the subject of therapeutic research, particularly in England. Mr. Lewis, of London, cures this disease in a very simple manner. He inserts several acupuncture needles, or common sewing ones, into the tumor, and leaves them there a few moments, twisting them between his fingers, in order to make the punctures round; the water becomes extravasated, drop by drop, into the cellular tissue of the scrotum, and is afterwards re-absorbed; the sac gradually returns to the testis, and the cure takes place without adhesive inflammation. The cure is radical, and is effected in a few days, without pain, and without confining the patient to his bed, or to his room. Nevertheless, relapses have sometimes occurred, in which case the operation has been performed again*.

The same treatment has lately been applied with success to idiopathic dropsy of the abdominal cavity.

Microscopic pathology seems of late to have got into favour with experimental physicians in different countries. M. Delle Chiaje, of Naples, has discovered the *polytoma* in the blood of man: it is a small worm, shaped like a leech, which is developed in the circulating fluid of some pa-

* The Gazette des Hôpitaux, of January 4th, contains a letter from Dr. Bonvier, in which he says that he prefers the method of operating which is censured in the text—namely, that of dividing the tendon from the skin inwards; and he asserts that he has never failed, either in the Hôtel-Dieu or in his own institution, or in private practice.—Translator.

* Mr. Lewis's claim to the invention of this method seems doubtful: our readers will find several controversial letters on the subject in the 19th vol. of the MED. GAZ.—Translator.

tients. M. Delle Chiaje has observed a great number in the blood which various phthisical patients have vomited in his presence, as well as in the blood which he has drawn from the veins of persons labouring under other diseases. The *poly-stoma* is found also, without the existence of disease, in the blood of several non-ver-tebrated animals. M. Delle Chiaje makes use of his discovery to explain the develop-ment of the disease called *helminthiasis*, or verminous affection, and the formation of hydatids in general; as, according to him, the blood secretes the germs of these animals. Another equally curious fact has been brought to light by microscopic ob-servation—we mean the animalization of the globules of milk, which M. Turpin seems to have confirmed.

Thus we see that the year which has passed away is more remarkable for im-provements than for great discoveries. At its beginning, certain persons proclaimed their appearance upon the medical hori-zon with a sort of *fracas*; they called them-selves reformers of the whole science, and loudly announced the fact in their jour-nals. Others, perhaps, unterrified by their fall, will succeed them, ready to wander in the same path, while they forget the first part of the saying of Archimedes—*give me a spot on which to stand!* Yet after, as before them, science will continue its habitual progress, slow, but still advanc-ing.—*From the Gazette des Hôpitaux of Jan. 2, 1838.*

EXPERIMENTS ON ANIMALS WITH THE BLOOD OF CHOLERA PATIENTS.

By DR. NAMIAS, OF VENICE.

UPON opening the body of a man, aged fifty, who had died in the cold stage of cholera after twenty-four hours' illness, at the hospital of St. Daniel, the blood in the cavities of the heart was found to be black and congealed together, with one or two polypous concretions. A portion of the congealed blood, of the size of a straw-berly, was inserted, without causing much suffering, under the skin of the thigh of an old and fat rabbit. The fur was shaved off, and an incision having been made through the skin, it was separated by the handle of the scalpel from the cellular tissue beneath; and into the cavity thus formed the blood was introduced, and the wound was then carefully closed with sutures. This mode of inoculation was followed in all the experiments.

Exp. 1.—Five days after the operation the rabbit appeared ill, its evacuations were

less solid than usual, and a whitish glu-tinous matter was observed upon the ground. The animal was found dead on the eighth day. The blood of the heart was black and grumous, with some fibrinous concretions; the bladder was full of urine; the injected blood had pervaded the surrounding tissues; the lips of the wound had their normal consistence; the internal surface of the whole of the skin was covered with blue spots of ecchymo-sis; but the rest of the organs exhibited no alteration.

Exp. 2.—An equal quantity of the blood of this rabbit was injected in a similar manner into the thigh of a grey female rabbit. It was found dead in twenty-four hours afterwards, with the same appear-ance of the whitish matter upon the ground. The body, when examined, ex-hibited similar results as in the former experiment. The author here judiciously remarks, that the rapid death of the second rabbit arose not only from its weaker age and sex, but also from the blood of an animal of the same species being more readily absorbed than human blood.

Exp. 3 and 4.—The blood of the last rabbit was inserted into two others that died in six days with the same marks of disease. These rabbits were much larger than the former.

The next experiments were performed with the blood of a man who died in the cold stage after twelve hours' illness. The blood was black and grumous, but there were no concretions.

Exp. 5.—This was a fat old grey rabbit, of the male sex. It died five days after the operation. There was no whitish matter on the floor; the bladder was empty; there were many brown spots on the inner surface of the skin. The state of the blood and of the wound, that was not of a kind to affect the health of the animal, was the same as in the other cases.

Exp. 6.—Performed with the blood of the last on a male rabbit, two pounds and a quarter in weight. It died in forty hours. Bladder full; blood black and fluid; the usual spots on the skin. In this instance also, the poison transmitted through a similar animal acted more rap-ly than when taken directly from man.

Exp. 7.—Another rabbit, inoculated with the blood of the last, was found dead in six days.

Exp. 8 and 9.—In these two experiments, for the sake of greater accuracy, the Doc-tor weighed both the rabbits and the blood. Into one, weighing three pounds and a half, he injected ten grains of blood from the last experiment; and into the other, weighing three pounds, he inserted

eight grains of the same blood. Both died in six days.

The next experiments were undertaken with the view of ascertaining whether human blood, taken from persons not dead of cholera, would produce the like results. Three rabbits were inoculated: one, of two pounds and a quarter, with seven grains of black fluid stinking blood, from the heart of a patient dead of gangrene of the bowels; a month afterwards the animal was well and vigorous. Another, of three pounds and a quarter, with the blood of an aneurismatic patient, of which twelve grains were used; and the third, of two pounds two ounces, with fourteen grains of the same blood, which by its quantity only would probably be fatal: on the twenty-sixth day afterwards the larger rabbit was sprightly and vigorous, the smaller dull and out of condition, with a large wound on the seat of the inoculation.

Dr. Namias considering the re-action of cholera as a beneficial effort of the vital powers to eliminate from the body matters that are incongruous with its tissues, to restore the deranged state of the sanguiferous system, and to renew the exhausted nervous energy, was inclined to believe that the blood of persons dying in this stage would be less injurious than that from persons in the pulseless state; and some experiments that he undertook with Professor Rima seemed to confirm this notion. Twelve grains of the blood of a female, dead after three days' illness with imperfect re-action, were inserted in the usual way into two rabbits, and a third was made to swallow a scruple of the same blood. All three survived, but a great number of spots, produced by the drying of a white glutinous matter, were found in the hutch of the two former. The other appeared to vomit the blood it had swallowed, and for some days after it vomited a similar white substance. Four scruples were injected under the skin at the back of the neck in a little dog. This blood had been taken from a woman dead of cholera in seventy-two hours after incomplete re-action. For the first two days the dog passed, along with natural faeces, many small white worms; on the third day he vomited milk he had lapped; and he died early on the fourth day. Incipient suppuration was observed under the separated skin; the bladder was quite empty; the heart contained very fluid blood in small quantity: and there was no evident cause of death. — *Bullettino delle Scienze Mediche*; and *British and Foreign Medical Review*.

ON THE

FIBROUS MEMBRANE BENEATH THE PLEURA PULMONALIS.

BY M. BAZIN.

AFTER quoting the opinion of Colombo, the pupil and successor of Vesalius, that the pleura is composed of two laminae, between which the blood-vessels and nerves are distributed, the author of this memoir states that the researches of succeeding anatomists have led to a different conclusion, in consequence of their having been confined to the pleura costalis. His own extended investigations into the structure of the respiratory organs in the series of vertebrated animals, have led him to the conclusion that the lungs, like other organs, possess a proper capsule. He remarks, that capsular envelopes are found to exist in three states: 1, a fibrous network with large interstices, frequently taken for cellular tissue; 2, a complete fibrous or sclerous membrane, whose density and thickness may be variable; 3, an osseous plate. The capsule of the lungs in most animals presents the first condition, that which exists in man; but in the elephant a distinct fibrous membrane is met with, consisting of bundles of parallel fibres interlacing at certain points with others, like the muscular coat of the bladder. The lung of a panther, which died of phthisis, presented M. Bazin with a hypertrophied condition of this membrane, which in the healthy state of this animal is not thicker than in man. — *Annales d'Anatomie et de Physiologie*; and *Brit. and For. Med. Rev.*

ROYAL INSTITUTION.

Friday, Feb. 2, 1838.

THE subject of this evening's lecture was—

The Skeleton of Insects displayed through a Gas Microscope. By Mr. GOADBY.

The first skeleton brought into view was very distinct, in which the lecturer pointed out the three great divisions, consisting of—1st, The head, which has attached to it the mouth, the antennae, and the eyes. The mouth consists of an upper and lower lip, a pair of upper and a pair of lower jaws. The antennae are two articulated bodies, one on each side of the head. The eyes are of two kinds, compound and simple. 2d, The thorax, consisting of the prothorax, mesothorax, and metathorax. 3d, The abdomen is made up of several

segments, the number varying in different animals. The insect displayed was the *Blatta Americana*, which has three simple, besides two compound eyes. The antennæ, or feelers, whether they are possessed of touch or not—a point which has given rise to much discussion—yield at least great assistance in holding the food. The wings of this insect are of a very beautiful texture; and the bones in them, which are mere hollow tubes, and serve the purpose of conveying nourishment, as well as the vessels by which blood is carried to and from them, were very distinctly seen.

The lecturer then proceeded to make some remarks on aquatic insects, and some peculiarities in them suited to the element in which they live. Among these he noticed the immense size of the coxæ, or hips, in which the muscles are fixed, and which adds considerably to their strength. He also alluded to the row of small apertures round the outside of the back of the skeleton, by means of which they inhale air when they come to the surface of the water. Thence he passed to the *Mantis Religiosa*, so called from its being worshipped by the Brahmins of India. The Chinese keep them, and make them fight like game-cocks, for which they are well adapted, being very cruel and carnivorous insects. Their wing-cases are articulated with particular beauty, and still more so the wings themselves. Mr. Goadby was then going on with some remarks on the dragon-fly; but the gas, which had not burnt well during the latter part of the lecture, now went out; so that, after apologizing for the insufficient supply of gas which he had prepared, and for the imperfection of the microscope, which he stated that he was in the course of improving, he was obliged to bring his lecture to rather a hasty conclusion.

PHYSICAL SOCIETY, GUY'S HOSPITAL,

January 27, 1838.

DR. ADDISON IN THE CHAIR.

MR. ASPLAND read part of a thesis on the physiological and pathological relations of the heart.

The chief points upon which the author dwelt, were—

1st. Physical evidence of hypertrophy. He doubted the existence of a bellows sound in this lesion, when unconnected with induration or contraction of an orifice. 2. Disease of valves. He had not unfrequently had opportunities of

examining *pure* cases, in conjunction with renal disease, which were afterwards demonstrated by post-mortem examination, but there had never been in these instances a bellows sound.

Amongst the causes of pericarditis, measles was adduced, and maintained by Mr. Aspland to obtain more frequently in very early life than any other.

The physical signs of morbid states of the pericardium were then entered upon, and cases illustrating partial "frottement" read.

After enumerating the symptoms referred by authors to adherent pericardium, two were selected, as most frequently present—epigastric undulation, and increased impulse towards the base of the heart. To these the author added contraction* of the intercostal spaces, synchronous with that of the epigastrium, that part of the chest opposed to the apex of the heart being at the same time impelled outwards more powerfully, and a greater fixedness of the point of impulsion of the apex, than during health; the difference being very marked on changing posture.

He then read four cases of adherent pericardium, where a distinct rubbing sound was audible: he had met with it in similar cases, believed it not uncommon when hypertrophy also existed, and was inclined to localise it in the pleura, as immediately caused by friction between the pericardial and pulmonary *pleura*. The three first cases were verified by post-mortem inspection; in the last the patient was convalescent. He was seized whilst in the hospital with acute pericarditis, complicated with pleuritis. A loud superficial to-and-fro sound accompanied the systole and diastole of the ventricles; this suddenly ceased, and was immediately succeeded by the phenomena mentioned above as indicative of the pericardial adhesions. During the course of convalescence a pleuritic rubbing sound, synchronous with inspiration and expiration, became developed; at the same time a similar sound became audible to the left of the præcordia, but synchronous with the heart's contractions. This he considered without doubt as seated in the pleura.

Amongst the complications of adherent pericardium, the author stated disease of the mitral valve to be very frequent: where adherence of the pericardium had been present for any length of time, and where the circulation had been active, he confidently anticipated mitral valve disease. He suggested that owing to the adhesion, the axis on which the blood was propelled from the ventricle might be altered, and

* Only perceptible where hypertrophy existed.

instead of finding directly the aortic orifice, impinged against the mitral curtains, and thus produced the effect mechanically.

Diseases of the mitral valve occupied a short time. The author thought he was not refining too much in classifying them into three, which allowed of ten of diagnosis.

1. Simple thickening of the curtains, which he had diagnosed in some cases by the existence of a click immediately after the first sound.

2. Excessive contraction of the orifice, not allowing of regurgitation. Amongst other peculiarities this condition was rarely attended with bruit, often not complicated with hypertrophy*; pulse more inclined to vary in power than frequency.

3. Contracted valve, but allowing of regurgitation, attended with bruit, and excessive irregularity of pulse.

Pure mitral valve disease he considered as not often attended with dropsy, or diseased liver; the lungs, whatever be the state of the tricuspid, bearing the brunt of the disease.

The discussion that arose upon this paper was long and animated, and bore chiefly upon two of the topics introduced by the author. The one was a question as to the value of "frottement" as a pathognomic sign of pericarditis; it being contended by several speakers that this sound existed occasionally without pericarditis, and was sometimes absent although pericarditis was present. It was further contended that no friction could occur when the pericardium was closely adherent, and that friction outside could not indicate inflammation inside the membrane.

Mr. THURNAM suggested that authors, such as Watson, Stokes, &c. had said that frottement only prevailed during that early stage of pericarditis when the effused lymph was first poured forth, and disappeared after adhesion.

The other question was in relation to mitral valve disease; some maintaining the occasional existence of bellows-murmur from regurgitation in this diseased condition, others denying it altogether.

Dr. ADDISON took occasion to state the following to be a general rule, which the result of a long experience upon the subject had led him to adopt. He had examined hearts of all sizes, affected with diseased mitral valves, and had never known bellows sound to exist during life, where he did not find some other lesion after death, besides that of the valve, competent to produce it; and on the other hand, where no lesion but that of the valve appeared after death, he had never heard bellows-murmur during life.

* A fact noticed by Dr. Addison, and also Dr. Latham, in his Croonian Lectures.

In the course of the evening, Mr. BRERETON took the opportunity of referring to some observations of Dr. Macleod's, which had been published lately in the GAZETTE, to the effect that pericarditis was connected with rheumatism of fasciæ, and tendinous structures, and not with synovial rheumatism. Mr. Brereton's attention had been attracted to the subject by the MEDICAL GAZETTE, and he had since seen several cases of pericarditis connected with rheumatism of joints alone, which were altogether in contradiction to Dr. Macleod's experience. Mr. B. related one of these cases, in confirmation of his statement.

The thanks of the Society having been presented to Mr. Aspland, for his Thesis, the meeting adjourned to Saturday, Feb. 10, at 8 P.M.; when Mr. Dendy will read some observations on the effusions that occur in the membranes of the brain and spinal marrow; Mr. Edward Cock in the chair.

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Surgeon for the Week, MR. LUKE.
Assistant-Surgeon, MR. CURLING.

Jan.	Sex.	Age.	Case.

(a.) The injury to the toes in this case was so severe that they have all mortified, and separation has taken place at the first articulation.

INQUEST ON MARY STONARD.

To the Editor of the Medical Gazette.

SIR,

I PERCEIVE from the *Times* of this morning that your last number makes the case of Mary Stonard, who died suddenly at Clapham, on Thursday the 11th instant, the subject of severe remark, and that it is designated as "another death from starvation."

I take the liberty of informing you that a more groundless misrepresentation never was palmed upon the public, and that every material circumstance of the original report has received the clearest and most decisive contradiction, upon the testimony of the husband, the daughter, and the regular medical attendant of the deceased, supported by a mass of corroborative evidence.

To go into detail would occupy too much of your space. I will therefore only mention, that the woman died of a violent fit of spasmodic asthma, to which she had long been subject, and that she and her family were in circumstances of comparative comfort, their earnings being nearly 16s. a week, and their cottage and large garden held of the parish rent free. They never were without food or firing; they had meat, by their own shewing, nearly, if not quite, every day; and on the day before her death the poor woman had fried bacon, potatoes, and greens, for dinner; tea, sugar, and dripping toast in the afternoon; and boiled bacon and parsnips again at supper. Before she left home, on the morning of her death, she had sugared tea and dripping toast for breakfast, and, except her asthma, looked as well as at any time this ten years.

The accessory circumstances of "potatoe parings," and the attendant said to have accompanied her to Clapham, are utterly false. Much of the present statement came out upon the inquest (from which, by the

by, the most important medical witnesses were excluded,) but was suppressed by the reporter or his superiors.

The present is not the first occasion on which, to my knowledge, the inventions or misrepresentations of the newspaper press have betrayed you into bitter but undeserved reflections upon respectable individuals implicated in occurrences connected, or supposed to be connected, with the New Poor Law.

I am, sir,
Your obedient servant,
BENJAMIN FIELD.

Clapham Common,
31st January, 1855.

[The part omitted contains a strong censure of certain newspapers, which we do not feel called upon to insert. In respect to what refers to ourselves, we can assure Mr. Field that we have been influenced merely by feelings of humanity. We have no other sources of information on the subject alluded to except the newspapers, and when we have been led into error, as appears to have happened in the present case, we shall always be glad to be set right.—ED. GAZ.]

PARACENTESIS THORACIS.

To the Editor of the Medical Gazette.

SIR,

WHEN I delivered the lecture reported in the last number but one of your journal, I forgot to include, among the cases of Paracentesis Thoracis which I had myself witnessed, one in which that operation was performed by my colleague, Mr. Mayo, upon a boy, in whom empyema had ensued after fracture of the ribs. Complete recovery followed. The case is alluded to in Mr. Mayo's *Outlines of Pathology*.

The addition of this example renders my own list still more encouraging, in respect to the success of well-timed operations. In three out of six instances perfect recovery took place. In a fourth, the patient's existence was apparently much prolonged by the tapping; and I do not know that, in either of the two remaining cases, the fatal termination was in any degree accelerated by it.

I have the honour to remain, sir,
Your obedient servant,
THOS. WATSON.

Henrietta-street, Cavendish Square,
February 7, 1855.

January, 1838.

UNIVERSITY OF LONDON.

A MINISTERIAL print informs us, that on Wednesday night the following resolution was adopted almost unanimously by a committee of the whole senate of the University of London, at which 25 members were present:—"That examination in the Hebrew text of the Old Testament, and in the Greek text of the New, and in Scripture history, shall be instituted by this University, to be followed by certificates of proficiency, and that all candidates for degrees in arts may, if they think proper, undergo such examination."—*Times*.

MEDICAL PROMOTIONS IN THE NAVY.

JOHN RICHARDSON, M.D., F.R.S., &c., the celebrated Arctic traveller and distinguished naturalist, has been appointed Physician to Haslar Hospital, from the Surgeoncy of the Chatham division of Royal Marines; Mr. Rae, the junior Surgeon of Plymouth Hospital, succeeds Dr. Richardson at Chatham; Mr. Johnson, of H. M. S. Britannia, to Plymouth Hospital; and Mr. Martin, late of H. M. S. Hastings, to the Britannia.

BOOKS FOR REVIEW.

The Stomach in its Morbid States. By Langston Parker, Esq.

A Short Treatise on the External Characters, Nature, and Treatment of the different forms of Porrigo, or Scalled Head and Ringworm. By Walter Dick, M.D.

Prize Thesis.—Observations on the Influence of Climate on Health and Mortality. By Arthur Saunders Thomson, M.D.

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine,

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE VIII.

Distension and Corrugation of the Dura Mater

—Inner surface spotted with clusters of Red Points—Deposition of Matter between its Laminae—Deposition of Bone—Tumors—Diseases of the Sinuses—Diseases of the Glandulae Pacchioni—Adhesions between the Dura Mater and the Arachnoid—Effusion of Serum between the Dura Mater and Arachnoid—Effusion of Blood—Aneurismal Sacs—Osification of the Arteries—Diseases of the Arachnoid and Pia Mater—Increased Vascularity sometimes accompanied with a deposition of False Membrane—Thickening and loss of Transparency—Effusion of Serum tinged with Blood—Ecchymoses—Deposition of Lymph, Pus, and Fibrin—Looseness or Separation of the Membranes—Preternatural Firmness of Adhesion—Tumors—Serous Cysts—Flattening of the Convulsions—Hypertrophy—Inanition.

Distension and corrugation of the dura mater.—On removing the calvaria, you may find the dura mater preternaturally distended, and presenting the appearance of a bladder fully inflated, and elastic to the touch. This you may regard as one appearance evidentiary that death has arisen from a natural cause. That cause may be hypertrophy of the brain, from too abundant nutrition causing too rapid growth; or it may arise from the effusion of fluid between the membranes or into

the ventricles. On the other hand, you may find the dura mater in the opposite state, corrugated and falling down quite loose upon the convulsions, conveying the idea that its contents had not filled its cavity. This condition may result from the want of the due nutrition of the brain, in consequence of diseases which have impaired the digestive organs and produced extreme emaciation, or in consequence of the gradual failure of the powers of nutrition in advanced age; or it may arise simply from the accidental puncture of the dura mater on the removal of the calvaria, and the consequent escape of fluid which had been contained beneath it.

You will generally find, when inflammation attacks the dura mater as an idiopathic disease, that the vascularity which denotes the existence of this affection is seated chiefly in the membrane which lines the internal surface of the dura mater, commonly regarded as a reflection of the arachnoid. How intensely red this membrane may become under acute inflammation, you see represented in this drawing. From a careful attention to the history of the case, you may distinctly trace the commencement of the inflammation to the dura mater; but it is seldom that the affection is confined to this membrane. It almost always extends in the progress of the disease at least to the arachnoid. The portion of the dura mater implicated in the state of inflammation, as has been already shown, is sometimes very distinctly circumscribed; but at other times it extends over all that part which covers one hemisphere, the longitudinal sinus affording the line of separation.

Inner surface spotted with clusters of red points.—Occasionally you may find the inner surface of the dura mater spotted over with clusters of red points like the effusion of blood in purpura. You will generally be safe in regarding this appear-

ance as the result of natural disease. The disease in which it has its origin may, indeed, be seated in some distant organ, the disease of such organ producing in its progress some irritation in the brain. Instead of red points, you will sometimes observe minute spots, or small lines, of a dark colour, which communicate to the membrane, for a considerable extent, a hue actually black. It is the result of extravasation of blood. At the moment the extravasation takes place it may have produced an attack of apoplexy or of palsy, which not terminating in death, and the other portions of the blood having been absorbed, the only remaining trace of the event may be the appearance which you see represented in this drawing.

Deposition of matter between its laminae.—

As the result of common inflammation, the dura mater is liable to a remarkable degree of thickening, and to the deposition of new matter between its laminae. The deposition may go on slowly increasing, without at first producing alarming symptoms, until, on reaching a certain point, violent convulsions supervene, in a paroxysm of which the patient may expire; at other times the deposition may take place with great rapidity, and occasion death quite suddenly. A gentleman, aged 60, had long been afflicted with severe pain in the head, and giddiness, the attacks of which generally went off with vomiting. At length the giddiness was attended with such a complete loss of muscular power, that on attempting to move he fell to the ground if not prevented. In these attacks he never lost his recollection, and he recovered completely in a few minutes. At length he was seized with hemiplegia, from which he partially recovered; but this was followed by a sudden attack of convulsions, in a violent paroxysm of which he died. Along the upper part of the right hemisphere of the brain, there lay a remarkable tumor, five and a half inches long, two and a half broad, and about half an inch in thickness. It was formed by a separation in the laminae of the dura mater, and a deposition of new matter between them. This new matter in some places was white and firm, in others it consisted of more recent coagulable lymph, firm, yellow, and semi-transparent; at its anterior part there was a cavity containing yellowish serous fluid. The dura mater all around the tumor was considerably thickened, and so were the coats of the longitudinal sinus. The surface of the brain where the tumor lay was depressed, so as to retain an impression of its figure; but the substance of the brain itself was healthy, both in this part and in every other.

A boy, six years of age, was seized suddenly with pain over a circumscribed spot on the left side of the head, followed by drowsiness; the attack proved rapidly fatal. On the part corresponding to the seat of the pain there was found a tumor, the size of a large hazel-nut, formed by the separation of the laminae of the dura mater, and the deposition between them of a bloody serous fluid. There were several similar tumors, but of smaller size, along the course of the longitudinal sinus on the left side.

Deposition of bone.—On the inner surface of the dura mater you may find deposited plates of bone, which may vary in extent from the most minute spiculae to the enormous masses of bony matter which you see in this specimen. Such depositions seldom fail to produce severe cerebral diseases—epilepsy, convulsions, coma, or apoplexy, in a violent paroxysm of some one of which, suddenly induced, death may take place with extreme rapidity.

Tumors.—From the same surface of the dura mater you may find growing tumors of different kinds, which, slowly increasing, at length produce such a pressure upon the brain as is no longer compatible with life, which may be extinguished quite suddenly in a paroxysm of convulsions, or in coma, terminating almost as rapidly in death.

Diseases of the sinuses.—Connected with these various diseases you will often find the sinuses of the dura mater changed in structure; their parietes thickened, solidified, almost cartilaginous; their cavity either entirely obliterated, or greatly diminished, and containing, instead of blood, purulent matter, or coagulable lymph, which may even become organized, and give to the vessels the appearance as if they were injected with wax. The calibre of the vessels being thus filled with solid matter, the transmission of blood through them may be impossible; and you may occasionally find hundreds of small vessels which have given way in consequence of this obstruction to the return of the blood. Such a condition of the blood-vessels must, of course, greatly add to the intensity of the cerebral disease.

Diseases of the glandulae Pacchioni.—Even the glandulae Pacchioni may become so exuberant in their growth as decidedly to obstruct the passage of the blood. In this manner they may lay the foundation of apoplexy, and other violent and rapidly fatal cerebral affections. Cases are on record in which they resemble fungous growths, and in which the patient has died in coma, or a paroxysm of dreadful convulsions. Sometimes, in connexion

with fungoid disease of the brain, these bodies assume the appearance of grumous blood.

Adhesions between the dura mater and the arachnoid.—Between the dura mater and the arachnoid you will often find preternatural adhesions, sometimes so slight that they are easily detached, but at other times so firm that they cannot be removed without bringing away parts of the brain. These adhesions are always the result of inflammation, and this inflammation may be caused by natural disease; but it may also be the result of external violence. You may find the adhesion connected either with a circumscribed spot of inflammation, or with superficial ulceration, or with abscess, tumors, and other lesions of long standing. When you find the adhesion connected with a circumscribed spot of inflammation, look carefully for some indication of external violence, of which it is very frequently the consequence.

Effusion of serum between the dura mater and arachnoid.—Between the dura mater and the arachnoid it is not common to find any accumulation of serum, although these tissues taken together form a very extended surface, which consists of serous membrane. In some cases of chronic hydrocephalus, however, this is the original situation of the accumulated fluid, and more especially in those in which the malady is accompanied by spina bifida; while in other cases of chronic hydrocephalus the fluid obtains this situation in the progress of the disease by escaping from the ventricles in which it was secreted.

Effusion of blood.—But the space between the dura mater and the convolutions is a very common situation for the effusion of blood; sometimes in consequence of the spontaneous rupture of blood-vessels at the surface of the brain, the ruptured vessels being occasionally visible; sometimes in consequence of the erosion of blood-vessels during the progress of ulceration seated in the cineritious substance; sometimes in consequence of the rupture of blood-vessels deeply seated in the substance of the brain, the effused blood tearing and breaking down the cerebral fibres, and thus finding its way to the surface of the convolutions. Effusions of this kind may be the sole result of natural disease. It is a very common situation for the blood to occupy which is forced out from a ruptured vessel during an apoplectic seizure. But such an effusion of blood may be the result of external violence. A blow on the head may produce it by causing a rupture of the capillary blood-vessels, and a laceration of the cerebral fibres. The quantity of blood effused from the direct effect of the blow may at first be small, but it may go on progressively increasing

until at length some violent cerebral affection supervenes, and life is suddenly extinguished. Whenever, therefore, you find blood effused in this situation, inquire minutely into the history of the case, and examine closely every part of the skull, with a view to the detection of some trace of external violence, the evidence of which will often be discovered if carefully sought for.

Aneurismal sacs.—Effusion of blood in this situation may be the consequence of the bursting of an aneurismal sac which you may find seated in the trunks of the carotids, or in their larger branches; but sometimes the aneurism so deranges the circulation as to cause the rupture of other vessels, while the aneurism itself escapes.

Ossification of the arteries.—Rupture of the vessels, and the consequent effusion of blood, may also be the consequence of ossification of the arteries. Between the coats of the arteries a quantity of osseous matter is sometimes deposited, by which they lose in a great degree their contractile and distensible powers; with this loss of contractility and distensibility their tenacity and strength are proportionally diminished, and hence, whenever any causes occur to quicken the circulation, or to retard the return of blood by the veins, an unusual quantity of blood accumulates in the arteries, and these vessels, no longer capable of any considerable degree of distension, are ruptured. It is seldom that the rupture takes place in the large arterial trunks; it is almost always in the minute capillaries.

The deposition of bony matter in the arteries of the brain may take place at any period of life; but it is a frequent occurrence in advanced age. It is usually found in the carotid and basilar arteries; but occasionally a large portion of the arteries of the brain are involved in the malady. Sometimes, without any deposition of bony matter, numerous arteries are entirely obliterated—a condition which deserves your notice, as one among other facts evidentiary of a diseased state of the circulation, which may have prepared the way for an attack of some violent cerebral disease proving rapidly mortal.

Diseases of the arachnoid and pia mater.—The other investing membranes of the brain, the arachnoid and the pia mater, are far more frequently the seats of fatal disease than the dura mater. These membranes are so similar in structure, and so associated in function, that their morbid states are intimately blended, and it is rare to find disease in one while the other is sound. The most common disease to which they are subject is inflammation, indicated by increased vascularity; so that these membranes, instead of being colour-

less and transparent, present in patches, or over a large portion of their surface, a bright scarlet colour. The fine arteries distributed to them gradually enlarge until they become capable of permanently admitting the red particles of the blood. When the vascularity is confined chiefly to the veins, instead of presenting a bright scarlet colour, the membranes assume a dusky or purple hue. The enlarged veins are often exceedingly turgid with dark-coloured blood, constituting the state of venous congestion.

Increased vascularity sometimes accompanied with the deposition of false membrane.—Often there is no other morbid appearance whatever in the brain but this increased vascularity of the membranes. You may find the vascularity confined to a small spot. You may find it very general, or even universal. In either case it is capable of proving fatal with great rapidity. A person may be seized suddenly with a paroxysm of violent convulsions. Headache may precede this attack, but it may not. Vomiting also may precede it, but this symptom likewise may be absent. The convulsions may pass into coma, and the coma may terminate rapidly in death. From a state of apparent health a person may be dead in a few hours with no other symptom than these, and on examining the brain, to ascertain the cause of death, you may find every portion of the cerebral substance perfectly sound; you may be able to detect no appearance but increased vascularity in the arachnoid and the pia mater. Often, however, this increased vascularity is accompanied by a deposition of false membrane between these tissues. This false membrane is sometimes spread uniformly over the surface of the convolutions, while at other times it dips considerably between them.

A child, two years of age, was seized suddenly in the morning with severe and long-continued convulsions, which left her in a dull and torpid state, in which she did not recognize the persons about her. In a few hours the convulsions returned, and continued to recur in paroxysms of great severity, in one of which she died, in the evening of the third day. The pia mater throughout was in the highest state of vascularity, more especially between the convolutions. When the brain was cut vertically, the spaces between the convolutions were marked by a bright line of vivid redness, produced by the inflamed membrane. There was likewise a deposition of adventitious matter between the arachnoid and the pia mater.

A girl, nine years of age, awoke suddenly in the middle of the night screaming from violent headache, and exclaiming that some person had given her a blow on

the head. Soon afterwards she was seized with violent and long-continued convulsions, followed rapidly by profound coma, out of which she never recovered, but died in this comatose state on the following day. The arachnoid and pia mater were unusually vascular, and a layer of adventitious deposit was spread out between the two membranes.

After some previous indisposition, a child, six years of age, was seized with severe headache, considerable hesitation in the speech, and occasional delirium, followed quickly by convulsions, in a violent paroxysm of which she continued without intermission for the space of two hours, and then died. Every part of the brain presented a perfectly healthy appearance, excepting a small spot on the lower surface of the anterior lobe of the right hemisphere, where it lies over the orbit. There was at this place a distinct deposition of adventitious matter, scarcely larger in extent than a shilling. No indication of disease could be discovered in any other organ.

But a highly vascular state of the pia mater may prove rapidly and unexpectedly fatal without convulsions or coma, apparently from a sudden depression of the vital powers after intense excitement. There may at first be no indication of disease, except an unusual quickness of manner; to this may succeed constant talkativeness, and a total want of sleep; a state of depression, alternating with an almost maniacal excitement: the patient either lapses into a state of coma, or sinks exhausted. A lady who had suffered much distress of mind, which had impaired her appetite and deprived her of sleep, fell into a state of incessant talking, alternating with screaming and singing. For two days she continued in a state of alternate excitement and coma, when she died. The only morbid appearance that could be discovered in any organ was a highly vascular state of the pia mater, with numerous red points in the substance of the brain.

All the circumstances and cases to which I have now adverted, are of the greatest interest in a judicial point of view. The sudden and unexpected seizure of a person, previously in apparent health, with such violent illness, the peculiar symptoms which have been described as accompanying such illness, and the rapid death, may often give rise to the suspicion of violence produced by human agency; it may be impossible to remove this suspicion, or to ascertain the truth, without an examination of the brain. On examining the brain, and finding no more appearances of disease than some of those which I have described, you may at first be in

doubt whether they are adequate to account for the fatal event; it is therefore of great importance that you should previously study these morbid appearances, as indications of natural and rapidly mortal disease, that you may be conducted to a correct conclusion by a clear and exact knowledge of the subject.

Thickening and loss of transparency.—You may find the arachnoid and pia mater thickened, opaque, or of a milky hue, either in spots or in large patches, following the course of the blood-vessels. Beneath these membranes there is frequently poured out a quantity of serum, which, collected in the delicate meshes of the pia mater, assumes a gelatinous appearance. This appearance is connected with a great variety of causes, which it is necessary that you should be capable of accurately discriminating. When the quantity is very small, it is doubtful whether it should be regarded as the indication of any morbid action during life, or should not be considered rather as the effect of that congestion which forms a part of the process of death. But in proportion as the quantity is large, it is indicative of disease. It may be the result of inflammation, having its primary seat in the membranes themselves; it may be caused by any condition of the system which obstructs the free circulation of the blood through the brain, and particularly by diseases of the lungs and heart; but it may also be produced by external violence—suspension, submersion, and suffocation; and you will often be called upon to determine to which of these two classes of causes it is to be referred.

Effusion of serum tinged with blood.—Occasionally you will find the serum effused in the meshes of the pia mater tinged with blood, an appearance which will deserve your careful attention. It may be the result of the rupture of the minute vessels of the pia mater caused by external violence, as concussions or blows; but it may also be produced by transudation after death, in those states of the system in which the blood retains its fluidity, and in which there is a tendency to transudation through the coats of the blood-vessels on the trunk and extremities; or by transudation consequent upon the commencement of the process of putrefaction. The importance, in a judicial point of view, of a cautious consideration of all these circumstances, must be obvious to you.

Echymoses.—You will often find blood effused in minute quantities between the arachnoid, and within the meshes of the pia mater, forming small patches of echymosis, varying in size from a sixpenny piece to that of a crown. This is some-

times the result of natural disease, especially when death has been preceded by violent convulsions, as in hooping-cough, epilepsy, hydrophobia, &c.; but at other times it is the consequence of external violence, concussions, blows, falls, &c. It may be produced by a narcotic poison, as opium, and it is not an unfrequent consequence of death from suffocation. Whenever, then, in a case which has given rise to suspicion, you meet with these circumscribed effusions of blood in the membranes, endeavour to ascertain whether death were preceded by convulsions, the consequence of some natural disease; and if there be no evidence of this, search diligently for the proofs of poison, suffocation, or some form of mechanical violence.

But sometimes the quantity of blood effused in this situation is extremely great, extensive coagula of which you may find lying either upon the surface of the convolutions, or occupying and very much increasing the interspaces between them. The ruptured vessels from which the blood has issued may be the minute capillaries on the surface, which have given way in consequence of some obstruction to the course of the blood in the large trunks; or the ruptured vessels may be seated deep in the substance of the brain, and the blood which has escaped from them may have forced its way to the surface. The violence of the symptoms produced by blood effused in this situation being commonly proportionate to the quantity which has escaped, when the quantity is very small, it may occasion no appreciable inconvenience; but when large, it may produce all the ordinary effects of pressure, from dulness, drowsiness, and coma, to complete apoplexy. It has been observed, that a given quantity of blood deposited between the convolutions produces severer symptoms than an equal quantity more diffused upon the surface of the brain.

Deposition of lymph, pus, or fibrin.—The meshes of the pia mater are also sometimes filled with lymph or pus; at other times a layer of fibrin is deposited between the pia mater and the cineritious substance, undoubted results of inflammation, the exact cause of which it will be the very purpose of your investigation to discriminate and verify.

Looseness or separation of the membranes.—On attempting to remove the membranes from the brain, you may find that they separate with unusual facility, by the slightest force applied to them, a condition which is generally connected either with congestion of the membranes, or with the effusion of a small quantity of serum in the pia mater. You may also find the membranes absolutely and com-

pletely separated from the convolutions. This is seldom the result of natural disease; it is generally the consequence of violent concussion, and is often accompanied with laceration of the convolutions.

Preternatural firmness of adhesion.—Sometimes, on the contrary, the membranes adhere to the convolutions with such firmness that they can be separated only in flakes and shreds; another undoubted result of inflammation. When the inflammation has been intense, the force which is necessary to remove the membranes seems to be on the point of tearing the cineritious substance; and when the inflammation has been both intense and long-continued, it is absolutely impossible to separate the membranes without bringing away portions of the cineritious substance. This morbid condition is sometimes circumscribed to a small and defined space; at other times it extends over a large surface of the brain. When circumscribed to a defined spot, it is often connected with external violence, but the more extensive it is, the stronger is the indication that it is connected with a general and not a local cause of inflammation.

Tumors.—When tumors grow from the arachnoid and pia mater, they are usually of a fungoid character, and are associated with fungoid diseases in other parts of the body, and, therefore, however rapidly they may have become developed in the brain, and however violent and sudden the cerebral symptoms produced by them, you cannot hesitate to refer their origin to some natural cause.

Serous cysts.—And equally to a natural cause must be referred those serous cysts which are occasionally formed in the membranes, and which are sometimes coeval with life itself, and always exceedingly slow in their growth. It is probably owing to this slowness in their growth that they produce so little inconvenience; not only the brain itself, but the bony parietes of the skull, being often moulded to their form.

Flattening of the convolutions.—A morbid change in the appearance of the convolutions, interesting from the number of natural causes which may give rise to it, is the obliteration of their defined and rounded figure, and the general flattening of their substance. Perhaps the most common cause of this change is the collection of serum within the ventricles, which occasionally accumulates in such quantity as altogether to destroy the divisions of the convolutions. It may also be occasioned by the effusion of blood into the ventricles, or into the substance of the brain; nay, even by a great degree of congestion of the blood-vessels; by abscess

at the surface or in the substance of the brain; by softening of the cerebral substance; by tumors, which, though generally limited to a confined space, yet often compress the convolutions of one hemisphere, or a portion of a hemisphere; by several diseases of the dura mater which have been already described; and by a morbid growth and thickening of some particular portion of the skull.

Hypertrophy of the brain.—But the most interesting cause of this flattening of the convolutions, as the result of natural disease, is the disproportion between the volume of the brain and the capacity of the skull, occasioned by too abundant nourishment, and consequently too rapid growth, of the brain. To this affection, which has been termed hypertrophy of the brain, the special attention of practitioners has been recently directed. On removing the calvaria, the dura mater (as has been already stated) looks preternaturally distended, and fits closely to the brain within. On taking away the membranes, the whole surface of the brain presents a flattened appearance, so that the distinction of convolutions is either entirely obliterated or is marked only by superficial lines. At first view it is impossible not to conceive that the ventricles are distended with fluid; yet, on examining these cavities, they are found smaller than natural, and containing less fluid than in the sound condition of the brain. There is, at the same time, a remarkable deficiency of fluid in the whole brain; so that when it is sliced in all directions, little or no serum, or blood, escapes. The blood-vessels are preternaturally empty, and the investing membranes are unusually dry. The cerebral substance is denser and firmer than natural, and conveys the idea that it is in great abundance and massive. On the removal of the calvaria, the brain instantly springs upwards, like an elastic body on the removal of a compressing force, as if the organ were too large for the case that contained it.

The early stage of this affection, which is generally slow in its progress, is completely latent; like several other diseases of the brain, it may go on increasing, up to a certain point, without giving any indication of its existence; but at last, passing beyond the point which is compatible with the due exercise of the functions of the brain, violent symptoms suddenly supervene, and the patient appears to die after a few hours' illness.

Hypertrophy of the brain is most common during the period of childhood, when all the nutritive functions continuing very active, the mental faculties are also in

constant operation. I have observed it particularly in children who, from the general configuration of the head and their precocious intellectual and moral attainments, afforded unusual promise, and excited expectations of future power and excellence, too soon buried with their object in the grave. The fair and pinky skin, the blue eye, the light hair, the quick and active mind, so often connected with this temperament, as well as the tendency to glandular disease, should always excite alarm, and lead to the adoption of every possible means that can strengthen the physical health, and retard the development of the mental faculties.

But this disease may take place in the adult, and may appear to be very suddenly induced, giving rise to an attack of illness perhaps produced by no manifest cause, and characterized by severe cerebral symptoms, the most prominent of which may be a lethargic drowsiness, attended with a preternatural slowness of the pulse.

It may also be the result of an inflammatory action set up in the brain by external violence, as a blow or a fall. A child, three weeks before its death, fell from a table and struck its head. At the time no serious symptoms were observed; but at length a large tumor, containing a fluid, made its appearance, from which, on being opened, a quantity of pus was evacuated. That day the child had a severe convulsion, which being followed by a continual succession of convulsive fits, in the intervals of which the child was sensible, death took place on the fourth day from the first appearance of the tumor. The most remarkable appearance in the brain was a flattening of the whole surface of the convolutions, with increased vascularity of the cerebral substance.

Inanition.—But you may find the very opposite condition, the convolutions shrunk, wasted, without their usual plump and rounded form; the cineritious substance diminished in thickness, separating easily from the medullary matter; and the whole mass of the latter appearing deficient in quantity. This state of the brain depends on a converse condition of the system—on deficient nourishment from an inadequate supply of nourishing and stimulating blood. It is the natural result of that failure in the nutritive process which is consequent on old age; but it may exist at any period of life, and may be induced by whatever causes impair the nutritive functions; by excessive blood-letting, which may remove suddenly from the system a larger proportion of the solid constituents of the blood than the digestive organs can resupply; by food bad in quality, and deficient in quantity, so that

the material requisite for forming healthy blood is not afforded; by long-continued confinement in impure air, and by the want of the general invigoration communicated to the system by active exercise.

LECTURES

ON THE

ENTOZOA,

OR

INTERNAL PARASITES OF THE HUMAN BODY,

Being part of a Course on Morbid Anatomy, delivered at the London Hospital,

By T. B. CURLING, Esq.

LECTURE V.

HAVING terminated the consideration of the various entozoa infesting man, and the lesions which they give rise to, and having briefly noticed the treatment most appropriate for their removal, it may appear necessary that I should allude to their origin and the mode of their development. From the nature of their local habitation, and the remarkable circumstances under which these animals are produced, this inquiry might be expected to be invested with a peculiar interest, and to throw light on one of the most intricate subjects that have ever occupied the human mind. It offers, indeed, a wide and difficult field of observation, and one, though not unexplored, from which it must be confessed that nothing satisfactory or conclusive has yet been deduced. It is evident that the entozoa must either come from without, or originate in the body of the animal in which they are found. That they have an external origin; that they are nothing more than aquatic or earth-worms, introduced either in their perfect state or in the form of ova, with their organization so modified as to be adapted to their extraordinary situation, though an hypothesis held by Linnæus and supported by Brera, is clearly shewn, both by Rudolphi and Bremser, to be incompatible with our knowledge of the economy of these animals, and of the laws of animated nature. The peculiarity of their organization; the limitation of particular kinds to certain species of animals, and peculiar situations in the body; their incapability of sustaining life when removed from their natural sphere of existence; and their occasional presence in the fœtus at birth, are powerful arguments in support of the opinion that they are deve-

loped in the interior of the animal in which they are observed. Dr. Barry has related, in the Transactions of the College of Physicians of Dublin, a case which is viewed by some as leaving no doubt respecting the external origin of the *ascaris vermicularis*. After a whole family, with their servants, had been infested with these worms for some time, it was discovered that the water of a well by which the inmates of the house were supplied contained an immense number of minute worms resembling the small ascarides, except that they were of a darker colour. Now I am by no means disposed to regard this observation as conclusive, especially as the identity of the worms found in the well was not satisfactorily established by examination of their organization. Besides, it cannot but be viewed as most extraordinary, that at a period when the animal kingdom has been the subject of such diligent investigation, the most common and most abundant of all the entozoa should, if existing out of the body, have only been discovered in this particular instance.

Some naturalists, and amongst others, Pallas, are inclined to believe that the existence of these animals is perpetuated by the ova being transmitted from generation to generation, or communicated from one individual to another. Pallas experimented upon the subject. He inserted the ova of the tænia of a dog into the abdominal cavity of another dog, and on opening the animal a month afterwards, he found some small tape-worms, about an inch in length, in the abdomen. Certain entozoa peculiar to fishes have been detected alive in the stomach and intestines of aquatic birds by which the fishes were devoured. That these worms cannot, however, be readily introduced into the system at all times in this way, is shewn by an experiment performed by M. Schreiber, of the Museum at Vienna. He fed a polecat during six months almost exclusively on different kinds of intestinal worms and their ova, mixed up with milk. On destroying the animal at the end of this period, not a single living worm of any description was found within it. If, then, the ova are communicable, as supposed by Pallas, they must be constantly exposed to causes tending to their destruction—a contingency which would seem to be fully provided for by nature, in supplying this class of animals with the most ample means of reproduction. In surveying, indeed, the economy of the entozoa, which present such great diversity of organization, and the type of almost every form of generation, there is no circumstance so remarkable as the care which seems to have

been taken to insure the continuance of the species, as well in the simple separation of the germ from the parent cyst in the acephalocyst, as in the oviparous generation of the *Sterelmintha*, and the viviparous progeny of the *Cœlelmintha*. Cruveilhier thinks that the more frequent appearance of hydatids in the liver and lungs, organs more abundantly supplied with blood than other parts, tends to show that the germs of these animals are transmitted in the circulating fluid. The ova, however, of some of the Entozoa, as for instance of the *Ascarus lumbricoides*, are so large and heavy, that they cannot be supposed to pass through the capillary blood-vessels, or to be transmitted through the medium of the atmosphere. There are, undoubtedly, several striking objections to Pallas' view of the origin of these animals. It is difficult to comprehend how hydatids and the other entozoa, insulated and included in a cyst, can be propagated in this way. We should expect, too, that some of the species, such as the *spiroptera* and *strongylus*, would be met with less rarely if they are transmitted in an uninterrupted line, and that there would be no interval in the hereditary succession. Notwithstanding these, and even other objections, the view which seems to me to accord best with the imperfect state of our knowledge respecting their origin, is, that the countless germs and ova of these animals are extensively diffused; that they are transmitted from generation to generation, and in various modes from individual to individual; that they enter the system with the food, and perhaps in other ways; and that, constantly subject to numerous destructive agencies, they are only developed under peculiar and highly favourable circumstances.

In conclusion, I may remark that some pathologists and naturalists have cut the matter short by rejecting Harvey's principle *omne vivum ex ovo*, and affirming that the entozoa are the result of spontaneous or equivocal generation, and have endeavoured to support this opinion by the evidence deducible from natural history as to the peculiar character of the animals inhabiting various parts of the earth, and by those facts revealed by the enterprising geologists of later years, which go to prove that different kinds of animals have been created at distinct epochs. To engage here, however, in a discussion on this plausible hypothesis, an hypothesis indebted to the phenomena displayed by the Entozoa for the most satisfactory evidence hitherto brought to its support, would be leading me far away from the course which it has been my aim to follow in the delivery of these lectures.

Spurious Worms.

I stated, when commencing the subject of the entozoa, that living beings are sometimes found in the interior of the body, which have evidently been introduced there from without, and I instanced the botts found in the stomach of the horse. These animals are termed by pathologists *spurious worms*. They are numerous and various, infest many animals as well as man, and gain ingress in different ways. They are generally introduced in the form of ova, or larvæ, and, finding a convenient situation and congenial temperature, undergo their natural changes. They have been known to enter by the nose, mouth, ear, anus, urethra, and vagina, and are sometimes lodged beneath the skin. They are found in the digestive organs, especially the stomach, more frequently than in any other part of the body, where they no doubt obtain admission with the food. They occur sometimes in the frontal and maxillary sinuses, causing headache and other distressing symptoms. A learned entomologist, the Rev. Mr. Hope, has lately communicated to the *MEDICAL GAZETTE* a set of curious tables, including 107 cases of spurious worms which have been found infesting the human body. He enumerates 45 different larval species, and 23 cases in which the species was unknown; 37 of the cases were female, and 32 male; 30 occurred in England, 15 in Sweden, 10 in Ireland, and 3 in Scotland. In seven instances they appear to have produced death. The most common, and perhaps the most curious, of the spurious worms, are the *Æstri*, which belong to the class of dipterous insects. They pass the state of larva and chrysalis, or that of larva only, in the body of the animal on which they prey. Different species are found infesting various animals. Some, as the *horse-botts*, inhabit the alimentary canal and rectum; others, as the *botts* of the ox, rein-deer, and goat, take up their abode under the skin; whilst others, as the *æstri* of the sheep and stag, occupy the nasal sinuses. The *æstrus humanus*, which is described by Linnæus and Humboldt, occurs only in the warmest regions of America. The larvæ reside beneath the skin for about six months, and deep seated pain and inflammation are induced if they are interfered with before they make their appearance at the surface, as small brown flies. Dr. Elliotson mentions the case of a child, who, having eaten part of a high pheasant, discharged from the bowels some months afterwards about a dozen live larvæ, maggots of the common fly. There is no end to the marvellous cases of spurious worms which the records of our profession furnish. Thus we have accounts of bees, caterpillars, spiders, millipedes,

flies of all kinds, earth-worms, leeches, snails, slugs, lizards, toads, frogs, and even serpents, having been thrown up from the stomach, or discharged from the intestines. Many of these cases we must admit, *cum grano salis*, and it is highly probable that in some instances deception has been practised. One of the most remarkable and best authenticated examples of this kind on record is that of a woman whose case is related in the Transactions of the College of Physicians of Dublin. From certain superstitious notions, she had been in the habit of drinking daily a mixture of water with the clay taken from the graves of two priests, and was likewise addicted to eating chalk. During three years and a quarter this woman discharged per anum above two thousand of the larvæ of the beetle, and most of them alive. Both the larvæ, pupæ, and the perfect insects, were simultaneously observed. Many made their escape the instant they were discharged, and ran off into holes in the floor; and two large-winged insects were so lively on their expulsion, that they immediately flew away and escaped!

The Ectozoa, or Parasitic Insects.

In addition to the various kinds of worms, there are numerous parasitic insects infesting the human body, which differ from the Entozoa in many points of their organization, but principally in the circumstance that, living in the open air, they possess organs of respiration which, you must have observed, are wanting in all the species of the internal parasitic worms which I have described. They are termed, in contra-distinction to the Entozoa, *Ectozoa*; but they are so seldom connected with morbid changes, that they can scarcely be said to come within the limits of these lectures, and I shall therefore only cursorily allude to them. With some of these parasitic insects you are no doubt sufficiently familiar, and have perhaps occasionally been troubled. The *Pulex irritans*, or flea, and the *Cimex lectularius*, or bug, are too well known to need any description; but if not, they may be observed with great advantage in the wards of the hospital, where, I regret to say, they abound. The *Pulex penetrans*, or *chigoe*, is a sort of large flea, which infests the inhabitants of the West India Islands, and is likewise very troublesome in some of the colonies of South America. These insects get under the skin, and there lodge their eggs, which are very numerous, and are hatched in this situation, often giving rise to ill-conditioned ulcers. They sometimes occasion so much irritation, and such troublesome sores, that amputation of the affected limb has been rendered necessary. *Pediculi*, or lice, the offspring of

filth, and the most offensive of these insects, may at all times be seen luxuriating on the persons of many of the hospital patients. Of these there are three species:—1. The *Pediculus humani corporis*, or body louse; 2 the *Pediculus capitis*; and 3, the *Pediculus pubis*. A due attention to cleanliness is, in general, a sufficient security against the annoyance of these disgusting vermin. Campbell, the poet, in his Letters from the South, mentions an ingenious mode adopted by the Arabs, to get relieved of their numerous companions. Stripping themselves naked, they spread their garments upon ants' hillocks; and the ants, after devouring all the vermin which they find on the clothes, retire from them well satisfied into their nests. Some individuals are more disposed than others to be infested with them. Parent-Duchatelet informs us, in his elaborate work on Prostitution in Paris, that the heads of very few of the unfortunate women on the town, even of the better class, are free from pediculi; but I am not aware whether they are equally abundant amongst the prostitutes in this country. It is stated that the members of one of the first aristocratic houses

in this country have some difficulty in keeping themselves free from the *Pediculus corporis*. Pediculi are said to be more common in cold climates than in warm. They are very numerous in Russia; and it is by no means uncommon to see one of the inhabitants engaged in the friendly act of ridding his neighbour of some of his troublesome associates, a process in which they acquire considerable dexterity. They exist in prodigious quantities in Greenland, where, according to the account of an English traveller, they constitute an article of diet. Pediculi are extremely prolific, and, as you are doubtless aware, may be communicated from one person to another. The *Pediculi pubis* are often caught in sexual connexion; and I may remark, that inunction with mercurial ointment is a tolerably certain mode of destroying them. In inveterate cases, an infusion of the tobacco leaf, or a mixture of turpentine, the strength being properly regulated, may be employed. Some caution is necessary in using the former remedy.

The last of the external parasites of which I shall speak is the *Acarus scabiei*, or itch insect. Although this insect is mentioned by some of the early writers, and has been

Acarus scabiei, or Itch insect.

long familiarly known to the inhabitants of southern climes, its existence has been repeatedly denied by modern authors, and is not even generally admitted at the present day. It was distinctly described by Mousset, an English author, who, in his *Theatrum Insectorum*, printed in 1634, quotes Avenzoar, an Arabian physician who flourished in the twelfth century, and other writers of the fifteenth and sixteenth centuries, as having noticed it. Mousset states that the *Acarus* does not reside in the vesicles, but near them,—a fact fully

confirmed by later observations. The *Acarus* was clearly ascertained and figured by Bonomo, an Italian physician, in 1683; and his account of it was communicated to the Royal Society of London, and afterwards published by Dr. Mead. De Geer gave an excellent representation of it. In 1805, Dr. Adams transmitted a good description of the insect from Madeira, in a letter to Sir Joseph Banks, which was inserted in the *Philosophical Transactions*; and when Dr. Adams published his work on Morbid Poisons, in 1807, this letter

was introduced, with some farther particulars, and a plate containing two accurate views of the *Acarus*. In France the search after this insect was less successful, and for a long period it escaped observation, until the year 1812, when M. Gales, after many experiments at the large hospital of St. Louis, at Paris, succeeded in extracting and designing an insect, which was generally regarded in France as the true *Acarus*. Unfortunately the artist employed by M. Gales figured a mite which had been placed near the *Acarus*, in order to be compared with it; so that when, in 1829, M. Raspail clearly shewed that this insect was nothing more than the common mite found in cheese, further disputes arose, and many of the physicians of Paris, and amongst others Lugol, positively denied the existence of the *Acarus*. Baron Alibert, however, still continued to believe that it existed, although frequently challenged to "produce the beast," by Lugol, who, moreover, offered a prize of 300 francs to any one who would shew it him. Thus matters rested in Paris until the month of August, 1834, when M. Renucci, a student from Corsica, happening to be in attendance at St. Louis, offered to remove all doubts; and stated that it was so commonly found in cases of itch in his own country, that the peasants were accustomed to extract them from each other with pins and needles. He publicly demonstrated the *Acarus*, and obtained the reward. According to Renucci, the itch insect is only to be met with in a small canal, indicated by a slight elevation of the epidermis, and a dull, white, opaque speck, adjoining the vesicle. The *Acarus* is so small as only to be just perceptible to the naked eye, appearing like a minute speck. It is about half a millimetre in diameter. When seen in a microscope, it presents the form of a tortoise, and a white opaque colour. The body is round, and striated with papillæ on its dorsal aspect. The head projects in front, and is provided with a sucker. There are eight articulated feet bristled with hairs: four in front, two on each side of the head, and four behind.

That there is some difficulty in detecting it, and a little tact required, cannot be doubted, since so many have searched for it in vain. The late Mr. Plumbe states that he has extracted many; but I cannot say that the few attempts which I have made were attended with success, though I have no doubt whatever of the existence of this insect, having seen it distinctly in Paris. That the *Acarus*, when placed upon the skin, can communicate the itch, has been fully proved; but whether they necessarily and invariably exist in the vicinity of the vesicles, and are the cause of their formation,

has not yet been satisfactorily determined. Cutaneous diseases, somewhat similar to the itch, to which some of the inferior animals, as the horse and sheep, are subject, have been shewn to depend on *Acaris*.

ON THE FUNCTIONS
OF THE
ENCEPHALON AND CEREBELLUM.

Cretâ an carbone notandum?

To the Editor of the Medical Gazette.

SIR,

In the last number of the *Lancet* there is a notice of a paper of mine communicated some time since to the Phrenological Society of London, in reply to which you will oblige me by inserting the accompanying. The notice alluded to has been communicated, I understand, by the secretary of the Society in his official capacity, but is not so much an analysis of the paper as a critique upon it, being, in its defects of omission and commission, much more like a reply in defence than an official abstract by the secretary of a learned Body. I wish very much, therefore, to be permitted to supply the deficiencies of that abstract, and, through the pages of the *MEDICAL GAZETTE*, to give to such readers of the medical weekly journals as care about such matters, the means of judging as to the objects aimed at in the paper, and the materials employed for the purpose of attaining those objects. All I shall attempt is an outline of the main facts and arguments which alone can be expected to interest the personally unconcerned readers of the *MEDICAL GAZETTE*; and, though not in possession of a copy of the paper, I have no difficulty in supplying from recollection, with the aid of memoranda and of the article in the *Lancet*, an outline of both, which, in its phrenological bearings, may be depended on as substantially correct. With the secretary's official reply to my paper in the *Lancet*, and my analysis of my paper in the *MEDICAL GAZETTE*, those that think it worth the trouble may easily satisfy themselves as to the pertinency of my facts and inferences, as well as of the value of the comments on them by the learned Secretary.

The paper was entitled "Facts and Inferences relating to the Development and Use of the Cerebellum." The

main object of the paper was to state some facts which had occurred to me in the course of inquiries respecting the nutrition, density, volume, &c. of the viscera under different circumstances of disease, age, sex, &c. &c. In the course of my observations upon the encephalon, I conceived I had found its development to be subject to a law not in harmony with the cerebral physiology of Gall, and that the cerebellum in particular appeared to increase and decrease in volume and weight, with the rest of the encephalon, and not contemporaneously with, or proportionally to, the development and activity of the functions attributed to it by Gall. From which I concluded that some error existed in the views of phrenologists respecting the cerebellum in particular, and that, taking the proofs of the Gallian views of the uses of that body as samples, and they are considered favourable samples of the evidence on which Gall has based his cerebral physiology, there is much reason to regard the whole fabric of phrenology as still hypothetical in science and conjectural in practice, and ample reason to distrust all phrenological diagnoses not aided or corrected by personal experience. Such was the scope of the original part of the paper, of the argument of which, as a whole, the following is an outline sketch.

After some introductory observations upon the reception experienced by Gall on the first publication of his system, and the necessity there was for reform in the methods of investigation employed in moral and mental science, and the tendency of Gall's labours to draw philosophy out of libraries into the field of nature, and from fruitless meditations to pregnant observations and experiments; and after avowing my conviction that Gall was right so far as he attributed to innate instinctive propensities and susceptibilities brought out in early life by sensible impulses acting as occasional causes merely, all our universal Judgments and Emotions, (such as the belief of the existence of external Nature, of Good and Evil, of Personal Identity, of personal Free Agency, of Supreme Power, &c. &c.; and the feelings of conjugal and parental Love, of Love of power, of praise, &c. &c.); and after making the further admission, that the old notion, that to certain classes of powers or affections of the mind were especially appropriated

certain parts or regions of the encephalon, as the seats of those faculties or affections respectively, was not destitute of plausibility, or even of probability,—I then proceeded to state that although I had often conversed on Phrenology with adepts, and had thought on it with some attention, and read several of the books of authority, I had been unable to satisfy myself that it had as yet attained to the rank of a true science in point of evidence, or to that of a useful art in point of practical certainty; and for several reasons, of which those that most influenced my own judgment, were—1. The impracticability of a correct estimate of the mass of the *living* encephalon, or of any part of it, in individual instances, without some as yet undiscovered measure of its density, which is variable. 2. The impracticability of an estimate more than conjectural, of the functional vigour of the encephalon, or of any part of it, in individual instances, without some as yet undiscovered measure of sensorial organic or vital power, *other than Experience*. 3. The want of satisfactory evidence that the frequent correspondencies between the form and the volume of the brain (as measured on the skull,) and the activity and energy of the mind, are really related to each other as *cause and effect*, and are not (like the parallel correspondencies between the temper, disposition, and other mental conditions, and the features of the face,) *mere coincidences*; or in other words, the want of proof that mental energy is not related to cerebral development by a *community of causation merely*, both being effects of the same higher and mysterious forces that form *in utero*, and sustain through life, in its personal identity, the moral-physical Being; but that the former (mind) is subject to and dependent on, and consequently, of necessity, proportional to the latter (brain) as a function on its organ, or an effect on its cause. Having, then, referred to other sources of doubt and difficulty, more especially to, 1. The want of subdivisions in the encephalon, corresponding even partially, to the Gallian organs; 2. The want of any means of estimating any organs seated at the base or in the interior of the brain, and the want of proof that there are not many so seated,—I proceeded to state that, in the course

of inquiries undertaken without any reference to the cranial physiognomy of Gall, I had met with new facts which appeared to me to harmonize with the considerations above referred to, as opposed to the Gallian Phrenology. Those facts were a tolerably numerous series of measurements by weight and volume of the encephalon as a whole, and of the cerebellum apart, from a comparison of which measurements it appeared that 1. the cerebellum is less in the female and greater in the male in the same ratio with the whole encephalon, and 2. less, likewise, at early and at advanced ages, as often as the encephalon is immature or decayed,—that, 3. the cerebellum, to which Gall attributes the sexual instinct as its principal if not sole function, bears after a few weeks from birth and up to extreme old age (that is, before the existence, during the activity, and after the failure of the generative power) one and the same proportion to the whole encephalon, viz. a ratio fluctuating between 0·125 and ·100, or between 8 and 10 to 1; and that 4. in females, in whom the physical appetite is comparatively feeble, and often almost if not altogether null, the same ratio prevails as in the male. These facts were detailed in two tables, containing the results of 150 and odd measurements of encephala and cerebella, belonging to as many subjects, of both sexes (nearly 80 of each sex), and of

various ages, from early infancy up to decrepitude. The first table gave the average weights of the encephalon and cerebellum at each age, for each sex separately; the second table contained the absolute weights of the cerebella, classified according to weight, sex, and age. From the first table it appeared that, with one exception, viz. that of an infant three weeks old, the cerebellum bore, as already stated, to the whole encephalon, a ratio varying from one-eighth to one-tenth, at all ages and in both sexes; while in the infant the ratio was one-sixteenth only. From the second table it appeared that the female cerebellum (like the female encephalon) differs by between —·12 and ·13 from that of the male, the former averaging nearly $4\frac{3}{4}$ ounces avoirdupois; the other, or male, averaging about $\frac{5}{8}$ of an ounce more, or something more than $5\frac{1}{4}$ ounces.

As the second table has been misunderstood both by some of the leading speakers on the occasion of the reading of the paper, and by the executive officer of the Society who drew up the imperfect abstract published, according to the usual practice of the Society, in the *Lancet*, I subjoin the facts in a form more simple, and less likely to be misapprehended by gentlemen not familiar with the tabular method of proof and illustration:—

MALE.			FEMALE.

15 to 30	10	5 4	10	4 10	10	
30 to 50	23	5 10	20	4 12	14	
50 to 70	32	5 12	20	4 10 $\frac{1}{2}$	17 $\frac{1}{2}$	
Above 70	7	4 9	8	4 4 $\frac{1}{2}$	4 $\frac{1}{2}$	

The preceding measurements were made with a balance by no means delicate, and therefore more advantageous to the male cerebellum as the larger, than to the female, but with a balance turning readily with a less weight than

ten grains. From those measurements it appears that the female cerebellum varies no more than half an ounce from infancy to age; that it is heaviest from 30 to 50; that it averages between 15 and 30, and between 50 and 70, about

the same weight, but weighs rather more in the advanced interval of age. Also, that in the male it varies, and much more than in the female, viz. nearly $1\frac{1}{2}$ ounces in the course of life, being heaviest between 50 and 70, in which interval of age it would appear to exceed the average for the quincennial, 15—30, by about half an ounce; that, under puberty, it outweighs the average of the years above 70; and that its average weight in the male (as in the female) increases steadily from youth to age, and only declines after 70. Now these facts, which are not improbably too few for scientifically accurate results, are notwithstanding, so far as they go, of some physiological interest, and of considerable weight, in my judgment, in their bearing on the Gallian views. From those facts, the medical statist will perceive that the supposed organs of the sexual instinct would appear to become, in both sexes, more developed as life culminates and declines, and the generative desires and powers ripen and decay—viz. from 15 to 70; and that they are most developed when sexual life is comparatively torpid, or quite extinct—viz. 50 to 70; and the weight of the inference is rather increased by the fact that half the males between 50 and 70 were 60 years of age and upwards, whereas of the females of the corresponding ages, 40 only were above, and the remainder (viz. 60, or three-fifths) under 60 years; also, that of the males between 30 and 50 years, more than half were 40 years and upwards, while, of the corresponding female cases, 75 exactly, or three-fourths, were over 40 years of age.

Since the preceding facts were tabulated for the Phrenological Society, I have collected about two dozen others of the same kind (including two or three negro cases), which, so far as I have examined, lead to pretty similar results; and I am still engaged in the collection of facts relating to the volume, weight, and density of the viscera in various circumstances, of which I mean to publish the results at no distant period. But in the meantime I conceive myself entitled *provisionally* to conclude that the cerebellum has other uses than those assigned to it by Gall; functions connecting it

rather with the well-being of the individual than the continuation of the species, and that the sexual instinct is, if attached to it in any especial manner, in all probability one of its subordinate uses, and by no means, as he seems to have conceived, its principal, if not sole, function.

Before concluding, I may mention that I have omitted all consideration of differences of volume, from finding the volume and weight so nearly parallel, that the former might, for every purpose of the paper, be without inconvenience omitted; and the same remark will probably apply to measures of density, respecting which, however, I have not yet facts sufficient for tabular exposition.

To conclude:—The Fellows of the Phrenological Society, speaking through their organ, the Secretary of the Society, seem (to judge by the official abstract and criticism contained in the *Lancet*) well satisfied with the results deducible from the facts I have collected. For my own part, having no system to defend, it was perfectly indifferent to me what conclusions I should arrive at; and I, of course, am contented with the results, however interpreted and estimated. My appearance before the Society was in some measure an accident, and wholly an after-thought. If that accident have in any degree contributed to fortify their science with new facts and arguments, I shall be amongst the last to regret it; and if, on the contrary, my observations shall in any way be found to weaken the evidences of phrenology, I shall, I conceive, have rendered important service to the Gallists, by drawing their attention to an assailable point in their defences. Thus, whatever be the result, I am not without hope, that, with that compassion which it is natural that the Secretary of the Phrenological Society should feel for my ignorance of the science, and of the writings of Gall, my learned friend will mingle a *tant soit peu* of grateful feeling for my happy temerity in venturing before the Society with a statement of my facts and inferences respecting the development and uses of the cerebellum.

Sec. R.M.C.S. L. &c. &c.

Wimpole-street, Feb. 1838.

FRACTURE OF THE FEMUR,
WITH SEPARATION OF THE EPIPHYSES.

To the Editor of the Medical Gazette.

SIR,

Nov. 27th, 1837. — Stillwell, aged 12 years, a youth of delicate appearance and fair complexion. In consequence of the wheel of an unloaded timber carriage passing over the right thigh, the bone was separated at each epiphysis, and fractured obliquely through its middle. The limb presented an unusual extent of deformity, the knee lying on its fibular side. That the bone was broken was evident on the most superficial view; but in what manner, and where fractured, was not so easily determined. On making gentle extension, the limb appeared straight, and the fracture adjusted; but on placing it over a pillow, the knee fell again to the outer side, as if it moved on a pivot. I then passed my finger slowly and carefully from the condyles upwards along the bone. About an inch above the patella I detected a transverse separation, attended with a soft inaudible crepitus. Continuing the examination, I found the fracture in the middle of the os femoris to be oblique. Still continuing the examination, I found another separation of the bone in a transverse direction, immediately under the trochanters, which conveyed the same sensation as the one above the condyles. Now the epiphyses are generally ossified at seven or eight years of age; but being for the most part moistened by the synovial fluid, their external surface is still somewhat cartilaginous, and they are not yet united to their bones. It is at eighteen or twenty years of age that the epiphyses are entirely ossified.

The limb was placed on a pillow upon a double-inclined plane, and kept steady by means of three splints (as described in the twelfth volume of the *MEDICAL GAZETTE*, page 607), loosely connected with broad tape, which was tightened at the end of the seventh day. On the fourteenth day I found the union of the epiphyses so firm that, on removing the lateral support, the limb maintained its position. On the twenty first day I was satisfied that union of the fracture had taken place, but not such

as would have justified me in allowing the thigh to be unsupported. At the end of the fifth week I permitted the boy to use the limb gradually; at the same time cautioned the parents of the great risk of the parts becoming again separated from another accident.

As it is in the dissecting-room only where we can prove our assertions, it is with some diffidence I have published the above case, knowing how easily statements may be made unaided by proof; and yet, with all the sincere desire to relate facts, I have only described that which was evident to my senses. I am not aware that the separation of the epiphyses from an act of violence has ever been described in any English work on surgery. I feel fully convinced I have in children overlooked such a fracture or separation; its nature at once shows how easy it is of replacement, and how much sooner a firm union takes place than when the bone is fractured. As regards the process of ossific union, I firmly believe in the following statement of M. Dupuytren: "That when the two ends of the broken long bone are brought together and maintained in accurate apposition, they become, in the first instance, united by a swelling and subsequent ossification of the soft parts immediately surrounding the ends of the broken bone. This forms a kind of case for the fracture, by which the broken ends are held together for a time; then the broken ends so held together unite, and become consolidated." Thus he distinguishes between the first or provisional union produced by the swelling and subsequent ossification of the surrounding soft parts, and the ultimate or definite union by the agglutination of the two broken ends. The former he calls the "cal provisional," the latter the "cal défini." "The first period from the occurrence of the fracture to the end of about the eighth day, the periosteum, the cellular substance, the muscles, and other soft parts immediately surrounding the broken bone, become swelled and form a considerable tumor, which can be felt externally. The thickest part is opposed to the situation of the fracture, and it is gradually lost on the natural surface of the bone in both directions from the fracture. In the commencement the tumor is somewhat red, that is, there is some determination of blood to it; towards the end of the eighth or tenth day this redness

disappears, and the swelling, when examined internally, has a white appearance. In the early part of the time there is, in fact, a mixture of coagulated and fluid blood; blood is effused from the vessels which are in the situation of the fracture, and it subsequently coagulates. At this period there is either a kind of viscid fluid found between the ends of the bone, or there is something like a reddish granular substance between them, a sort of spongy substance, nothing osseous. From the tenth to the twentieth or twenty-fifth day, the swelling becomes less in size; it is considerably firmer in its structure. It begins to assume a fibrous or cartilaginous, or something of an osseous structure, and during the same time the medullary cavity goes through the same process; it likewise begins to assume an osseous or cartilaginous structure. During this period, the second period, the parts admit of motion, that is, the broken ends can be moved on each other, but no *crepitus* (*i.e.* from the 10th to the 20th or 25th day.) The third period, extending from the 20th or 25th to the 40th, 50th, or 60th day, and in that third period the external swelling becomes ossified. The internal swelling of the medullary matter becomes ossified in like manner; and, in fact, the external and internal ossification becomes firm enough to allow the patient to employ the broken bone, yet the actual extremities of the fracture are not united; they still remain connected with the red spongy substance." Although the fracture is at this time sufficiently consolidated to enable the patient to use the limb, yet it is weak enough, from an act of violence, to become separated again. "The fourth period extends from the fortieth, fiftieth, or sixtieth day, to the fifth or sixth month; and in that time the external swelling becomes completely and firmly ossified, and when you then examine it externally it seems as if the periosteum were continued over the swelling to the sound parts of the bone. It has assumed a strong ossific character; the medullary membrane is ossified also, and the ends of the bone which have not been closely united are found to be connected by bone; so that you only see the situation in which they have been previously separated, as a faint line, when the fracture is sawn through. In the fifth

period, which extends from the fifth or sixth month to the twelfth month, the external provisional callus is entirely absorbed, and the union of the bone becomes so firm that the bone will break more easily in any other part than at the seat of fracture. The provisional callus having served its purpose of keeping the broken ends of the bone together for a given period, is entirely removed; and that portion of callus produced by the medullary membrane is equally completely removed." This, then, is the course taken by nature in repairing the fractures of long bones, when the two ends are kept in proper apposition. This surely must be an answer to the *no-splint* treatment, though, generally speaking, it is better to let an error die away, which it invariably will do when tried by experience. Yet, on a review of the "days gone by," we cannot but be struck with surprise with the numerous theories and modes of practice recommended, adopted, and condemned; then lying dormant for a century or more, and again revived with all the ardour and impetuosity of an original idea;—witness the treatment of curvature of the spine. My case in a measure affords an example why some fractures are united in a much shorter period of time than has been taught by surgeons of the present day; it will also assist in explaining why the "no-splint" treatment has enlisted some supporters, their cases having occurred in children. Those who have advanced the doctrine of treating fractures without splints only reason from a negative premise, from which nothing can be inferred. They have opposed the universal with the particular. Much of the confusion, fallacy, and sophistry of reasoning, arises from these points not being sufficiently attended to, and distinctly and rigidly investigated. In reflecting on the mechanical part of the treatment of fractures it must be borne in mind that bones possess the property of solidity and a non-yielding, for the purpose of giving origin and insertion to the muscular system, and forming levers, which are moved by the muscles in various directions. Now the muscular system is in a state of constant action, and dependent on the nerves of volition and reflexion. The movement of the fractured portions must, if displaced, lacerate, irritate, and disturb the healthy process of ossific union; also undue

compression on a tumefied part will produce inflammation and muscular irritation. My patient suffered from an oblique fracture—a kind of fracture the most frequent. In the first volume of the *Edinburgh Medical Essays*, published in 1747, Dr. Alexander Monro has a paper wherein he has given, from the pen of Dr. Porterfield, some abstract mathematical calculations why long bones are generally fractured in an oblique direction: they are worth perusal. Dr. Porterfield's demonstration is as follows:—"The absolute force whereby bones resist being broken transversely is the power of cohesion uniformly diffused over the whole cohering surface; and this power of cohesion is compounded of all the powers exerted in every point of that surface. But these powers resist in parallel directions (being all perpendicular to the transverse section of the bone) with velocities proportional to their distance from their centres of revolution; and therefore the strength of the bone, or total resistance of all these powers, shall be as their sum multiplied into the velocity of their common centre of gravity—that is, as the area of the transverse section of the bone multiplied into the distance of its centre of gravity from the fulcrum or centre of revolution."

Your obedient servant,

JOHN GRANTHAM.

Crayford, Kent, Jan. 27th, 1838.

P.S. Feb. 12.—On Saturday I received the *Brit. and Foreign Medical Review*, for January 1838, wherein is an extract of a paper by M. Roux de Brignolle, from the 55th No. of the *Medical Press* of July 12, 1837, on the Separation of the Epiphyses. He records cases as having occurred in subjects up to the eighteenth year; therefore I am not right in my remark, as to my case being the only one recorded in an English work which I sent you. In M. Roux's paper, he vindicates his claim to originality against M. Guérin.

CASES OF HYDATIDS.

To the Editor of the Medical Gazette.

SIR,

If the following cases of hydatids possess sufficient interest to merit a place

533.—XXI.

in your respectable journal, I shall feel obliged by your inserting them.

I am, sir,

Your obedient servant,

H. BARRETT.

Feb. 7, 1838.

Thomas Jordan, a labourer, aged 32, after suffering with dyspeptic symptoms for two or three years, was seized about a year and a half ago with acute lancinating pain in the left side of the chest, inability to lie on that side, fever, and other symptoms of pleuritis. There were dulness on percussion, and ægophony. He was bled, and took calomel, opium, and tartarized antimony, and in six days was much better. He was then attacked with violent vomiting and purging, acute pain in the epigastrium, dry brown tongue, weak rapid pulse, and great prostration of strength. On examination, I observed an elastic tumor extending from the epigastrium to the umbilicus, and occupying the anterior half of both hypochondria. This was painful on pressure, and dull on percussion.

In the fluid matters which had been discharged by vomiting and by stool, there was a quantity of hydatids, all burst, and resembling the skins of green gooseberries, for which, indeed, I at first mistook them. Some of these, when entire, must have been as large as hens' eggs.

A large blister was applied to the epigastrium; effervescing saline medicines, and chalk mixture with opium, were given, and in a few days the more urgent symptoms abated. The purging, however, continued four or five weeks longer, but was ultimately checked by euphr. sulph. gr. ss., et opii, gr. ss., taken three times a day, the hydatids having ceased to come away three weeks before. The vomiting has continued more or less ever since.

The tumor was now somewhat contracted in its lateral dimensions, and softer, still emitting a dead sound on percussion. The most prominent and painful part of it was situated midway between the pit of the stomach and umbilicus, and a little to the left of the median line. Pulse 100; dyspnoea, cold perspirations, and acceleration of the pulse on slight exertion; pain in the tumor on pressure, and during deep inspiration; tongue quite clean; appetite tolerably good; but eating, and

even pressure on the tumor, generally caused vomiting.

Considering that a state of chronic inflammation existed in the cyst containing the hydatids, I now endeavoured to remove this by means of counter-irritants. Several blisters were successively applied, and small doses of calomel were given, so as to affect the gums, with considerable benefit. A plaster containing tartarized antimony was then applied, which caused sloughing and two deep ulcers, each as large as a half-crown. These continued discharging for several weeks, with relief to the pain and difficulty of breathing, and with a manifest diminution of the tumor. Ung. iodini and Lugol's solution were now tried; but as the man was getting worse they were quickly laid aside, and a seton was inserted over the most painful part of the tumor, and retained more than six months. During this time he gained flesh and strength. The vomiting has frequently occurred, but has always been relieved by hydrocyanic acid or creosote. He resumed his employment last Michaelmas, but some time after complained of pain and "a knob," in the middle of the left clavicle; and a few days after the bone broke in this place as he was turning in bed. Contrary to my expectations firm union took place at the usual time.

The tumor has not much diminished latterly, but is not so distinct in its outline as it was. The digestive functions are naturally performed, with the exception of slight sickness occasionally felt after eating.

It is probable that the cyst is connected with the liver, though there has been no particular disturbance of the functions of this organ. It must also be in contact with the stomach and some part of the intestines, and must have discharged some of its contents through openings formed by ulceration, into these viscera. I am inclined also to believe that the pleuritis arose from the irritation caused by the hydatids extending to the pleura. The fracture of the clavicle from so slight a force might lead us to suspect malignity, but the man's appearance does not warrant such a supposition.

Thomas Judge, a labourer, aged 44, previously healthy, but whose brother has scrofulous disease of the humerus

and tibia, was attacked, about five years ago, with inflammation of the lungs terminating in abscess. Since then he has been constantly suffering from dyspnoea, cough, and profuse expectoration, and has remained weak and pallid.

The expectoration appears, from his description, to have been muco-purulent, occasionally mixed with blood, and sometimes containing "finger-like substances, consisting of a skin filled with thick matter." He has, however, continued his work with very little intermission.

On the 30th of last October he was seized with rigors, constriction, and obtuse pain in the chest extending to the right shoulder, cough, and expectoration of mucus tinged with blood, inability to lie on the right side, &c. There was dulness on percussion, and absence of respiratory murmur at the lower part of the right side of the chest, but above this there was distinct crepitous rattle; bowels costive; urine high coloured. Pulse 90, and weak; face pale and slightly yellow.

As pneumonia existed, I bled him twice till he became faint, the blood each time being covered with a thick, tenacious buff, and deeply cupped. He took calomel, opium, and tartarized antimony, and had a large blister applied to the chest.

Nov. 5th.—The month became sore; the crepitous rattle had nearly subsided, and was replaced by the mucous and sonorous; the latter continually varying in situation and intensity. Still no respiration in the lower part of the right lung. Headache, cough, appetite, &c. not much better.

7th.—He began to expectorate hydatids in considerable quantities, some as large as walnuts, and others as small as a pin's head. The sputa consisted of tough mucus, lying at the bottom of a watery fluid in which the hydatids were swimming. Headache and dyspnoea rather better; cough and appetite still very bad, with a sensation of fulness at the stomach after taking food; pulse 84.

Omit the Cal. and Opium. T. Hyoscyami ʒij.; Tinct. Camph. co. ʒiv.; Vin. Ipecac. ʒij.; Aq. Pur. ʒvij. M. Cap. Coch. iij. t. d.; P. Doveri, gr. v., o. n.

The hydatids continued to be discharged, and the symptoms to improve,

till the 12th, when they ceased; the headache, cough, pain in the chest, &c. became aggravated, and there were now profuse night-sweats. Pain in the right hypochondria on pressure.

Mist. rep.; Morph. mur. gr. ss. o. n.

On the 16th the hydatids reappeared in the sputa, and the night-sweats abated; other symptoms better. Pulse 80; soft.

R. Tine. Hyosey. 5ij.; Tinet. Camph. co. 5ij.; Inf. Cascariæ ʒviiss. M. Cap. Coeh. iij. t. d.; Pil. Mur. Morph. o. n.

22d.—No hydatids discharged, consequently the cough, dyspnoea, headache, night-sweats, and appetite, much worse; but on the 24th these symptoms were alleviated by their reappearance. Pulse 84.

R. Inf. Gent. co. e. Pot. Carb. &c.; Morph. Mur. gr. ʒ. o. n. Emp. Picis. co. e. Ant. Tart. pectori.

The hydatids continued to be discharged, and the health to improve, till December 1st, when they ceased, and the usual effects followed. The night sweats were so profuse, that a vapour hung round the bed.

5th. Expecterated hydatids, and was much better.

R. Quinin. Sulph. gr. ss.; Acid. Sulph. dil. ℥xxv.; T. Hyoseyam. ℥xx.; Aq. Pur. ʒiiss. M. t. d. sumend.

The opiate at bed-time was omitted, as it seemed to increase the perspirations.

I did not visit him till the 11th, when I found that on the 6th the cough and dyspnoea had come on violently, with spitting of blood and hydatids, and that he had not perspired since. Appetite much better; no pain; pulse 80.

Quinin. &c. rep.

There was now dulness in percussion at the lower part of the right side of the chest, in which situation no respiratory sound could be heard, except when the chest was fully expanded, when there was a harsh, short, sonorous rattle at the bottom of the chest. The cough came on at times with great violence, and before these paroxysms occurred, loud, mucous, and sonorous rattles could be heard without applying the ear to the chest. The man continued to improve till the 15th, when the hydatids ceased, and the cough, head-ache, night sweats, &c., returned.

17th.—He expectorated in 24 hours as much as a pint of mucous watery fluid, and a number of small hydatids, and one as large as a nutmeg, which was not burst as the larger ones had hitherto been. Cough still very troublesome, but the other symptoms much better; no sweats; appetite good; pulse 72.

Quinin. gr. j. &c. rep.

26th.—Much better; expectorates nearly a pint daily, containing hydatids; sweats a little every night, but feels stronger; pulse 70.

Resumed his work on the 28th. Continued to spit hydatids, and to improve in strength and flesh. The perspirations and cough were still troublesome at night, and his breath was short.

The last time I saw him was on the 20th of January: he was still discharging hydatids, but had very much improved in his general health.

In this case, as in all others of the kind, the liver appears to be the birth-place of the hydatids. The opening which was first formed into the lungs was too small to allow of their free expulsion; but as it became larger, the checks to their discharge were not so frequent, or so long-continued. The large hydatids which were expelled at the commencement were all burst, but latterly several of considerable size have been discharged in an entire state; these are white, semi-transparent, and mostly round; some, however, are long, and have small round appendages, which communicate with the parent hydatid by a minute opening.

In regard to the treatment, after the inflammation had been subdued, I saw no indication but to support the strength. The opiate, which he took for some time, by checking the cough, favoured the accumulation of mucus, and prevented the expulsion of the hydatids, which was invariably followed by night-sweats, headache, &c., these symptoms subsiding as soon as a free expectoration had been re-established. To produce the latter effect I at one time gave him a scruple of ipecacuanha, but with so little benefit that I was not inclined to repeat it*.

* If the opening between the cyst and the lungs should remain sufficiently large to allow the free exit of the contents of the former, it is possible that a gradual contraction of its cavity may take place, and that the man may live some years with some degree of comfort. But it is more probable that he will ultimately die with the symptoms of hectic fever.

ON INHALATION IN TUBERCULAR
PHTHISIS PULMONALIS.*To the Editor of the Medical Gazette.*

SIR,

THE favour of your insertion of the following further observations, on the subject of inhalation in Tubercular Phthisis Pulmonalis, will oblige, sir,

Your obedient servant,
CHARLES SCUDAMORE.

Wimpole Street,
Feb. 10, 1838.

Three years have elapsed since my last communication in the *MEDICAL GAZETTE*, of the successful treatment of some cases of phthisis pulmonalis, in which the inhalation of iodine and conium formed a material remedy. I hope, therefore, that a concise summary account of my further experience in this lamentable disease, and in chronic bronchitis, may prove an acceptable offering to the profession. That it has been my fate to meet with a much larger portion of failure than success, in phthisis, cannot fairly be made the reproach of my plan of treatment; for it has happened to me, for the most part, that I have not been consulted till the advanced stage of the disease, when the lungs having become extensively disorganised by the spread of tubercles almost universal, by cavities the consequence of the softening process, and often with the complication of ulcers in the intestinal canal, my task could only be that of studying to alleviate symptoms, and to soothe, by tender care, the last weeks or days of life.

It not unfrequently happens with consumption to be overlooked in the early stage of the disease, when probably attentive appropriate measures might be attended with happy results. The danger is serious, however delayed the consummation of the event, when tubercles have begun to infest the lungs. But from the fear and anxiety of friends inducing a flattering rather than a true view of the case, with a reluctance to listen to any voice that gives a warning of danger; and from the tenderness probably more than the better judgment of the medical adviser, which makes him join in the delusion, it follows, unhappily, that the early indications of dangerous disease are not detected or sufficiently regarded, and the most valuable period for giving assistance is lost;

perhaps irrevocably. I have known very many instances exactly exemplifying this statement. The consoling opinion has been pronounced, "that at present the lungs appear to be safe," or that, notwithstanding the evident delicacy of constitution, and necessity for care, yet "that there is no reason to consider the lungs at all affected;" while at this very time tubercles do exist, and consequently danger is established.

It will be said, that in the commencement of tubercular phthisis, there is much obscurity in the symptoms, and that we cannot discover by auscultation whether or not tubercles exist, as they may be so minute and disseminated, or so very partially clustered, as not materially to interfere with the vesicular respiration. I freely admit the insufficiency of the stethoscope to detect the early state of the tubercular disease, on many occasions at least; but there are several circumstances largely instructive.

If the patient have lost strength and flesh, without apparent cause; have recently become short-breathed on slight exertion, especially on making the least ascent; have more or less of short dry cough, a quickness of pulse, night-restlessness, and perhaps some dulness on percussion, here and there, in the upper parts of the chest, we have surely great reason to fear that there are tubercles formed. If other members of the family have died from consumption, the suspicion is painfully increased.

This is the most important period for the adoption of a systematic plan of treatment, and the one at which I should have the most confidence in the efficacy of the inhalation of iodine and conium. But a suitable treatment embraces many other points of management.

I believe I may state with truth, that when the symptoms become so conspicuous as to receive medical notice, the most general principle of practice has been to seek, as the *summum bonum*, a retardation of the pulse, and that by means of sedative medicines, the use of digitalis especially, with a slender, light, and cooling diet. Sometimes this is restrained to farinaceous food, milk, vegetables, and fruits. I apprehend that only in the very acute cases of consumption, which occasionally happen to young persons, is such a mode of treatment at all proper. When it is not for-

bidden, as in such cases, by the high degree of hectic fever so prevailing as to be almost continued, it appears to me of great importance to sustain the powers of the constitution by a very generous and supporting diet, with some porter; and with or without the addition of diluted wine, instead of aqueous beverage. I also make choice of tonic alternative medicines rather than those of a debilitating nature; soothe the nervous system at night by anodynes or sedatives, and employ such mode of external counter-irritation as may be best suited to the individual case, for this must be varied. Some patients are so much lowered and distressed by blisters, that they become inadmissible. I find the oil of croton liniment often to be very useful, and much less inconvenient in its effects than the tartar emetic ointment. I attach importance to the daily ablution of the chest with a mixture of purified acetic acid, Eau de Cologne and water, substituting for water an infusion of tannin, when perspirations are excessive. All the general means of Hygieia are of course to be pursued. Lastly, and what, in my mind, is a most important link in the chain, I make use of the inhalation of iodine with conium, according to the formula stated in the second edition of my work*, and in the MEDICAL GAZETTE, vol. viii. p. 157. And here I will take occasion to make some further remarks on the use of this remedy.

It is of the utmost importance that all the medicines used for inhalation should be quite pure, and that the tinctures should be saturated with their ingredients. If the iodine be in the dry state it requires an equal portion of the iodide of potassium, that it may remain in permanent solution in the mixture; for "three" grains of this salt, expressed in my formula, read "five;" and according to the strength of the solution, so the proportions used are to be smaller. It is better always to add the conium at the time of using the inhaling. At the temperature of 90° the volatile properties of the iodine are given off very sensibly; but the conium requires more heat, and that of 120° is not too much for the iodine. This degree, therefore, I most recommend; or if the patient have not a thermometer, let the instruction be, to

put the water into the inhaler (first warming it a little to prepare it,) quite as hot as the finger can bear without pain. The inhaler should be kept immersed in rather hotter water during the process. A good glass inhaler also is a material consideration. If it be small, and the tubes too contracted in the bore, the difficulty of inhaling would be great to the invalid, whose respiration is easily embarrassed; whereas, with a fit apparatus*, the process is perfectly easy, and not fatiguing.

It would be inconsistent with my present purpose to enter at length into the *ratio medendi*; for which and other particulars I beg leave to refer the reader to my publication.

The Case V., detailed in my second edition, very clearly demonstrates the useful power of the inhaling treatment. This gentleman was labouring under the well-marked symptoms of pulmonary tubercles, much increased beyond the usual degree in which he had been for some time affected, and so as to excite immediate alarm for his safety. He recovered in so satisfactory a manner under my care, that he was enabled to pass the two following years at his seat in Scotland, and to enjoy the pleasures of his gun and hunting. He wrote me the most cheerful accounts, and described himself as perfectly well. I received a similar statement from his friends. He was of the most active disposition, too convivial, and passionately fond of field sports. At the end of the second year he became quite careless of his safety, often exposing himself to the most unfavourable weather, and frequently committing great excess at the table in wine and mixed spirits. Thus he renewed in the most active manner the disease which had been so satisfactorily controlled. I learnt that in a short time hæmoptysis occurred, attended with urgent cough; this was followed by a severe attack of influenza; and when, at a late period, I saw him in London, his situation was hopeless. A large excavation had formed in the upper part of the right lung, and a smaller one in the left. He was much emaciated, but he combated with his disease for a considerable time, till at last the strength of his constitution yielded.

I allude to this case for the purpose

* Cases illustrating and confirming the remedial power of the Inhalation of Iodine and Conium in Tubercular Phtthisis, and various disordered states of the lungs and air-passages.

* The best inhalers which I have seen are to be procured at Garden's, chemist, 372, Oxford-street; and Perkins's, chemist, 147, Oxford-street.

of shewing, as it appears to me, the beneficial influence of the inhalation, in the first instance, on the tubercular disease. Had the patient led a life of proper care, it is reasonable to suppose that the recovery which he had obtained might have been lasting.

I wish now to refer to some of my other published cases; and first to those which will be found in the number for February, of the fifteenth volume of the *GAZETTE*.

J. A., Case I. He had remained comfortably well from November 1834, till the period of influenza*, in the beginning of 1837. He was violently attacked with the worst symptoms of the epidemic, and fell a victim in a short time.

CASE II.—This gentleman continues to enjoy very excellent health, has married, and established himself in life.

The subject of Case III. has been free from all returns of disease.

CASE IV.—This gentleman has acquired so settled a state of health, that within the last few months he has married.

CASE V.—This young woman informs me, that since the period of my last report, she has very seldom had occasion to resort to the inhalation; but that when she has done so, she has never been disappointed in its good effects.

Of much the larger part of the cases related in my second edition, I could make an equally favourable report. I shall advert only to some of the most important examples.

CASE I. (2d series).—This lady has continued in the enjoyment of very comfortable health, possessing good strength and spirits up to the present time, with the exception of having suffered from influenza on each occasion of the epidemic occurring. It is most satisfactory to consider, that her remarkable recovery was so perfect as to admit of such a trial of its stability.

CASE VIII.—I have received the most agreeable accounts of the continued health of this gentleman.

CASE IX.—This young woman has continued to enjoy comfortable health.

I will now offer an outline of a small part of my more recent experience in consumptive cases:—

A lady, aged 22, mother of three children, consulted me in April 1835. She had been falling off in health for a year past. Her youngest child was fifteen months old, and she had nursed it for twelve, but with difficulty. She related that she had within the last few months lost flesh and strength very rapidly; that on six or seven occasions she had coughed up small quantities of pure blood, but latterly it had only appeared occasionally, streaking the expectoration.

At my visit I found her suffering from harassing cough, with the inspiration easily hurried by slight exertion, and a distressing sense of restraint over the chest. She had daily hectic fever, and severe night perspirations; the pulse upwards of 100; the animal heat 100°; the appetite was lost, and the spirits much depressed. The sputum was considerable in quantity, purulent in appearance, offensive in odour, and slightly streaked with blood. The signs by auscultation were, much mucous rale on each side, but on the right especially, and there mixed with the sibilant. In this part also the voice was very resonant, and on percussion the sound was dull. I considered that there were tubercles, but that no softening had taken place.

It had been thought proper to keep her on very low diet; and it had been candidly stated to her friends, that as further trials with medical treatment could not in all probability render any benefit, it would be most expedient to try change of air, and trust to that alone.

Without delay I prescribed the inhalation of iodine and conium; gave tonic and alterative medicines; used counter-irritation by means of oil of croton diluted with spir. ammon. comp. over the most affected parts of the chest; and elsewhere it was washed daily with a lotion of infusion of tannin, purified acetic acid, and eau de Cologne, slightly tepid.

She experienced very sensible relief from the inhalation, and in a short time was enabled to lie down in bed comfortably on either side, from which she had been long prevented, and the embarrassment of her breathing on exercise was most satisfactorily relieved;

* How severely did this epidemic test the vital power of all delicate constitutions, and more especially all those affected with pulmonary disease, or predisposed to phthisis pulmonalis.

she could take a considerable walk without inconvenience.

This lady quite recovered her health at the end of four months, and has since continued well, a period of almost three years.

A gentleman, aged 25, tall and slight, of consumptive family, and had recently lost a brother from consumption, when under the influence of mercury, exposed himself to wet and cold, and in consequence was attacked by acute rheumatism. Having, after a long period, regained his health, he joined in the sports of the field; and one day, when much heated and in a perspiration, forded a river, and kept on his wet clothes for some hours. Catarrhal fever and cough quickly ensued, and in a short time his state, as described to me, was that of a person labouring under the first symptoms of consumption. He took an early opportunity of visiting Torquay, and resided there some months, but made no progress towards health, although he had diligently followed the advice of his medical friends. One acquaintance had recommended him to consult me; but another, and he was medical, dissuaded him, assuring him that inhaling iodine would do him serious mischief. He passed through London on his way to the continent, Rome being his destination; and consulted a physician, who, with other means, prescribed the inhaling of creosote, which he tried steadily. It did not disagree, but proved of no benefit. He was exposed to many inconveniences in travelling, and at one place was detained in quarantine on account of cholera. His disease increased so much before and after his arrival at Rome, that his state became truly alarming; and his debility and emaciation had reached a fearful height. It occurred to him that, having possession of my book, he might adopt the treatment recommended in it, under the guidance of an English physician whom he selected*. He went afterwards to Naples, and followed up the treatment

there. The terms of approbation in which he expressed himself, when he described the extraordinary benefit which he derived from the inhaling of the iodine with conium, were enthusiastic; and he declared himself to have amended from the first moment. In the account which he gave me of his case at that time, when at Rome, he stated that he had daily two paroxysms of hectic fever, and suffered most severely from cough, attended with an offensive expectoration, which was frequently coloured; shortness of breath; loss of sleep at night; copious perspirations, and other bad symptoms. The hectic fever was immediately controlled by the inhalation, and the respiration remarkably relieved.

I found him still an invalid, but, according to his report, surprisingly increased in flesh and strength; and he was in good spirits. His weight, he said, was within seven pounds of what it had been formerly in his best health. By auscultation and percussion I discovered evident signs of obstruction at the upper part of the right lung, and slighter in the same situation of the left. There was no indication of cavity, but the mucous membrane of the bronchial tubes was not in a healthy state, and there was still cough. The pulse was moderate, and the animal heat 97°.

I recommended that the inhalation should be resumed; internally sarsaparilla, with small doses of the iodide of potassium; and externally, the daily use of ablution with the lotion of which I have before spoken, together with friction; that he should live well, regulating his diet, and lead a life of care.

The following statement of a young lady, who was evidently suffering from the early symptoms of tubercular irritation, and whose sister died from consumption, is, I think, sufficiently interesting to be related. I will give it in her own natural language:—

“At a period when I was suffering from one of my usual attacks of painful constriction of the chest, accompanied by general depression of spirits, and sometimes with shivering, followed by heat, shortness of breathing, and a troublesome cough, I was recommended by Sir C. Scudamore to make trial of his iodine and hemlock inhalation; and I cannot too strongly express my gratitude for the effects which it produced in relieving all my symptoms. After seve-

* This was Dr. Thompson, whom I have just now had the pleasure of seeing. He informs me that when he first saw this gentleman, he was evidently labouring under tubercular phthisis, and having a cavity in the upper part of the right lung. After some interval he consented to the use of inhalation, although with some reluctance. Recourse was soon had to the mixture of iodine with conium; and Dr. Thompson confesses himself quite satisfied with the benefit which the patient received from the inhaling.

ral times inhaling, the sense of soreness seemed healed, the pain removed, and I felt more expansion and strength of chest than I had experienced for a long period. To express more strongly my feeling from the inhaling, I should say, the effect was like the opening of valves that had long been closed."

Were space convenient, I should relate the cases of a gentleman, aged 54; of a young lady, aged 20; and of a medical practitioner, aged 30; in which the most unequivocal symptoms of tubercular disease were strongly developed; in which there was every threatening of danger; and in all of them I was happily quite successful.

I prefer, however, to substitute the case of Dr. Davidson, of Setham, near Forfar, subjoining the communication with which he has favoured me of other cases, and requesting that his letter may be copied *verbatim* :—

Case of Dr. Davidson.—About the 1st of September (1836), I was seized with catarrh, which continued with slight aggravation till the 1st of October, when I was affected with severe pain in the left mammary region, and all at once the sputa, which had usually been from one to two ounces in quantity in the twenty-four hours, assumed a puriform appearance. By general and topical bleeding the pain of my side was relieved, but soon returned in a slight degree, and was then removed by a blister; yet I felt uneasiness behind the sternum. I was confined to bed, and my strength was much reduced. My pulse, which in health is 60, was then between 80 and 90.

He proceeded to state he was apprehensive of phthisis, and wished my opinion as to the treatment of his case. In his second communication, in January 1837, he reported that he had inhaled the mixture of iodine with conium, and taken the medicines which I had prescribed, with much benefit; but that a severe attack of the epidemic influenza had reproduced his symptoms, and compelled him to suspend the treatment for a short time. In his third letter, Jan. 22, 1838, he relates that, after an interval of three weeks from the time of being attacked with the influenza, he had returned to my method of treatment, of which he thus speaks :—"I resumed the inhalation, and with the same happy effect as formerly, for in the course of about three weeks the puru-

lent expectoration gradually subsided, along with the cough and pains of the chest, and by the 1st of April I was so much improved in health and strength, that I was able again to fulfil my active professional duties. It is proper to mention that, while using the inhalation, I took at bed-time a small dose of the solution of acetate of morphia, and once or twice in the day a few drops of acid. hydrocyan. in an effervescing draught. Over the site of pain in the left mammary region, I kept up counter-irritation from time to time, by emplast. cantharid., or by ung. antimon. tartarizat. I regulated the bowels by a powder composed of pulv. rhei. carbon. sodæ, p. zingib. et sulph. ferri.

My much lamented friend, the late Dr. Mackintosh, of Edinburgh, as well as others, assured me that the left lobes of my lungs were rather emphysematous, which renders me somewhat more liable to catch cold; but, with that one exception, thanks to Divine Providence and your kind assistance, I am now in as good health as I have been for many years past. With two exceptions, I have not even had a catarrh during the present winter. These attacks were slight and of short duration, although I have been daily and nightly exposed, in the discharge of my professional duties. Having given you these particulars of my own case, I will now offer you the relation of a few other cases, in which I have given the inhalation of iodine and conium a fair trial.

January 7, 1837, I was requested to visit Mr. G—, aged 66, parish schoolmaster, of Kirkden. My assistant stated that he complained much of tightness across the chest, pain in the left mammary region, severe cough, with mucopurulent expectoration; bowels costive; tongue dirty towards the root; fauces red and tender; pulse 100, and the body weak and much emaciated. My assistant attended the patient, and treated his case with much skill, till the 3d of March, when I visited him myself, and found that from the usual remedies which had been tried he had derived no benefit whatever. Upon auscultating the chest, I found the vesicular murmur faint on the left side, and marked by bronchial respiration, or mucous râle. The mucopurulent expectoration had greatly increased since he came under our care, and his body was reduced to a perfect skeleton. I

recommended the inhalation of iodine and conium, and gave him your work to read. He commenced on the 6th, and inhaled the medicated vapour three times a day till the 1st of May, when he had recovered so much that I made him reduce it to twice; and by the 15th of the said month he gave it up, and resumed his teaching by the 25th, and has continued in the full enjoyment of good health ever since. It is proper to state, that with the exception of one small blister, and occasionally a gentle dose of some opening medicine, he used no medicine whatever after he commenced the inhalation.

Mrs. F—, a woman of a very delicate constitution, *æt.* 40, had been complaining from the 9th December 1836. As Dr. McDonald, my assistant, attended her during the early part of her illness, I am not able to give you the early history of her case. When I saw her, about the beginning of February, she was much emaciated, complained of severe pain in her right side, with tightness across her chest; incessant cough, with copious expectoration, amounting to two English pints every twenty-four hours. Copious night sweats, with well-marked hectic fever. Pulse 120. The matter expectorated was of a highly purulent nature, and her relations and others who saw her were of opinion that she could not survive many weeks. The stethoscope applied under the right clavicle detected well-marked pectoriloquism, and the respiration absent to a very considerable extent. The parts were very dull on percussion. I prescribed the inhalation of the iodine mixture, &c. renewed the blister, and ordered a wine-glassful of the *mistura ferri composita* of the London Dispensatory, to be taken three times a day. The change which was effected in this patient in the course of a fortnight, was quite remarkable. Want of room prevents me from giving you particulars, but I am proud to say that, in the course of one month, her cure was greatly advanced, and, on the 10th of April, she paid me a domiciliary visit, having walked a distance of three miles. I saw her lately, in perfect good health.

June 14th, Mrs. S—, a farmer's lady, about 47 years of age, who had been long subject to winter colds and weakness of the chest, requested me to visit her. I found her in bed. She complained of tightness across the chest, with shooting pains betwixt the

shoulders. Her cough was quite distressing, and she expectorated, with much difficulty, about *x.* of mucopurulent matter every twenty-four hours. Pulse 96. Auscultation detected bronchophony in the right axilla; respiratory murmur absent over a great portion of the right side, and very weak over the whole. She had night sweats, and had lost much flesh. I prescribed the inhaling mixture, and iron medicine, all of which she used with much diligence. Being at a distance, I saw her but seldom. On the 20th she expressed herself better, and her pulse down to 86. On the 25th she was visibly improved, and on the 6th July she was able to drive this length along with her husband. I did not see her again until last week, when I had occasion to visit one of her daughters; and I am happy to state that she continues well.

Mrs. Y—, the wife of a very respectable farmer, *æt.* 34, who had been subject to severe attacks of inflammation of the lungs and pleura, was delivered of a child on the 15th July last. Had a fair recovery, but a cough, which had annoyed her during pregnancy, now became much worse, and her sputa assumed a purulent appearance. Pulse 70, tongue clean, and bowels nearly regular. Complained of severe tightness across the chest. Auscultation discovered that the vesicular murmur was weak all over the chest, and nearly extinct in the scapular and interscapular regions on the left side. On the 5th of August I prescribed the inhaling mixture, which she continued to use, with many of the other auxiliary remedies used in such cases, for nearly two months, but, I am sorry to say, without deriving the least benefit from any one of them, when I considered her case quite hopeless, and for some time past I have adopted a palliative course of treatment only. She is still in life, but ere many weeks elapse she will have closed her earthly account. The now evident issue of her case has both surprised and disappointed me, as I, at the outset, had every reason to expect a favourable termination.

July 30th, Mrs. W—, *æt.* 27, of a dark complexion and narrow chest, the lady of a minister of the Church of Scotland, in the Highlands, came to her father's in this neighbourhood, and was placed under my care. She had been mostly confined, since January

1837, with a hard confined cough, which prevented her from obtaining any thing like regular rest in the night; shooting pains in, and tightness across, the chest, and great difficulty of breathing; and for the last four months she had purulent expectoration, to the extent of 5 oz. or 6 oz. every twenty-four hours, with occasional night sweats, and slight accessions of hectic fever at night. Pulse 120. She was very thin, and had much anxiety in the expression of her countenance. Respiratory murmur very faint, and nearly extinct in the subclavian region on the left side. Percussion natural. I ordered the medicated vapour of iodine and conium to be used three times a day; the body to be sponged with vinegar, &c. with the use of the flesh brush; a blister to the chest, and the *mistura ferri comp.* to be taken three times a day. In the course of a week her breathing was much relieved, expectoration much freer, the circulation somewhat mitigated, and she slept soundly at night.

She continued under my care till the 30th of August, during which period she had been regular in using the iodine mixture, in form of vapour, and also the *mist. ferri*; and at that time, so much had she improved, that had it not been that her sputa, though much diminished in quantity, still continued purulent. I should have pronounced her cure complete. When she went home, she took a supply of medicines with her; but her husband wrote me, some time afterwards, that she had given up the inhalation, as the use of it distressed her much, and she got considerably worse. Again he wrote about a month ago, for a fresh supply of the iodine mixture, and also for a few bottles of the *ferri* mixture; and I learned from her sister, a few days since, that she is again much better.

I have only left myself room to say, that from the very favourable issue of a great majority of these cases, my opinion of the influence of the inhalation of iodine and conium is highly favourable; and you are at full liberty to make any use of this letter that you think proper. With many thanks for your disinterested kindness to me, and with every good wish, I am, with the highest respect,

Yours ever,

A. DAVIDSON.

Setham, Jan. 22, 1838.*

I indulge the hope that my present communication, and these unreserved details, will procure a large share of increased attention to the subject of inhalation: from many medical friends I have received the most agreeable assurances of their approbation of it. Unfortunately the larger number of cases of this melancholy disease, tubercular phthisis pulmonalis, admit only of palliative relief; but even in those the inhalation is not only admissible, but very useful in alleviating the symptoms.

A medical gentleman, in the last stage of the disease, came to me, from a considerable distance, in the hope of procuring some relief to his sufferings, which were unusually great and complicated. He was fully aware that he had no probable chance of recovery, but much desired to try the inhalation of iodine and conium. He received such sensible relief from it, that he repeatedly declared he was fully repaid for all the exertions he had made in taking the journey, in the unexpected mitigation of the cough, expectoration, breathing, and general feelings of the chest.

I should too much lengthen this article were I to advance all the arguments which are at my command, derived from experience, in favour of the combined method of treatment which it is my wish to advocate. I say *combined*, for I should regret to be considered as placing my confidence in inhalation alone.

Every one must admit the necessity of seeking for new remedies in phthisis pulmonalis. Is it not true that when once a case is pronounced to be consumptive, the sentence of death is more than half uttered? Urged alike by science and humanity, let us increase our exertions to overcome any particular disease, in proportion to the difficulties by which we are assailed.

As one very leading principle of practice, I apprehend that we should study to overcome the tubercular diathesis*,

* Lately I had an opportunity of seeing the character of hereditary tubercular disease strongly exemplified, in an infant that died in a state of the most extreme emaciation, at the age of four months. The lungs, liver, and spleen, were universally and very closely studded with tubercles: some minute, some large, some hard, others partly or wholly softened. Nor were the intestines free. The mother had died a month before, from the worst complication of pulmonary and intestinal disease I have ever seen;—the lungs broken up into cavities, ulcers in the intestines, and tubercles in their coats.

and to counteract the fresh formation of tubercles; for it very commonly happens that the relapse of the patient is owing to this cause. This comprehensive view can only be acted upon by using all the means, general and specific, which we think may be best calculated to effect a change in the circulating mass of blood. In addition to the medical treatment, all the jvantia are to be sought for in the general regimen, and all the ludentia are to be avoided; and without which care, no great disease can be cured.

In the employment of the inhalation, perseverance is necessary, and, in some instances, for many months. The object sought to be obtained is not merely palliative benefit—not merely a temporary impression on the morbid function—but the superseding of the diseased action by a healthy one, and the effecting some organic change.

Many other medicines may be employed usefully in the way of inhalation for tubercular irritation, chronic bronchitis, spasmodic asthma, and certain conditions of tracheal disease. These, with the exception of creosote and purified acetic acid, I have noticed in my publication. For the tubercular disease of the lungs, it is in the use of the iodine and conium alone that I place my hopes as a curative agent; I will not say confidence, for that never can be entirely felt in any known treatment of this most fatal of all diseases.

I conclude with expressing my hope that my professional brethren will make fair trial of the plan which I have recommended; and I shall be obliged by receiving communications from them, whether in favour of or against it, for truth is my object. I trust that none will condemn the practice without experience, for this would be prejudice and injustice.

SPINAL IRRITATION.

To the Editor of the Medical Gazette.

SIR,

IF you should think the following case and observations worthy of insertion in your valuable journal, at your own convenience, by so doing you will oblige,

Yours respectfully, &c.

GEO. C. WATSON, M.D.

Surgeon, &c.

Edge Hill, Liverpool,
Jan. 29, 1835.

Some time ago, I read in your pages a critique upon a treatise published by a Dr. Griffith, I think, containing some observations on morbid irritation of the spinal cord, along with a series of cases. The tenor of his work, as far as I recollect, was to point out that in many cases, where the expression of pain, and other symptoms of morbid nervous affection, were confined to the part, or organ, supplied by nervous filaments from the spinal centre, the true seat of the disease would frequently be found to be in the *origin* of those nervous trunks in the medulla spinalis; and that from having observed this difference in locality between the disease and its expression by pain, &c. at some distance from the real irritation, he inferred that accuracy of observation, and careful interrogation, alone could point out the true situation where local remedies should be applied. At the time, I read your extracts from Dr. G.'s work with much interest, and felt convinced of the value of his observations and suggestions, and resolved to follow up his plan of interrogating the nervous system the earliest opportunities that might present themselves. It was not long before such did occur, and in several cases I reaped the benefit of Dr. G.'s remarks; through attention to them being enabled to direct my treatment to the true seat of the disease, which issued in more or less complete success, where the old routine plan effected nothing at all; but the following case, which I have to lay briefly before you, was the most unequivocal instance which has come under my notice of the *practical* utility of Dr. G.'s hints, and which, therefore, I hope, will not be occupying your columns uselessly.

W. H., æt. 45, phlegmatic temperament, came to me complaining of acute pain running down the outer side of the left fibula, and thence shooting down to the sole of the foot. The ankle-joint, and indeed the whole limb, appeared quite free from any tumefaction or other evidence of inflammation; nor in the line of the pain, which he traced with his finger, was any thing to be perceived save only increase of it on pressure. The pain did not appear to be at all of a rheumatic character. He did not ascribe the affection to any immediate exciting cause. The pain was

sufficient then to cause a limp in his walk. He did not complain of any other part, and his general health, though never what could be called "rude," yet did not seem particularly deranged at this time. Some months previously he had been under my care with an obstinate catarrh, which yielded through perseverance in the usual remedies.

I contented myself with ordering some purgative medicine, and a lotion containing liq. plumbi diacetis. After some days he returned to me, complaining still of the same constant pain. I ordered him to apply six leeches to the leg, and prescribed a mixture containing diaphoretic doses of the potassio tart. of antimony. The leeches afforded but little relief, and for a short time. No other inflammatory symptom having set in, which could contraindicate the trial of the opposite plan, I ventured to prescribe a tonic mixture, consisting of di-sulph. quinine, dilute sulph. acid, and inf. rosæ, thus exhibiting about five grains of the quinine daily, whilst he discontinued all other remedies except a purgative. After giving what I thought a fair trial to the quinine, I found that the pain still persisted, and that he especially had to complain of it when the leg was in a depending posture, so that he was generally obliged to pass the day with it supported on a chair, and was frequently obliged to desist from his occupation, at which he still continued to employ himself, as well as he could. At this time I told him to try light warm bread poultices for a few days over the painful part of the leg, and requested a friend of mine, a surgeon of much intelligence and many years' experience, to examine the leg with me; on doing which carefully, we discovered a small *cicatrix* which appeared to be the chief focus of the pain. His general health seemed to suffer more now, in the shape of a *malaise*, his tongue getting a whitish fur; his bowels had been kept open all along; he informed us that the leg felt a little colder than the other. All we could further detect was a slight puffiness of the part around the *cicatrix*, and we were induced to recommend the practising of a small incision for about an inch and a half long, which we thought might relieve him, either by discharging any little pus which might be formed, or by liberating the *cicatrix*;

at all events we determined (with the consent of the patient) in case the neuralgic character of the pain should be shown *negatively* by the absence of any consequences of active inflammation, to establish counter-irritation in the wound by the stimulating dressings. Accordingly the incision was made, and the alternative of counter-irritation had recourse to, exhibiting, at the same time, ses. carb. of iron and soda, along with small quantities of ginger: the acute form of pain around the *cicatrix* rather abated after this, but the limb grew in some degree numb, and the singular sensation of modified pain and numbness began to run upwards towards the sciatic nerve, and followed that large trunk to its emergence out of the sciatic notch. This new feature in the case most annoyingly added difficulty of sitting to that of walking. It was not until we could acquire a larger insight into the case that we could discover the true nature of the disease, and from the tracing out of such, direct our remedies to the right quarter. The remarks of Dr. G., which I had only just then become acquainted with, served to draw our attention and direct our interrogations to the spinal column, for the probable origin of the pain; we, therefore, carefully examined the spine, by exerting uniform and steady pressure from the dorsal region downwards, with a wet towel: no indications of tenderness were perceived till reaching the last lumbar vertebra, when we observed the patient to wince, and complain of decided tenderness at its junction with the sacrum. We were now, for the first time, made acquainted with the real locality of the irritation, and felt some surprise that the patient had never spontaneously referred us to this spot, by expression of pain or uneasiness there. Of course it now became a straight-forward case, and the setting up of an active counter-irritation over this region soon ended in procuring almost simultaneously the total relief of both the spinal irritation and the distant pain.

In concluding this case, I would venture, Mr. Editor, to remark, that it seems probable to me that at first the irritation might have been confined to the minute nervous filaments which supply the integuments around the *cicatrix*, and that it extended itself very early to

the cauda equina, thence to be reflected with additional intensity towards the leg; or it is possible that it was an instance of distant pain in a lower extremity, particularly felt in the most recent deposit of soft parts, not alone the only prominent symptom of irritation of the lumbar portion of the spinal column, but the first expression of sympathy with that affection. This view of the case will recal the mind of the reader to the well-known analogous fact of cicatrices being the first to become affected, getting tender, and taking on an inflammatory disorganization, when the constitution is suffering much, from whatever cause. The cicatrix was from a slight wound of many years' standing, and it never troubled him before. He has not had any return of the attack, which was more than a year since. Whichever view of the case be the true solution of it, I feel that thanks are due to the accurate remarks of Dr. Griffith for whatever benefit the patient has obtained, or instruction we have derived.

P.S.—I recollect some observations resembling those of Dr. G., in Sir Benjamin Brodie's valuable clinical lectures on Hysterical Affections of the Knee-joint, as reported in your Gazette.

ON RUPTURE OF THE HEART, AND ON HÆMORRHAGE INTO THE PERICARDIUM,

WITHOUT RUPTURE OF THE HEART OR
GREAT VESSELS:

With Cases.

By JOHN THURNAM.

Our knowledge of rupture of the heart is not so complete but that the publication of fresh cases, and especially of such as bear upon the previous symptoms, is still desirable. For the particulars of the first of the following cases I am chiefly indebted to my friend, Mr. Thomas Davies, of Chester.

CASE I.—*Spontaneous Rupture of the Right Auricle and Ventricle of the Heart, with extraordinary and general softening of that organ.*

Mr. —, aged 60, a surgeon, formerly in extensive practice in this me-

ropolis, but who had resided for many years in the country, was of active and temperate habits, and had enjoyed remarkably good health until within about four years of his death. At this period he had severe, and often-repeated, attacks of gall-stones, the passage of which was accompanied by hæmorrhage from the stomach; but, after having suffered in this way for some time, his health was gradually re-established. For three years, or longer, after this, with the exception of an occasionally disordered state of the bowels, and of rheumatic pains in the shoulder and hip joints, his health appeared very good. He had never been the subject of acute rheumatism.

During the month of May, 1837, he frequently complained of wandering pains in the chest, with oppression, and a sense of hurry and uneasiness when walking more quickly than usual, but these symptoms were not so urgent as to attract much of his own or of his friends' attention, nor to prevent his leaving home, on business, on the 29th of May. Having proceeded a considerable distance by coach, he walked ten miles further, partly in the rain, and clothed in a Mackintosh cloak, by which he was much overheated. On his arrival, he complained of a pain in the left shoulder and in the right side, which he attributed to an attack of gall-stones. After taking some slight refreshment, he retired to bed much fatigued. The next morning he rose early, expressed himself better, and, after having breakfasted, he walked about two and a half miles, to the house of a friend; but on the road he again suffered from such severe pain in the right side and left shoulder, as to have much difficulty in proceeding. His friend observed that he appeared dull, dispirited, and disposed to sleep, and requested him to recline on a sofa, and in this way he slept for about an hour. Upon awaking he felt refreshed, and walked out until three in the afternoon. At this time he dined, eating and drinking moderately; but, upon taking a cup of tea in the evening, he vomited his food along with much bile. He now complained of increased pain in the upper half of the left humerus, which extended backwards to the scapula; this pain, he said, was different to any which he had felt before. He took a dose of laudanum, and

retired early to bed; but when visited by his friend in the course of the night, he was found sleepless and uneasy; the pulse was full and rather slow; the countenance somewhat anxious; the surface of the body warm. He got up several times during the night; at five A.M. he vomited a little bile; at six A.M., upon being visited, he said that he had been altogether sleepless, but that he apprehended no immediate danger, and that he hoped he was merely suffering from a transient attack of gall-stones. He consented to try the effect of a warm bath, and while his friend had left the room, to see it prepared, he expired without a groan.

Dissection.—A medico-legal investigation being thought desirable, the thorax was opened at the place of death, and the pericardium, having been punctured, was found to be filled with blood. The body, in the meantime, having been removed home, the examination was resumed three days after death.

The body was found to be muscular, and furnished with a considerable quantity of fat; not the least decomposition having taken place. Upon removing the fluid blood with which the pericardium was filled, a clot, about the size of a filbert, which required a slight degree of force for its removal, was found attached to the surface of the heart, in the furrow between the right auricle and ventricle. A rupture, which had been closed by the coagulum, was now made visible, and was found to communicate with the cavities both of the auricle and ventricle. The whole of the muscular substance of the heart was so extraordinarily softened, as to give way, in every direction, to the least pressure of the finger; its texture was of a dark brown colour, and resembled the pulp of which common brown paper is made. The softening and separation of the muscular fibres had proceeded to such an extent, that the rupture might be said to have been simply one of the pericardium, for by this merely were the softened fibres held together. The heart was neither enlarged nor thickened, nor otherwise diseased, and the state of the valves and of the aorta was normal. No other disease was observed in the cavity of the thorax. Upon examining the liver, it was found that there was considerable disease of the biliary ducts and gall-blad-

der; the latter being remarkably contracted, and containing a few small biliary calculi.

This case would appear to have considerable analogy to four instances of rupture of the heart which have been reported by M. Bland,* and which were accompanied by a "gelatiniform degeneration." These cases all occurred in males, and in persons of the ages of 58, 66, 84, and 86, respectively; from the latter of which circumstances, coupled with the peculiar alteration of the muscular substance, the author concludes that they are examples of a peculiar form of rupture of the heart, to which he gives the name of "senile rupture." Two cases of rupture of the heart, in males, of the ages of 60 and 71 years respectively, are also recorded by M. Taxil St. Vincent†, and these appear, at all events one of them, to have been of the same nature as those of M. Bland. Should further inquiry confirm the view of this form of rupture being confined to the aged, and persons advanced in life, there can be little doubt that the case now narrated must be considered as of the same description.

In an important memoir on rupture of the heart, by M. Pigeaux‡, in which he gives the results of an analysis of fifty-four cases, I find that in thirteen the lesion was accompanied by general softening of the organ.

There can, I think, be little question that, in the case which I have related, the wandering pains in the chest, the oppression, uneasiness, and sense of hurry upon exertion, which were experienced for about a month before the fatal termination, formed a class of symptoms which are to be attributed to a gradually advancing softening of the heart. And I should presume that it will be equally admitted, that the fatigue and exertion which the patient underwent on the day of his journey, were the determining causes of the rupture, the occurrence of which was announced by the peculiar pain in the left shoulder, the mental dejection, and slightly anxious aspect, by the sleeplessness, vomiting, and slow pulse. Why the pain was also experienced in the right

* Journ. Gen. de Med. t. 72, p. 231.

† Journ. Gen. de Med. t. 73.

‡ Journ. Hebdom. t. 8, 1832, p. 407.

side I know not how we are to explain, unless we may be allowed to suppose that it depended upon some sympathetic disturbance of the liver, to which it was exposed from a previously diseased condition. The case, at all events, is valuable, from its throwing light upon the symptoms of softening of the heart, which it must be observed differ materially from those assigned to this lesion by Laennec and Dr. Hope; and were of a more local character, or more distinctly referrible to the central organ of the circulation.

There can be little or no question that the softening of the muscular tissue of the heart, which had in this case advanced to so great an extent, was altogether unconnected with any inflammatory affection: that it was, in fact, a primary lesion dependent upon some peculiar and inexplicable condition of the organism generally; upon a cachexy, as this would have been termed by the nosologists of a preceding generation.

CASE II.—Rupture of the right Auricle and left Ventricle of the Heart from external violence, without penetrating wound—Fracture of the Ribs and Sternum.

A stout man, porter to a cyder merchant, aged about 50, fell off his cart, the wheel of which passed obliquely over the left side of his chest. He was picked up in the street, and brought directly to the Westminster Hospital, Oct. 20th, 1837. When I saw him there was no pulse at the wrist nor at the heart, and the pupils were insensible; in fact, there was no sign of vitality, unless a strange semblance of life in his countenance could be so considered. The only external marks of injury that I detected were two or three abrasions of the skin on the left side of the front of the chest. I endeavoured to restore the action of the heart, by performing artificial respiration, but without effect. I observed at the time to one of the pupils that the heart was probably ruptured.

Dissection.—Upon examining the body I found that the sixth and seventh left ribs were fractured about 2½ inches from the cartilages, and that the neck of the eighth rib was broken very obliquely. The sternum was broken transversely in its lower third, but there was no displacement. There was serum in both

sides of the chest; and under the left pleura there was a considerable ecchymosis, and also in the muscular fibres of the diaphragm; but the lungs were not injured. The pericardium was not lacerated; it contained several ounces of coagulated blood and serum. There was a rupture of the right auricle, more than two inch & in length, just above the attachment of the tricuspid valve, extending from the appendage of the auricle almost to the inferior vena cava. There was a slight superficial rupture of the interventricular septum, at its highest part. There was likewise a rupture of the apex of the heart, which, externally, was about an inch in length, and extended into the substance of the septum, but which admitted only of the passage of a bougie into the left ventricle.

The spleen was extensively lacerated and bruised, and had given rise to a hemorrhage into the peritoneal cavity. The stomach and intestines were distended with half-digested food, which exhaled a strong odour of beer. With the exception of a mottled condition of the kidneys, there was no deviation from healthy structure detected in any of the viscera.

As there was no injury of the pericardium, and as no displaced splinters of bone were detected, the ruptures of the heart in this instance, which occurred in two of its thinnest points, were in all probability the effect of the inordinate contractions of this organ, excited by the compression of the thorax under the wheel.

The important bearing of a case of this description in a medico-legal point of view is obvious, and it may be observed that this point has been ably illustrated by Mr. Watson, of Edinburgh, in a recent work* of his, in which he adduces some analogous cases. Cases in which the rupture has originated in the same manner that it did in this, are, I should suppose, far from uncommon. Thus M. Bouillaud† reports four cases (137, 138, 139, and 140), in which a rupture of the heart was caused by severe violence applied to the præcordial region. In the first of these, the chest had been crushed by the wheel of a carriage, as in the case which I have

* Medico-legal Treatise on Homicide, 1838, see Brit. and For. Med. Review, vol. 5.

† Traité Clinique des Maladies de Cœur, t. ii. p. 504.

related, but neither in this nor in any of the other cases does it appear that the ribs or sternum were fractured. There is, however, a case reported by Mr. G. Bennett, in the *MEDICAL GAZETTE*,* about five years since, which is almost precisely parallel to the one now related. The rupture was seated in the left auricle and pulmonary vein, and occurred in consequence of a crash against the wall by the wheel of some vehicle, I think a cart. In this case the sternum and some of the ribs were fractured, but nevertheless the author, taking the same view as I have done, looked upon the rupture of the heart as, in one sense, spontaneous, and only as being excited, not determined by the external violence.

Injuries of a similar character, however, sometimes occasion a solution of continuity of the heart in a different way. The sternum, or ribs, or both, being fractured, a splinter of one of these is displaced, and leads to a true laceration of some part of the heart. A good example of this description is cited by Bonillaud† from M. Choisy. These two kinds of injury form connecting links between the altogether spontaneous rupture, such as occurred in the first case given in this paper, and penetrating wounds of the chest, involving the heart. There are, in fact, two forms of *rupture of the heart*; *first*, the purely spontaneous, or those the causes of which are seated in the organism itself; and, *secondly*, those the causes of which are external to the body, but not attended by a direct mechanical injury of the organ. On the other hand, there are also two forms of *wounds of the heart*; *first*, lacerated or contused wounds, occasioned by detached and depressed portions of the osseous system; and, *secondly*, penetrating wounds which are simple extensions of similar forms of injury of the thoracic parietes. This classification is a slight modification of that of M. Bouillaud.

Cases are on record, and Dr. Baillie‡ has particularly adverted to them, in which blood, to a large amount, has been found in the pericardium, but in which, after the most diligent search, no rupture, either in the heart itself or any of its vessels, could be detected. Cases

of this description have puzzled their observers, and have given rise to various surmises with the view of accounting for them. I am inclined to believe that they may be most, if not all of them, explained upon one of two suppositions.

It has been well shewn by Laennec, that the pleura, when under the influence of inflammation, is often the seat of other than the usual products of this morbid action, serum and lymph; in fact, that these may contain a considerable proportion of the blood-globules themselves, so that in many cases the pleuritic effusion in general appearance closely resembles the blood itself. As is well known, to cases of this description the distinguished pathologist alluded to gave the appropriate name of *hæmorrhagic pleuritis*. Cruveilhier and others have since shewn that we may also have cases of *hæmorrhagic pericarditis*, and there can be little doubt that the same form of inflammation occurs, more or less frequently, in all the serous membranes. It has been my lot, on two distinct occasions (one of which occurred some years ago, when I was studying in another institution) to be present at dissections in which hæmorrhagic pleurisy was overlooked, and its undoubted characters mistaken, in the one case, for the rupture of a blood-vessel, which was most diligently but unsuccessfully sought for, and in the other, for the effects of a scorbutic diathesis, which had permitted of an exosmose from the smaller vessels. On the ground, then, of analogy alone, I have but little doubt that many of the cases alluded to by Dr. Baillie were really instances of hæmorrhagic pericarditis.

In other cases I think it not improbable that the blood found in the pericardium, without apparent rupture of the heart, or of the pericardial portion of the great vessels, has originated in the rupture of one or more of the large veins or other vessels at the root of the neck, the extravasated blood of which having followed the course of the superior vena cava and arch of the aorta, has made its way into the pericardium, by simply raising and rupturing this membrane where it is reflected over the roots of the large vessels. I have, at the least, satisfied myself that this was the case in the instance which I will now relate, which at first sight, and indeed, until after a very scrupulous

* For 1832, vol. ix. p. 582.

† Op. cit. t. ii. p. 499.

‡ Morbid Anatomy, 2nd edit. p. 34.

examination, baffled us exceedingly in determining the source of the blood.

CASE III.—Blood in the Pericardium, without rupture of the Heart or pericardial portions of the vessels.—Fracture of the Cranium, Ribs, and Clavicles.

William Shingleton, aged 42, was brought to the Westminster Hospital, Dec. 2, 1837, with very extensive injuries of the bones of the head, ribs, and clavicles; he died almost immediately after being seen by Mr. Bury Dacent, the house-surgeon. It appeared that during the dense fog which prevailed at the time, he had been knocked down by a runaway horse and chaise, as he was entering St. James's Park, through Story's gate.

Inspection of the body.—Upon the calvarium being removed, the anterior and posterior portions of the base of the skull were found to be moveable upon each other, as if by an irregular kind of hinge-joint, from a fracture having traversed completely the middle cerebral fossæ. The left temporal bone was more injured than the right, the fracture on this side having implicated the internal organ of hearing, and petrous portion of the bone. Both the clavicles were fractured at about their sternal thirds, and two or three of the left upper ribs were also broken.

Upon opening the pericardium it was found to contain a considerable quantity of black fluid blood. Both the right and left cavities of the heart contained semi-fluid black grumous blood, but there was no rupture in any part of this organ, nor in the large vessels contained within the pericardium. In the upper portion of the mediastinum, and reaching to the root of the neck, there was found a considerable layer of coagulated black blood surrounding the bifurcation of the trachea, the œsophagus, superior vena cava, and ascending aorta; and upon tracing this ecchymosis carefully downwards, it was seen to terminate on the surface of the cava within the pericardium at its highest part, and at the same point there was found to be an irregular laceration of the fibres forming this membrane, through which the blood had evidently gained access into its cavity. Although I did not succeed in demonstrating it, yet I have little doubt that the extravasation had originated in the rupture of some of the large veins in

the front of the trachea above the sternum, and that this rupture had been occasioned by the displaced portions of the fractured clavicles.

Westminster Hospital,
Jan. 29, 1838.

CASE OF CÆSAREAN OPERATION.

To the Editor of the Medical Gazette.

SIR,

SHOULD the inclosed case appear to you of sufficient interest to merit a place in the columns of your journal, I will feel obliged by your giving it insertion.

I am, sir,

Your obedient servant,
J. WARD.

Sunderland, Dec.* 1837.

On the 18th of October, at half-past nine A.M., I was requested by Mr. F. D. Thompson to visit E. Hull, an unmarried female, aged 25, very much deformed in the spine and pelvis, with very short crooked thighs and legs. She had been in labour all the previous day, and attended during the night by Mr. F. D. Thompson. On examination per vaginam, duplicature of the funis was protruding through the os uteri to the extent of six inches. The occiput could be felt, but, from the great deformity, it was with some difficulty it could be reached by the finger; the promontory of the sacrum projected so far forward that there was only an inch between it and the pelvis; and the spine curved forward over the small aperture, so as to shut in the pelvis above.

At my suggestion a consultation was requested; and accordingly Mr. Gregory, Mr. Dixon, and Mr. Saville, saw the patient, when it was decided on performing the Cæsarean section, as the only possible way of delivering her. There was no pulsation to be felt in the funis; and likewise, from other circumstances, it was concluded the child was dead, which was proved to be the case.

At half-past 12 at noon the patient was laid upon a table; an incision was made in the direction and over the linea alba, commencing at the umbilicus, and

* The manuscript was accidentally mislaid.—
ED. GAZ.

continued to the extent of six inches; the parietes were carefully dissected until an opening was made through the peritoneum; two fingers were introduced as a guide, and the remainder of the opening down to the pubes accomplished. A second opening being made through the uterus, the placenta was brought to view, through which the hand was passed and the child brought away, followed by the membranes, the uterus contracting immediately on being relieved of its contents.

The parts were sponged from the little hæmorrhage which took place during the operation, and the extensive incision closed by the twisted suture. An anodyne was administered, and the patient, being placed in bed, remained in a tranquil state through the course of the afternoon and evening. Was visited at 6 P.M., when the pulse was 100. A saline mixture was then prescribed, and she was left in the care of an assistant through this and the subsequent nights during her illness.

Oct. 19th, 10 A.M.—Has had a tranquil night, with three hours' sleep; passed some coagula by the vagina. Pulse 120; countenance tranquil; skin moist; tongue clean; very slight thirst; complains of pain at the scrobiculus cordis; slight tenderness over the abdomen. Has passed no urine since the operation; the catheter was introduced, and ℥ij. of water drawn off; no evacuation from the bowels; lochial discharge continues. She remained during this day very tranquil till the evening.

6 P.M.—Pulse 130; tongue dry; countenance calm; bowels slightly evacuated by enema; passed urine freely; more coagula per vaginam; abdomen tympanitic, with tenderness. The bandages were removed, as causing uneasiness by their pressure.

Habeat Hydrargyri Chloridi, gr. x.

9 P.M.—Much in the same state; twelve leeches were applied to each side of the abdomen; enema repeated. Had two grains of opium, with three grains of calomel, which was repeated at one o'clock; a large poultice applied over the whole surface of the abdomen, and continued through the night.

20th, 10 A.M.—Has had five hours' sleep during the night; bowels relieved, and passed urine freely. Pulse 100; countenance tranquil; abdomen less tympanitic; tenderness much relieved; has thirst, with brown tongue. Bowels

continue open; skin moist; lochial discharge continues, and expresses herself considerably relieved.

6 P.M.—Pulse 100; perfectly tranquil; bowels acted freely; passed urine; lochial discharge continues; slight perspiration; gums a little affected; tympanitic feeling less; bears pressure better.

Pills of calomel and opium, and saline medicines continued.

21st, 10 A.M.—Has passed a comfortable night, with three hours' tranquil sleep, and expresses herself much refreshed. Bladder continues to perform its functions naturally; pulse 98; less tenderness of the abdomen; feels easy; no evacuation from the bowels.

To take a saline purgative.

6 P.M.—Pulse 126; skin moist; slight hiccup; no operation from the purgative.

Habeat Ol. Ricini, ℥j., and to have an enema. The pills of calomel and opium after the bowels have acted.

22d, 10 A.M.—The bowels have acted freely through the night, and has had some sleep. Pulse 120; irritable and restless; skin moist; tongue dry.

Febrifuge mixture ordered.

6 P.M.—Pulse 130; skin moist; tenderness of the abdomen; frequent eructations of flatus; bowels freely opened; tongue moist and furred; lochial discharge continues.

Repeat pills and mixture.

23d, 10 A.M.—Has had a restless night; pulse 140; eructations and hiccup.

Ordered a mixture containing sesquicarbonate of ammonia, with wine negus.

Mid-day.—Continues to get worse; stimulants freely administered, from which time she continued to sink, and died at half-past eleven at night.

Post-mortem examination on the 24th October.—The external wound was partly healed by the first intention; there were traces of considerable peritoneal inflammation. The uterus was of the usual size; the opening was closed, but there was no appearance of adhesion. From the presence of the friends, and the objections they made, we could not proceed further with the examination.

It must be remarked that, up to the morning of the 22d, it will appear by this report that the patient was doing

well; but on that day a drunken and uproarious quarrel took place between the brother of the deceased and the father of the child, in the adjoining room, from which time she appeared (from the agitation caused by the quarrel) to get into a state of great nervous irritability; and had it not been from the bad effects evidently produced by the above-mentioned circumstance, the patient in all probability would have done well.

I have omitted to mention that, after the operation, her diet was of a bland nature, consisting of sago and arrow-root with milk, and chicken-broth occasionally, all of which she partook of with a natural relish.

IRISH COLLEGE OF SURGEONS.

EDITORIAL NOTE.

[It will be observed that the subjoined letter, under almost identically the same signature, contradicts flatly and unequivocally almost every statement made in that of last week. Both have been authenticated to us by the names of the writers, and the author of that inserted this week (which we shall call No. 2) gives us permission to publish his name if we think proper. Under these circumstances we have withheld the second part of the communication of last week, and have determined to insert no more letters upon the subject to which they refer without the real signatures of the writers being attached to them, so that the responsibility as to the accuracy of the statements may rest exclusively with those who make them.—ED. GAZ.]

To the Editor of the Medical Gazette.

SIR,

I REGRET to perceive that you have been (no doubt unintentionally upon your part) led to insert, in your number of Saturday last, a letter, purporting to be from "A Member of the College of Surgeons in Ireland," in which the grossest and most calumnious untruths have been asserted with respect to the proceedings and views of that College. The letter itself being neither more nor less than a collection of direct falsehoods, I shall confine my reply to an enumeration and flat contradiction of a few of them, pledging myself to support my statements by reference to the minutes of the College and its committees.

Falsehood No. 1—States that the publication of an article headed "Irish College of Surgeons—Pharmacy Laws," and which appeared in your number of the 20th January, was not sanctioned by the College. This is absolutely untrue, the article in question having been agreed to and directed to be published by a large and open committee of the College, and the expense of its insertion in certain newspapers defrayed out of the common fund of the College.

Falsehood No. 2—States that "all the provisions which it is intended that the act of parliament shall contain, have not been made public." This is altogether false, as can be proved by the minutes of the committee, to which every member of the College has free access.

Falsehood No. 3—"The proposed change has not received due consideration or sufficient sanction from the College or the profession." In reply to this, I offer the following statements:—The proposed change has been under consideration since the commencement of the month of November last; the appointment of a committee to take measures for its accomplishment was, at that time, made in the regular way by motion in a full College, notice having been given at a previous meeting, and inserted in the printed summonses; a notice of the sittings of the committee was posted in the College-hall; a circular letter, explaining the objects in view, and asking for advice and private opinions respecting them, was addressed to every member and licentiate of the College throughout the United Kingdom—the postages of those letters were paid; statements of a similar nature were published in all the Dublin, and in many of the provincial papers; many hundred copies of those papers were purchased and forwarded by post to medical persons throughout Ireland, both in and out of the College; after all these measures for attaining publicity had been taken, and several weeks had elapsed, the College was called together by a printed summons expressly to receive the report of the committee. The report was unanimously agreed to at one of the largest meetings of the College known for years; and a second meeting was again called, by summons, at which a petition founded upon the report was also unanimously agreed to.

Equivocation No. 1.—"The College contains between 130 and 140 members,

and on no occasion has one-third of the number ever voted upon the question." The College does contain nearly the number of members stated, but of these there are altogether not more than 90 resident in Dublin, and of these again, more than one-third, in consequence of old age, indolence, &c., never attend the meetings, although they are upon every occasion invited to do so by printed summonses, stating the business to be transacted, and sent to the house of each member by the servants of the College.

Falsehood No. 4.—"The proportion of those (communications from members and licentiates resident in the country) favourable to the change, does not exceed a third of the entire." Ninety-seven or ninety-eight communications were received, of which two were adverse, one doubtful, and the remainder unreservedly favourable.

Falsehood No. 5.—"The licentiates of Dublin have actually protested against the measure." This is totally false! The licentiates, with very few exceptions, heartily concur in the proposed change. All of them advocate some change, but some of them think that before actually becoming *general practitioners* it would be advisable to ask the legislature to restrain the apothecaries to their counters and prohibit them from practising; the persons who adopt this opinion being nevertheless willing and anxious, in the event of such a plan being impracticable, to recur to the general practitioner system as an alternative.

Falsehood No. 6.—"They appear to me to be only a mask for another, as yet not avowed, design." I can only, on the part of the College, the committee, and myself, flatly deny this statement.

In addition, sir, I may be permitted to state that within the last three weeks a requisition was attempted to be got up for the purpose of calling the College together to reconsider its proceedings with regard to the matter in question, but although such a document only requires twelve names, these could not be procured, and the project fell to the ground. At the quarterly meeting, subsequently, held upon the first Monday of the present month, neither notice nor remark was offered upon the subject.

I trust that as you have been unwittingly led to circulate calumnious falsehoods respecting a public body, you

will permit as short a time as possible to elapse before giving equal publicity to this contradiction of them.

Your most obedient servant,
A MEMBER OF THE ROYAL COLLEGE OF
SURGEONS IN IRELAND.

Feb. 12, 1838.

MEDICAL GAZETTE.

Saturday, February 17, 1838.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tuæ: potestas modo veniendi in
publicum sit, decendi periculum non recuso."
CICERO.

THE UNIVERSITY OF LONDON.

TRULY, to borrow the language of brother Jonathan, the University of London "progresses, we guess." Ill-natured persons were disposed to marvel at its inactivity, and to insinuate that it had no character at all; that taunt, however, is no longer appropriate, for it has within the last few weeks established a reputation for discretion and consistency which cannot fail to endure—at least as long as the establishment itself. Seeing it was set forth in the charter that the University was instituted for the furtherance of "Religion," among other purposes, it was solemnly decreed, after much, and, as the result has shewn, very mature deliberation, that candidates for the honour of their degree should be examined on Church History, and on the New Testament in the original Greek. Nothing could possibly have been more judicious or discreet. The avowed purpose of the Institution was to make up for the exclusion practised at the old Universities, and to open a path to the honours of science alike to Jew and Gentile. Our readers, therefore, cannot fail at once to perceive the sound policy and discrimination which led to this sapient regulation, by which those of the Hebrew persuasion were to construe the Greek Testament.

But if there was wisdom in this decree—the first overt act of the University of London—how much more profound was the sagacity displayed in their second appearance before the public. This, which was made through the medium of a government paper, and doubtless on good authority, conveyed to the world the astounding fact that the decision allotted to had been reversed, and that no such test was to be required. Simple people might suppose that certain persons who were absent on the first voting had been present on the second, and thus led to a different result. But not so; for there is this unlucky addition to the announcement, namely, that on the second occasion just the reverse of what had before been passed by a majority was carried “almost unanimously.” There is something more in this than meets the eye—if philosophy could find it out. What could have wrought so sudden a change? whence came the new light which so quickly enabled the worthy Senators to see the error of their ways? Why simply this: a letter from Lord John Russell, to the purport that if *they* did not reverse the decree, *he* would; nothing more. Oh! there is nothing like an argument from the Home Office for settling a point of this kind—nothing like your modern improvements in political economy, for the promotion of liberty and independence. Formerly, the interference of a minister of the Crown with the regulations issued by a *Senatus Academicus* would have been thought arbitrary, and inimical to free agency; but now it is quite otherwise: the *Senatus* is free to discuss, the Secretary of State is free to decide, and so, most palpably, the amount of freedom is doubled. But perhaps we go too far; his Lordship does not decree, he does but suggest: speaking of the regulation passed by the

University, he just “hints a fault, and hesitates dislike”—but in the gentlest manner possible. He asks “whether it might not be possible to frame a rule which should leave it to the candidates for degrees to be examined in the Greek Testament and Church History *at their own express desire*?” which means, that if any candidate finds that he does not incur risk enough of being plucked on the ordinary examination, he may add to the danger by making its increased difficulty the subject of express solicitation. To be sure, this is a title different from making such examination a *sine qua non*, as had been previously decreed; but then, says his Lordship—and the argument was evidently not lost upon the Senate—it would be “most unfortunate” to make the University “an object of suspicion.” After which, he very pithily adds, “It would scarcely be less of a calamity were the authority of the Secretary of State to interpose a bar to regulations deemed essential by the senate!”—which we humbly submit, being interpreted, means, “Gentlemen Senators, you have made a most stupid and uncalled-for regulation, and if you do not vote black to be white (as some of your betters have offered to do for us in the House of Commons), and at your next meeting reverse all you did at the last, I—even I, by myself I—Lord John Russell, one of her Majesty’s Secretaries of State, will annihilate your decree with one stroke of my pen, and show you that the independence of your University consists in being always independence on the occupant of my present quarters in Downing-street.”

A hint so palpable was not to be misunderstood, and the senate accordingly voted as directed. Now we request it may be observed that we do not advocate the propriety of their first resolution; on the contrary, we think it was inex-

pedient, and at variance with the ostensible object for which the University was founded. To tell us, as some pretend to do, that reading the New Testament, in the original, was intended merely to test the candidate's knowledge of Greek, is absurd; for any one in the least acquainted with that language must be aware that it is quite unfitted for such a purpose. No; the simple truth is, that a majority of the senate thought it right to require some evidence as to the religious sentiments of candidates for their diploma; but their own opinions on the subject were not sufficiently decided to enable them to resist the *arguments* of Lord John Russell, backed by the "scarcely less of a calamity," which he so significantly hinted was to follow, in case they proved contumacious.

It really must be a very pleasant thing to belong to an University so constituted. Any one who is in a minority in the council chamber at Somerset House has but to make interest at the Home Office, and straightway the decision is open to be reversed. Another very pleasant part of the system is the mode to which it gives rise of filling up any vacancies which may occur. To suppose a case by way of illustration:—Mr. Warburton might be desirous of having a *protégé* of his own appointed: he is rather a troublesome customer in the "House," and the required nomination at once takes place. The astonished "senators" find they are thus provided with a colleague whose appointment cannot fail to be most gratifying, viewed, as it naturally comes to be, as indicative of the measure the noble secretary has taken of themselves--their rank, place, and position in their profession and in society.

But to carry the case a little further; still hypothetically, however, and by way of illustration. Suppose that a large proportion of the senate should think so

highly of themselves, or so lowly of their new associate, as to address a remonstrance to the Secretary for the Home Department, how gratifying, how satisfactory, how atoning it would be, to be told—"I really knew nothing about him; I made the appointment at the solicitation of his friend; but the matter shall be investigated." That is to say, the appointment is made first, and the inquiry about its propriety is to follow! But softly, gentlemen. Here is a royal charter, with the Queen's sign manual attached to it; and where and what, we beg to inquire, is the power, which can erase one letter which it contains? That the party nominated was the best fitted that could possibly have been found, we have not ventured to assume; we do but assert that if once appointed, nothing but his own resignation can displace him; and that, under such circumstances, to resign would be perfectly suicidal of his reputation. If any such case as we have supposed should actually occur, our readers will, we think, admit that, taken in conjunction with what we alluded to in the former part of the present article, it would fully warrant the high encomiums we have ventured to bestow on the foresight, wisdom, and consistency, which rule over the destinies of the University of London.

A RESURRECTIONIST PHYSICIAN.

A curious incident has lately taken place in France. A Dr. Belhas is asserted to succeed in the radical cure of hernia by obliterating the neck of the sac with some animal substance capable of being absorbed; he has cured several of the patients of Dr. Féron, a physician at Theuville-aux-Maillots, and returns to Normandy every year to renew his operations. Satisfactory as the operation had always been, the two friends still wished to know what was the exact physical change effected in the diseased part; but from their uniform success they had never enjoyed the opportunity. At last one presented itself. A man

named Cottard, who had been operated upon two years before by Dr. Belmas, died of an inflammation of the brain and stomach. Dr. Féron was desirous to have a post-mortem examination, and was well aware that it was requisite to obtain permission; but *where* was this to be got? To try to get it from the family was useless, so unpopular is dissection in that part of the country. He might have asked permission of the Mayor, a man of sense; but, unluckily, he was absent. It might have been granted by the Attorney-General; but the distance was great, the event of taking this step was uncertain, and time pressed; what was to be done?

What M. Féron *did* do is matter of history, and inscribed on the tablets of a court of record. At the favourite hour of unquiet spirits and eager dissectors, he betook himself to the church-yard, dug up Cottard's grave, cut out the region he wanted with his scalpel, and, having replaced matters as well as he could, reached home in safety.

The next day it was perceived that the ground had been stirred; the legal authorities visited the spot, the grave of Cottard was again opened, and the coffin exposed to public view. Dr. Féron being informed of what was going on, hastened to the spot, told what he had done, and begged them to put an end to the scandal by restoring the remains of Cottard to the earth. In spite, however, of the frankness of this declaration, and the purity of his intentions, legal proceedings went on, and he soon heard himself condemned by the Court at Ivetot to a week's imprisonment. Dr. Féron was surprised at the severity of the sentence, and appealed to the Royal Court at Rouen.

M. Grainville, his counsel, showed with the utmost clearness that a fine would be a sufficient expiation of the misdemeanor charged upon his client, and that it would be an unheard-of thing to imprison him for an action which should be looked upon only as the overflowing of his zeal for science. He seemed to carry the Court with him, when the advocate-general rose to support the judgment of the Court at Ivetot. Our reverence for the grave, he said, ought to predominate over the fanaticism of science; and he was foolish enough to add, that the structure of quadrupeds, and that of man, are sufficiently similar to enable us to dispense

with the dissection of human bodies. In fact, he asked, why should we be more indulgent in France towards those who perform clandestine post-mortem examinations, than they are in England to resurrection-men?

The judgment of the Court below was confirmed.

The French journal from which we borrow this account* is very angry with the advocate-general for saying that we may dissect quadrupeds instead of men; and this is really a *bêtise*, though the learned counsel would probably defend it by asserting that he knew whom he had to deal with, and that it was a good *argumentum ad curiam*. The Gazette des Hôpitaux is also much displeased with his comparing a zealous and enlightened physician to English resurrection-men, eager for gain alone. But when our contemporary talks of the affair as a *scandale amené par la seule ignorance*, we cannot quite agree with him, and must confess that science had a hand in the matter too. In other words, we feel ourselves unable to throw the whole blame on the lawyers, by considering M. Féron as purely passive; his excess of zeal at night, and excess of frankness in the morning, must surely pass for something. In the discussion of this delicate subject, the interests of common sense seem in danger of suffering from the violence of two opposite parties. The one would have us dissect animals instead of men; the other, equally unreasonable, would have us pursue dissection with such ardour as to forget the very purpose which makes anatomy and medicine valuable—namely, the diminution of human suffering; for we must take into account the pain endured by these old-fashioned villagers, on finding their sole practitioner converted into an unlicensed exhumator, just as we do their unmitigated sufferings from *gastrites* and *enterites* during the time that Dr. Féron is shut up. It appears that his seclusion for a week deprives several communes of their only practitioner for the same period. Hence we learn that France is not quite so overrun with medical men as this country; for in England it would be difficult to find a village which was not within a moderate distance of two or three practitioners.

* The Gazette des Hôpitaux of February 3d.

HUNTERIAN ORATION.

THE annual oration was delivered on Thursday by B. Travers, Esq. It consisted principally of a history of surgical science, pointing out especially the evident connexion in rapidity of progress which had existed between it and anatomy. Among several interesting facts, he mentioned the origin of the barber-surgeons, in the necessity under which the priests, who had previously been the only practitioners, were placed, of employing their servants as barbers, in consequence of a papal edict strictly ordering the observance of the tonsure. The servants, by their frequent intercourse with the priests, who then were the only possessors of any kind of knowledge, obtained some little learning, and as their masters were confined within the monastic walls, were employed by them to visit their patients at their houses, and to perform the minor operations which they were themselves forbidden to do. The pupils soon became themselves masters of their art, and went on to such an extent, that they obtained reputation in this and many continental kingdoms, and were here incorporated, and remained under legislative sanction till 1745.

The oration was delivered with a remarkable degree of clearness, and was well received by a numerous audience.

TRIBUTE TO MR. EARLE.

ON Saturday last a meeting was held at the Freemasons' Tavern, of the friends and pupils of the late Henry Earle, Esq., to consider the propriety of entering into a subscription for the purpose of recording his talents and many estimable qualities. Mr. Sergeant Atcherley took the chair, and, with Dr. Latham and Mr. Skey, addressed the meeting, which was fully attended. Before it broke up upwards of 120 guineas were subscribed by those present. We understand it is intended to place a bust of this lamented gentleman in some part of St. Bartholomew's Hospital, or the school attached to it.

THE BRIDGEWATER UNION.

WE beg to direct the attention of our readers to an important pamphlet entitled "Facts connected with the Medical Relief of the Poor in the Bridgewater Union," the second edition of which is now ready, and may be had as specified in the advertisement on our wrapper.

ON ANIMAL MAGNETISM.

No. I.

WE have given our readers an opportunity of acquainting themselves with the doctrines of animal magnetism, as set forth by M. Du Potet, the chief promulgator of that art in England, and with its practice, as exercised by M. Berna, its champion in Paris. In our number for Sept. 16th, 1837, we briefly stated our opinions on the subject; we shall now enter on the principal points of the evidence on which we had formed them. That we shall do this with impartiality we have given a sufficient guarantee, by having, in the interspace, afforded to the supporters of what we still believe to be erroneous doctrines, an opportunity of appearing before a large portion of that profession which is alone capable of judging correctly in this matter.

We will first consider the theories of animal magnetism that have been proposed by its chief supporters. We are aware that some of the modern practitioners allow that none of them is sufficient to explain the phenomena; but it is of importance that their absurdity should be seen, not merely because they exhibit the real character of their authors, but because the language of the theoretical explanations being adopted by all who have written upon the subject, gives an appearance of mystery and marvel to their facts, which mislead the unwary reader, if not the author himself. Stripped of such terms as *rapport*, *crisis*, *exterior* and *interior prevision*, *clairvoyance*, &c. many of their most rare histories will be recognized as facts of frequent occurrence; and it will be seen that the very existence of the art has mainly depended on the plumage which it has borrowed from the pompous phraseology of sciences.

Mesmer's perfected theory was as follows*:—There is a mutual influence between the heavenly bodies, the earth, and inanimate objects, by means of a subtle fluid universally existing, and filling all space, capable of receiving, propagating, and communicating, all the impressions of motion by mechanical laws at present unknown, and producing alternating effects, a flux and

* Mémoire sur la découverte du Magnétisme Animal, 1779.

reflux. The properties of matter, and of organized bodies, depend on this operation. This agent affects immediately the substance of the nerves into which it insinuates itself. The human body especially presents properties analogous to those of the magnet; it has opposite poles, which may be reversed, destroyed, or strengthened; it presents even the phenomena of inclination. The magnetic power operates at considerable distances, and without the help of any intermediate body. Glass reflects and increases it, like light; sound communicates, propagates, and increases it; it may be accumulated, concentrated, and transported. There are (though very rarely) animate bodies which have properties so opposed to it, that their mere presence destroys all the effects of the magnetism in other bodies. (We need not say, that this was the grand loophole-clause of the theory and unsuccessful practice of the art.) This opposite virtue, like the real and positive one, penetrates all bodies, may be reflected, accumulated, &c. The common magnet may be animally magnetized, or receive the opposite property, without exhibiting any change in its properties as a mineral magnet, attracting iron, &c.; and when it, or any similar agents, act in diseases, it is only by means of the animal magnetism communicated through them.

This theory (of the origin of which M. Du Potet says he is uncertain) was drawn from the doctrines of *spirits* and *emanations*, which were supported (as M. Thouret* satisfactorily shewed) under the name of magnetism, long before the birth of Mesmer, by Van Helmont, Paracelsus, Libavius, Santanelli, de Locques, Wirdig, Maxwell, Kircher, and many others. By all these, and especially by Maxwell†, the theories of the poles of the human body—of a flux and reflux of an universal fluid, forming a communication between the stars and organized bodies, and passing into the nerves—of the magnetic influence of music—of the *anima mundi*—had been treated of, and fully set forth. Indeed, Mesmer's Inaugural Thesis on the Influence of the Planets was a mere digest of these foolish notions, though it con-

tained all the chief points of the theory we have quoted.

But their theories were not the only things in which Mesmer agreed with the authors of emanations; their *facts* had a corresponding similarity. By magnetism, in its days of youthful vigour, if not in these degenerate times, persons separated by vast tracts of sea and land could, at fixed periods, hold sweet and secret converse; and a somnambule might, by a wish, have rid the world of evil and disease; while by the emanating spirit, and Sir Kenelm Digby's sympathetic powder rubbed on the bloody vesture, the wounds of men afar off were healed. Magnetism had its cures by passes, and the prescriptions of sleeping peasants; emanations had theirs by the royal touch for scrofula, by amulets and incantations, and the crossings of monks and other empirics.

And while magnetism was the *anima mundi*, and the cause of the important influence which the stars, at immeasurable distances, exercise upon us, it had also, long before Mesmer's time, been tangibly employed by vast numbers of physicians on the continent, as afterwards in this country by Perkins, as a cure for rheumatism, toothache, and various nervous affections. Mesmer's instructor in this part of his art was a Jesuit father, Hell, who had himself seemed to have been thus cured of rheumatism. The disciple at once seized his master's facts as examples of the action of the pervading fluid, and commenced the practice of mineral magnetism with zeal worthy of a better cause. It was but a step to consider that the fluid did not need a magnet to convey it from one human body to another; and he laid aside all apparatus, and using his fingers only as tractors, gave origin to animal magnetism. The inutility of magnets, which Mesmer only imagined, was proved by Dr. Haygarth, who soon after discovered that wooden tractors served the purpose equally well, and that the whole affair was a matter of chance, or the effect of faith or imagination in those operated on.

All this theory needs little refutation; the *facts* advanced in it require proofs rather than explanations. Let a man demonstrate the influence of the stars or planets on us, and then he may explain it; or let him prove that there are oppo-

* Recherches et doutes sur le Magnetisme Animal.

† De Medicinâ Magneticâ, 1679.

site magnetic poles in the human body, or that cures are actually performed by the magnet, without the possibility of any other cause being in action, and then he might theorize. But the truth is, that these things do not exist at all. The stars have no more power over us than we over them; nor the magnet on our nerves, or any part of us, than on the stars; while all Mesmer's facts admit of a ready explanation on other grounds. But what can we think of a theory, or its author, which so impudently provides for cases that would contradict it, by supposing two contrary fluids, each all-pervading, such that the presence of one (*which is itself inactive*) in one body, prevents the other from exercising its influence in others? What should we think of a man who said that his galvanic battery would not act, because there was some one in the room who did not believe there was such a thing as electricity? Yet M. Deleuze says that the presence of a person who does not believe in magnetism is sufficient to prevent the manifestation of extraordinary senses in somnambulism. In short, all that is intelligible in this theory is self-evident and utter nonsense; but we may draw from it valuable information. Mesmer is represented by his followers as a wondrous philosopher—a man who dared to break from the trammels of scholastic bigotry—who looked to nature alone for his guide; and they rank him (most impudently, if not ignorantly) with Galileo, Columbus, Harvey, and others, whose doctrines were at first rejected. They try to make of him a martyred sage. His theory shews him to have been an ill-judging plagiarist—an ignorant and credulous man, if he believed the things he affirmed—a designing impostor, if he disbelieved them—a visionary almost to insanity, or a mere juggler—"atrum horum mayis accipe;" in either case his personal authority is valueless, his statements must have corroboration by others capable of judging, and must even then be examined with scrupulous and almost incredulous care.

This theory was at first adopted, to a considerable extent, by Mesmer's pupils, but they seem soon to have found it too heavy for the slender collection of facts they had to support it, and they threw off the planets and stars. Most

of them still talked of a subtle fluid (a condition of matter of inestimable value for theories), and they drew various analogies between animal magnetism and electricity; a science which then consisting of little more than separate facts connected together by very extensive theories, was well adapted for their purpose, because, when they used the same explanations for their assertions and the facts of electrical science, each appeared to have the same degree of truth. We would here point out the different progress of the two sciences, if both can be fairly so called in the same sentence. In Mesmer's time, animal magnetism and electricity might be regarded about in an equally advanced condition. Why has one remained stationary, or even retrograded, while the other has made the most extraordinary progress known in the history of sciences? The bigotry of learned societies, the early prejudices, and the senile objection to novelty, which are said to have marred the one, can scarcely have made the other. The magnetizers point to the discoveries of Harvey, and Galileo, and Jenner, and others, as proofs of the opposition which facts meet when they are first announced, and they would make their art another of those persecuted sciences; but we would point to these facts as evidence *against* them. Let them tell us of any other discovery (especially during the last century) which has made no progress for 50 years, or, taking this from its real origin, for 300 years, but has rather retrograded by becoming more confused; and particularly we would point to the history of vaccination, of electricity, in its various forms of galvanism, electro-magnetism, thermo-electricity, &c.; of the applications of steam, of the stethoscope, of the atomic theory, and of a hundred others, which in their infancy during Mesmer's time, or born since his death, already present the giant forms of exact sciences. Never, indeed, were times so favourable for the development of discoveries—men's minds are athirst for novelties; the floods of knowledge that have continually poured in have not satiated, nor have the streams of quackery nauseated them. Why is animal magnetism still rejected and ridiculed?

But to proceed:—The most exclu-

sively electrical in his views was Petetin. He thought that a woman could neither hear nor see with the pit of her stomach when a piece of glass, sealing-wax, or other non-conductor of electricity, was placed there, and he found hysterical girls, and his somnambules, much affected by thunder-storms, or electrical shocks. He considered that the electric fluid was elaborated in the brain, and passed thence along the nerves, and by the *nervus vagus*, to the stomach, where, accumulated in cases of hysteria, it produced so marked a degree of sensibility that the nerves there could perceive the impressions generally perceived by those of special sense only—as of sight, hearing, &c. But in all this we look in vain for a fact: there is no proof that either an electric or any other fluid is formed in the brain, or passes along the nerves, nor that, if there were, it could be accumulated in any part, or then produce extreme sensibility; nor that the special senses require more concentrated nervous power than common sensation. Besides, all these histories of extraordinary vision, hearing, &c. are, we shall see, but idle tales; and as far as M. Petetin's authority on the subject is concerned, we would observe that that part of his history which he deems most important, and must therefore be supposed to have examined most carefully—viz. that non-conductors of electricity prevented the *clair-voyance*—is contradicted by other magnetizers; who say that the interposition of these, or of any other substances, has no influence whatever. One who could make so great a mistake on one part, can scarcely be regarded as an unquestionable observer on the rest.

M. Puysegur, the discoverer of the somnambule state, took great pains to overthrow M. Petetin's theory, and to establish one of his own; which may be called the theory of faith, hope, and charity. Expressing his belief in the facts which M. Petetin had advanced, as quoted above, he says that they were the result of his preconceived ideas of, and desire for, what would take place; and adds, "if by chance, or by having adopted beforehand some other system, he had imagined that he could not obtain an answer from his cataleptic patients, except through a rose-leaf, or at the decline of the moon in May, these

unhappy creatures, alas! would have remained dumb eleven months and a half in the year; then, at least, with some appearance of reason, he might have cried out, what a prodigy! and many people would have been of his opinion." We confess we should too; and we agree with the author in thinking M. Petetin's facts were the result of his wish, only we would say that "his wish was father to his thought," while M. Puysegur would have it the progenitor of facts. His theory is, that the fluid which he takes from Mesmer to be universal, subtle, penetrant, &c. may be moved by the thought, or will, in any direction, or to produce any purpose that any person desires; and he writes in a most exalted strain on the moral and physical influence which we may by its means obtain over others; coming at last to the fortunate conclusion, that the empire of the magnetizer over the patient extends only to the conferring of benefits on him, because, if he were meditating harm, the patient would have a sensation as if mischief were in the wind, and would wake from the somnambule state. He says, very gravely, that he asked a young lady one day whether he could not, by the power he possessed over her while in somnambulism, make her undress herself; but she said, "No, you can never force me to take off all my clothes; my shoes and my cap as much as you please, but beyond that you will obtain nothing*." Another girl, very properly, expressed the same decision; and a man insisted on it that he should wake directly, if any body were to try to make him sign a blank acceptance while he was somnambulizing.

Need we refute such a theory as this, which in plain words declares that by wishing well, with faith, we may produce any beneficial change in the bodies of the sick? Surely not. M. Puysegur was the most credulous of philanthropists: from the style of his book, and his having no motive to deceive, we do believe that he actually believed his own theory, even though in spite of the opinion of his favourite somnambule, that by a wish he might rid the world of evil, disease still made its ravages. But

* *Mémoires pour servir à l'Histoire du Magnétisme Animal*, p. 196.

what can we think of the statements which a man who could invent and believe such nonsense sets forth as facts? or what of an art in which such a man is revered as a chief discoverer, and one of the brightest ornaments?

M. Deleuze had scarcely a theory. He believed all the statements presented to him (his occupation was not such as to make him a competent judge in cases of this kind), and traced apparent analogies between them and the facts of other sciences, however remote, which seem to have been taken for explanations.

The only remaining hypothesis which we need notice is that of M. Rostan, the most plausible of any, because it pretends to be founded on physiological facts, and comes from a practical physician. We take his views as given by M. Du Potet, at p. 375, *et seq.* He says, "Every thing leads us to consider the brain as an organ secreting a peculiar substance, the principal property of which is, to transmit and to receive volition and sensation, and which appears to circulate in the nerves." Now we affirm, that *nothing leads us to consider any such thing*; the brain has not the structure of a secreting organ; no peculiar secreted substance is visible; no motion of fluid, or any thing else, is perceptible in the interior of the nerves; they do not communicate as the vessels do, so as to permit any fluid to circulate. Nothing, in short, has ever yet been seen of a fluid circulating, or of an agent propelling, or of a canal conveying. The whole of these things, which are the fundamental facts of M. Rostan's theory, had been themselves imagined by others, in order to explain some difficult phenomena of nervous action. Again, "The labours" of M. Bogros seem to prove materially the existence of canals containing a fluid in the nerves. M. Bogros, it is now well known, had injected mercury between the nerve and its neurilema, and had thought it had passed into a canal in the nervous filament itself.

Again, he says that "MM. Prevost and Dumas have demonstrated that muscular contraction is the result of a real electric shock;" and, "Beclard affirmed that he had caused the magnetic pole to deviate by bringing it into contact with an exposed nerve in a living animal;" and he mentions other

things which he thinks prove the identity of the nervous agent and electricity. But, in fact, a far greater number of better-determined facts prove them to be different. The phenomena of the deviation of the magnetic needle, when they did occur (which was very rarely,) were referable to the influence of thermoelectricity. Galvanism acts merely as a powerful stimulus to the nerves, and has no different power over them to that of any other irritation. The isolating property of the neurilema is altogether hypothetical, and nerves are no better conductors of electricity than other equally moist tissues, for it always passes by the shortest passage from one part of the body to another, and diffuses itself in all the surrounding tissues on its way.

But leaving this question as unsettled, or even, for argument's sake, granting the identity of the two agents, the next supposition is altogether unwarranted: that "this agent does not confine itself within the muscles and the skin; it throws itself off with a certain degree of force, and thus forms a real nervous atmosphere, a sphere of activity absolutely similar to that of electrified bodies." Humboldt had invented the basis of this theory, to explain the fact that if a nerve were divided, and its extremities placed near each other, a powerful galvanic current would sometimes pass along the upper portion, and across the interval into the lower portion, so as to produce contraction of the muscle supplied by it. But this is clearly owing to the electricity being conducted through the moist tissues, or the vapour which existed between the divided portions; and the fact itself makes the difference of the nervous and electric agents more probable, because the action of the former cannot be exerted across this interval, as it should be if there were a nervous atmosphere similar to an electrical one between the divided extremities. This phenomenon was the only one which could lead Humboldt to the idea of a nervous atmosphere; it is clearly explicable in the manner above stated. Besides, when, to help his theory, M. Rostan assumed an isolating property in the neurilema, which does not possess any thing of the kind, why did he forget that the cuticle has really such a power in a slight degree, and would be sufficient to prevent the trans-

mission of electricity of so slight intensity as the nervous agent must be? But a pseudo-fact, theorized on by one of so good a name as Humboldt, was too good for the magnetizers to lose, and carefully avoiding any examination of it, M. Rostan has built a lofty theory on it; thus, "the nervous and active atmosphere of the magnetizer, increased, no doubt, by the impulse of his volition, mixes, and is brought into contact with the nervous atmosphere of the magnetized person;" and so on. To refute it all in a word, the ideas he takes of the structure and functions of the brain and nerves are *all erroneous or imaginary*; the identity of the nervous and electric agents is *improved*; the existence of a nervous atmosphere is *disproved*; the influences of the nerves on mind, on any thing beyond the body, is suggested only by what they are wanted to prove—animal magnetism.

We shall quote no more theories; taking these together, even in these slight sketches (to the accuracy of which, though slight, we pledge ourselves) we think it will be agreed that no one art or science ever produced such a set, such an assemblage of errors, based on such unsupported imagination. There is not one which bears even a semblance of scientific reasoning in it. We should have passed them all over in the silence they justly merit, had it not been desirable to show the origin of the mysterious and obscuring phraseology of the art, and the characters of its principal supporters. With men who could form such opinions, and obstinately uphold them, every one is privileged to deal severely: if they believed them, their credulity must have been too great to permit them to have been fair judges either of the apparent evidence of their own senses, or of the probable truth of what was reported to them; if they did not believe them, they were impostors, and their *facts* must be treated, like their theories, with ridicule and contempt. In any case, the facts (so called) of animal magnetism, must be received with the greatest caution; statements contrary to common observation, or common sense, may without compunction be disbelieved, when the authority of the witness has no greater weight than that of most of those we have quoted from.

It may be said that bad theories may be formed to explain facts, as those of the

ancient physicians and philosophers, whose statements are not disbelieved because explained by absurd hypotheses, and couched in their language; but we answer, that these theories were the best that the facts then known permitted them to form; and that many of their statements are really so perverted to suit their theories, that they are, though not intentionally false, yet not wholly true. But the theories of the magnetizers are contrary to facts established at the time they wrote, which, if they were acquainted with, they must have wilfully overlooked; while, if they were ignorant of them, their statements must be received as those of illiterate men.

We must repeat, the authors of the facts on which this theory is based are men on whose evidence we cannot implicitly rely. Many have been proved impostors, or to have been actuated by interested motives; many more have been ignorant of the sciences by the laws of which the phenomena they witnessed must be judged. They are but a few whom we would not include in one of these classes.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Feb. 13, 1838.

THE PRESIDENT IN THE CHAIR.

A PAPER—

On Aneurisms of the Heart; with Cases,
By JOHN THURNAM, Esq.

partly read at the last meeting, was concluded.

Mr. Thurnam's paper consists of three essential parts, which treat of aneurism of the ventricles, aneurism of the auricles, and aneurism of the valves, respectively; and, together with the necessary introductory and supplementary matter, and an appendix of cases, constituted the essay.

After explaining that, by aneurism of the heart, the author means partial dilatation and sacculated aneurism of one or more cavities of that organ, the author proceeds to sketch the literary history of the affection. The first satisfactory account he finds to be that of Breschet, published in 1827; and the first correctly described case that of Galeati, in the *Comment. Bononiensis* for 1757. With regard to the anatomical characters of the affection, the author maintains that they are neither exclusively those of what is

called, in the diseases of arteries, true aneurism, or those of false aneurism; but that they occur of both kinds, and are each produced by various causes; after an elaborate discussion of which, as well argumentative as historical, the author enters upon the history of the first and principal species of the disease—viz. aneurism of the left ventricle. After noticing the fact that the right ventricle is, comparatively with the left, very rarely if ever the seat of aneurism, and discussing the reasons of the exemption, which he finds to be partly mechanical and depending on the structures of the mitral and tricuspid valves, and partly vital and depending on the difference of quality between the venous and arterial currents, he proceeds to detail seven cases of partial dilatation, or aneurism, of the left ventricle. To those details he subjoins a history of the disease, after the numerical method of Louis, and founded on the seven aneurismal cases above referred to (of which four are from the MS. of Mr. Hunter), and on fifty-four more, to which references are given in the Appendix. Aneurisms of the heart he finds to vary much in shape and magnitude, and in their relation to surrounding parts and to other lesions of the heart or its teguments; and of all the pathological changes connected with aneurism, he finds the principal agents to be modifications of nutrition, constituting inflammation and its effects in one class, and simple hypertrophy in the other. The author finds the disease to predominate in the male sex, and in the adult age, and that its principal remote causes are, intemperance, rheumatism, external violence, respiratory efforts, &c. The author then, after a variety of observations on the symptoms and genera of aneurism of the heart, its mode of terminating life, and its organic complication, proceeds to the consideration of the diagnosis and prognosis of the disease. Under the former head the author communicated some observation from the pen of Dr. C. J. B. Williams, contained in a letter to the author, after which the subject of treatment is discussed. The author then proceeds to the history of aneurism of the auricles, after which he considers dilatations of the valves, founding his observations on the latter, on three cases, of which particulars are given. He closes his communication by an appendix, in which are given references to a large number of cases recorded in published works, or in the catalogues of some of the many pathological collections visited by the author in the course of his researches.

ROYAL INSTITUTION.

Friday, Feb. 9th, 1835.

On the Formation of Shells.

MR. GRAY, whose papers in the *Philosophical Transactions* are well known, delivered an interesting lecture on the growth and structure of shells. He explained how shell is secreted by a portion of the skin of the animal termed the mantle, at the edge of which, termed the collar, the process usually goes on with the greatest vigour. The simplest form of shell known to us is that of a more or less flattened cone, as exemplified in the common limpet, and all other varieties of form may be shown to be modifications of this type; the whorled structure of shells being caused by the animal's growing most to one side, and thus turning round a spiral axis. Shells are subject to periods of unusual increase, at which time strong bands or ribs are secreted, which add materially to their strength; the causes of this phenomenon are however unknown. In many shells we find large spines; these at one time corresponded to certain processes of the body of the animal. But when a shell continues to increase in size, and to turn round its axis, these spines might form a serious obstacle to its further growth. To provide, then, against this inconvenience, nature has bestowed on the animal a power of removing such spines as may be in its way. Mr. Gray did not explain how this is effected; we presume he means by some process of absorption, but we may remark, that the question as to the mode of this removal is not as yet set at rest by naturalists. At different periods of their growth, some shells vary so much in their appearance, that naturalists generally, even including Lamarck, have believed that the animals had the power of casting their shells, like many of the crustacea. This opinion has, however, been satisfactorily disproved: and the great change in their appearance is caused by the animal's turning back the alæ of its mantle over the edges of the shell, and secreting a fresh layer of shell, as in the case of the cowries. The beautiful variety of colours in shells is produced by a number of glands which secrete colouring matter, and are usually seated around the neck of the mantle. If these glands secrete constantly, then the shell is marked by coloured bands, but if they do so only at times, spots are produced; and thus every variety of colouring and marking may be explained.

When the minute structure of shells is examined, it is found that the materials are in many cases not deposited in parallel layers, but in a method which greatly increases their mechanical strength, and

which has been applied to the timbering of ships. Some shells are provided with an external membrane, which may be considered as analogous to the periosteum of bone, and has been termed the *periostæum*, while others are devoid of it. The animals inhabiting shells are very generally provided with a flat round layer of bone situated on the inferior surface of their bodies, with which they close the aperture of their shells, when their bodies have been retracted within. These have been termed *opercula*. Mr. Gray concluded by alluding hastily to the structure of the bivalves, whose shells are constructed on the same plan as those of the univalves; and by explaining the beautiful provision in their hinges, by means of which the two valves are kept open by ligamentous bands when the animal is in its natural situation with its body exposed to the waters of the ocean, while by means of a mouth it is enabled to counteract the natural action of the ligaments, and to close its shell at pleasure.

MEDICAL DIRECTIONS FOR THE USE OF PEDESTRIAN TRAVELLERS.

If any one intends to make a long tour on foot, it is necessary to take some precaution. I need not say that English shoes are the best. I do not mean new shoes, but those of which the upper leathers are good and soft, and have been worn to fit the shape of the foot. To such a pair of shoes let an additional sole be put, with small nails at the toes and sides, care being taken that the heel be not either too high or heavy. Let them be laced a short way up the instep, and of a size to allow the foot to sit easy without being loose, when a woollen stocking is on. Of these strong shoes have two pair, and a third pair, not of such strong material, to be worn when you come to the end of your journey. As to the stockings the greatest care must be taken in the choice, as such as are generally sold in shops are sure to cause blisters both at heel and toe. If you examine the ordinary qualities of stockings in shops, you will find that the threads are drawn together to a point in the middle of the heel, and about the ball of the big toe. Avoid such stockings, as they are sure to cause misery. The stockings made by old women on wires are the best, and the finer the wool the better. Of these there should be four pairs; and if a stocking be put over each shoe, (the outside innermost,) they will not take much room, and will at the same time prevent the shoes from soiling the other things in the knapsack. As to other requisites, the first to be provided is a good knapsack of the best oil-skin. It

is to be had in all the military store-shops in London. Care should be had to have the straps of the best patent leather, and a degree broader than usual. The proper breadth for ease is the regulation strap for the Guards' knapsack. They should be so long that you can use them in the foreign manner if you choose. By this I mean, that in the foreign knapsack the fixture from which the shoulder straps play, is placed in the centre of the knapsack, while the English fixtures are placed on the points of the shoulders, just in a line with the shoulder straps, so that the whole weight of the knapsack is on the upper part of the arms, instead of being divided over the back. In the French manner the knapsack sticks closer to the back, consequently you do not feel its weight so oppressive.

When provided with a knapsack, get a wide cloak, (so wide as to go over the knapsack,) of the very finest silk oil-skin, long enough to reach to the middle of the thigh; likewise an oil-skin to the hat. Caps are recommended, but a hat is preferable, as you can carry things in the hollow of it. For a cat, nothing is so good as a surtout made of the finest cloth; it should button up close to the neck to avoid cold: the oil-skin cloak can be used either for sitting or laying on the ground. Have two pairs of trowsers of dark gambrin. As it is of consequence to walk cool, if possible, march without drawers, but be sure to put them on at the end of the journey; one pair is enough; they can be washed and dried while you are in bed. As to shirts, have one in the knapsack, and a very long night shirt made of the finest and lightest cotton, which will be found of the greatest benefit, when you are not sure of the cleanliness of the bed. If your trowsers are wide you can even wear it at the end of a day's journey. Of course a fresh flannel nether-vest must always be in the knapsack. The best gaiters to wear, are those used by the French when shooting. They are made of the strongest soft leather, with straps to tighten, if necessary. They should be as high as the knee, and buckled over the trowsers, so that, however dirty the roads may be, on throwing them off, you find your trowsers quite clean and dry. The great difficulty in walking is to keep the feet in good order. This can be done if a little attention be paid at first. For some days before starting dip your feet in hot water as often as possible for a few moments, and then rub them quite dry. Let this be done morning and evening, till you find the feet quite free from a damp feeling. Provide yourself with a good sized tin box, full of the best yellow, or, as it is called in some places, soft soap. It has something the

appearance of honey in the comb. Before starting in the morning, rub the soles of the feet, especially about the heels and toes, with the soap, until it has the appearance of a good lather for shaving, and then put your woollen stockings on. Let this be done every morning before starting, and you will find, even in the hottest or wettest weather, you will be able to do a great deal of work, and at the end of the day find your feet cool and free from blisters. Instead of washing the feet at the end of a journey, rub them first with a damp cloth, and then dry them completely. In some places on the continent, it is not possible to get this soap; but in almost every apothecary's shop you can purchase stag fat, which does very well; and if you cannot get stag fat, buy goose fat or hog's lard. With these fats, I first rubbed the feet with spirits, which is an improvement; but nothing can stand comparison with yellow soap. Have your stockings washed as often as possible; and if they have not time to dry during the night, they can be easily buckled on the outside of the knapsack. By attending to these directions, and by instantly rubbing yourself dry, and putting on fresh flannels and linen at the end of your day's work, and eating as much animal food as possible, yet drinking no more than is necessary, both body and feet will be in the highest condition.

To prevent thirst in hot weather, nothing is better than to take a great quantity of fresh butter with your bread for breakfast. Avoid drinking water as you would poison; in short, drink as little as possible of any thing, and do not give way to the first sensation of thirst. I strongly recommend starting at day-break, having previously taken breakfast.—*Dublin Journal, from Colonel Shaw's Memoirs.*

HOLLOWAY'S UNIVERSAL OINTMENT.

To the Editor of the Medical Gazette.

SIR,

HAVING lately seen a printed hand-bill, being an advertisement of "Holloway's Universal Ointment," which contains what is represented to be a copy of a letter from me, in recommendation of this nostrum, I think it due, both to the profession to which I belong, and to myself, that I should make known the following circumstances:—

Several months ago a Mr. Holloway, of whom I was led at that time to believe that he was a respectable person, sent me a pot of ointment, which he said had been sent to him by an acquaintance, from abroad, requesting me, at the same time, to make a trial of its medicinal properties. Accordingly, I took it with me to St. George's Hospital, and made use of it in some cases of ulcer. Some time afterwards I received another communication from Mr. Holloway, inquiring what were the results of my experience as to its effects. I wrote to him in answer, that I had not found it to be at all superior to the (commonly-called) digestive ointments already in use, and that I preferred using the latter, as he had neglected to inform me of the composition of the new ointment.

I suppose that this letter has been used as the foundation of that which is published as mine in the printed hand-bill; and I think it not improbable that there may be no words contained in the latter which are not to be found in the one which I actually wrote. The greater part of my letter, however, has been omitted; and the result of this piece of effrontery is, that the sense of it has been entirely perverted, to suit the purpose of those by whom this nostrum is vended.—I am, sir,

Your obedient servant,

B. C. BRODIE.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

BY CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE XIV.

Diseases of the Air-tubes (continued)—Altered Sensibility or Mobility—Spasmodic Asthma; Pathology and Course; Physical Signs; Extent and Effects of the Bronchial Spasm—Paralytic or Atonic Asthma; Mode of Production and Signs—Treatment of Spasmodic Asthma; Treatment of the Paroxysm; General Treatment; Signs of Improvement; Treatment of Paralytic or Atonic Asthma—Treatment of Increased Sensibility of the Bronchial Membrane.

WE have surveyed in outline the features of those affections of the air-tubes which are either inflammatory or characterized by a change of their secretion. But besides such affections, there may be diseases of the *sensitive* and *moving* functions of these tubes. There may be an excess or a diminution of their sensibility, and of the contractility of their muscular fibres, which may vary with the sensibility, or independently of it. We have already noticed these modifications of properties as producing certain varieties of cough; excessive contraction of the bronchi giving the wheezing and whooping characters to cough, and their defective contraction oc-

causing it to be hollow, sonorous, and without expectoration. We have now to advert to the same modifications extending to the ordinary acts of breathing, and constituting what is commonly called *nervous* or *spasmodic asthma*. But from what I have just said, you may perceive that such disorders may be of very opposite kinds, and that the term *spasmodic asthma* will apply only to those cases in which the sensibility or contractility of the air tubes, or both, are exalted, and that there may be another class of cases depending on a diminution of these properties, and to which may be applied the name *relaxed* or *paralytic asthma*. We have both spasmodic and paralytic affections of other muscular organs and canals—of the bladder and urethra, the intestines, &c.; and analogy favours the supposition that we may have similar conditions of the muscular fibres of the air-tubes. But this subject has not yet been duly investigated; and although I have seen many facts which support the view thus presented by analogy, further research both at the bed-side and in the dead-house will be required to establish it in a practicable manner. That very able physician, Dr. W. Stokes, has drawn the attention of the profession to this subject, in connexion with dilatation of the air-cells; and, if I mistake not, we shall do well to think of it in connexion with the function of the tubes also. Let us first, however, attend to the better-known complaint, spasmodic asthma.

The term asthma is generally given to dyspnoea occurring in paroxysms; but we have seen that attacks of bronchial congestion, and bronchial flux, or dry and pituitous catarrhs, may come on suddenly, last a longer or shorter period, and cease in such a manner as to merit the name asthma; by which term, in fact, they are generally known in this country. In the greater number of cases of asthma there is good reason to suppose that one or other of these affections, or some degree of in-

flammation, is present, and by increasing the irritability or the irritation of the bronchi, causes an undue contraction of their circular fibres. An increased vascularity of the bronchial membrane may heighten its sensibility, and augment the contraction of those fibres that are in relation to it, and the same result may ensue from the irritation of an unusual quantity or quality of secretion within these tubes. So, on the other hand, the continuance of inflammation, the thickened and altered condition of the membranes which it induces, may tend to impair their sensibility, and to injure in proportion the contractility of the tubes. In all these cases the modification of the sensibility and contractility of the air-tubes is secondary to other lesions which are more essentially vascular. But there are also cases of a purely nervous character, in which the disease is truly a neurosis; and the temperament of the patient, the nature of the exciting causes, the very sudden attack and removal, and the irregular duration of the affection, sufficiently point out this character. Thus they commonly occur in nervous or hysterical persons. The attacks are excited by strong or peculiar odours, the smell of a stable, close rooms, particular conditions of the atmosphere, irritations of the stomach, or mental emotions; and these causes often quite suddenly bring on the attack, which, if severe, obliges the patient to assume a remarkable and very characteristic attitude, with the body bowed forwards, the arms resting on the knees, the chest contracted, with the feeling of a tight cord or heavy weight on it, the face suffused with an expression of great distress, the veins turgid, and perspiration soon beginning to flow freely; whilst all the muscles of respiration, ordinary and supplementary, are trying their utmost to introduce air into the chest. With what success these efforts are made, we may learn by applying our ear to the chest, where, in spite of the force of the motions, scarcely any sound of passing air is heard. The contractions of the muscles often give an external muscular sound; but within the chest there is only a very weak respiratory murmur, with occasional wheezings or whistlings. The violent action of the muscles of inspiration seems to diminish rather than to increase the entry of air; when the efforts are less violent, especially towards the end of the paroxysms, now and then the air will be heard to enter quite well, as if the obstacle were suddenly removed, but at the next breath all is as obscure as before. At these instants we must suppose that the spasm of the bronchial muscles is momentarily relaxed, and Laennec has pointed out a method of causing at will this relaxation,

which may be useful in enabling us to determine the nature of the disease. If we desire a patient, who labours under the asthmatic spasm, to restrain his efforts of breathing, and to hold his breath altogether for a few seconds, or what amounts to the same thing, to count with his voice as many numbers as he can without taking breath, and then as quietly as possible to breathe again, the air will then be heard to enter freely into every part of the lungs, but in a breath or two after the spasm regains its hold, and the respiration becomes as obscure as ever.

Now how does this happen? How does a moderate inspiration, *after holding the breath*, introduce air freely, when the strongest efforts are otherwise unavailing to produce the same effect? Laennec used to say that the spasm was thus overcome *by surprise!* This explanation is too poetical to be received in physiology. A surprise of the bronchial muscles conveys no definite idea to us, unless we suppose the tissues to be endowed with the mental faculty of *marvellousness*. I do not see how we can explain the phenomenon in question under any other supposition than that there is, as Laennec supposed, a temporary relaxation of a tonic spasm of muscular fibres; and this relaxation I should ascribe to an increased degree of the same cause, which usually and naturally effects the relaxation of these fibres. We have before dwelt on this point in speaking of the physiology of respiration. We were then led to consider the contraction of the circular fibres, excited by a certain degree of foulness of the air within them, as an essential part of normal expiration. Now the foulness of the air being increased by holding the breath long, would stimulate these fibres to their utmost contraction—a contraction even beyond the state of asthmatic spasm: their irritability is thereby for the moment exhausted, and the spasm becomes consequently relaxed, and the air is heard to enter freely; but after a few moments' relaxation the irritability is again restored, and the exciting cause of the spasm remaining, the next breath may find the contraction as strong as ever.

Such I believe to be the true explanation of the phenomenon in question; and, did time admit, I should like to illustrate the principle on which it is founded by several examples of other spasmodic diseases, for it is one of much practical interest, and has not been sufficiently recognised. It is in this way that electricity will sometimes relax a spasm: it stimulates a muscle to a contraction still more forcible than that of the spasm; the irritability of the muscle is thus, as far as relates to the exciting cause of the spasm, exhausted; and a continued application

of the same stimulus may remove the excessive irritability, or subvert the morbid relations that habit has established between the contraction of the affected muscle and some irritating cause in the system. Some of you have heard Sir Benjamin Brodie, on the same principle, explain how a spasmodic constriction in the urethra may be relaxed by the application of a bougie: the stricture refuses it passage at first; but by keeping the end of the bougie in contact with the stricture for a few minutes, the irritability of the contractile fibres is exhausted, the spasm is relaxed, and the bougie passes.

The distinctive physical sign, then, of spasmodic asthma is this imperfect sound of the respiratory murmur, even with forcible breathing, *except after holding the breath*, when it becomes as loud as, or louder than, usual. When the bronchial spasm is considerable, especially during the paroxysms, the chest sounds ill on percussion, not with the absolutely dull *mat* sound produced when solid or liquid is in the chest, but a short, tight, unresonant sound, like that which the chest yields on a forced expiration. This is caused by the contracted state of the lungs when under the influence of the bronchial spasm; the walls of the chest, therefore, being pressed inwards by atmospheric pressure, are not so free to vibrate as usual, when there is more of a balance of pressure on either side. You may generally obtain a better sound by striking on a *finger* or pleximeter pressed on the chest strongly enough to exceed the contraction of the lungs; this restores to them their springing resistant quality, by which they give a regularity to the vibrations of the thoracic walls. The same contraction of the lungs, when excessive, sometimes causes the diaphragm to rise higher than usual in the chest, and to produce a remarkable hollow at the epigastrium; and the whole chest presents a tight and contracted appearance.

Now you must perceive from all these signs that the contraction or spasm of the air-tubes must be very general, and extend to their very terminations; for spasmodic constriction of the large and middle-sized tubes cannot be complete on account of their cartilages; and with partial obstruction of these, the smaller ones and their terminations being free to expand, you would have the respiratory murmur more noisy than usual, and accompanied with all sorts of dry rhonchi, produced by the resisted passage of the air to these expandable parts, as we find in the first stage of bronchitis. But in spasmodic asthma there is very little sound, and so little expansion of the chest, that we are constrained to suppose that the smallest tubes

are constricted likewise, and that either from their almost total occlusion, or from the presence of spasm in their very terminations, the vesicular structure itself is but imperfectly expanded. It may occur to you that I am assuming largely, in attributing these great effects to the operation of the tiny circular fibres of the air-tubes, whose muscularity has been questioned by many, and whose very existence in the smallest tubes is a matter rather of analogy than of demonstration. Well, I admit that we want further information respecting the physiology of the lungs, before we can put forth these views with confidence; but assuming that the whole system of the air-tubes does possess a power of muscular contractility (which I do on the authority of Vernier and Wedemeyer, who saw the smaller tubes contract almost to obliteration on the application of a mechanical or chemical stimulus), it is plain that a very minute force, contracting the caliber of each tube, will be enough to countervail a great force exerted by the muscles of inspiration. Recollect that the muscles of inspiration expand the lungs only indirectly, by atmospheric pressure; that this atmospheric pressure amounts to a weight of fifteen pounds to the square inch; that this amount of pressure is never realized by the power of the muscles; and that which is exerted, when distributed over the vast bronchial surface, becomes very small in each tube,—and you will be able to understand that the bronchial muscles, delicate as they are, may be sufficient to command the passage of the individual tubes, and to resist collectively the full introduction of air into the lungs.

Those who suffer much from spasmodic asthma are seldom free from a shortness of breathing in the intervals; and the frequent recurrence of the paroxysms generally brings with it more of this habitual dyspnoea. If we examine their chests we find the same diminution of respiratory sound as during the paroxysm, but in a less marked degree; and the test of holding the breath proves that spasm exists here also, having become in a measure habitual. No doubt the frequent recurrence, or long continuance of these spasmodic contractions of the tubes, must lead to a permanent diminution of their caliber, and the other tissues change and fix them in this constricted size. We see the parallel of this in the irritable bladder, which, after long continued attacks of spasm, eventually becomes permanently contracted. Where the disease is purely spasmodic, this more lasting change might not ensue for a very long period: but I have before mentioned to you, that with spasm of the circular fibres there is so commonly associated congestion, irritation, or inflamma-

tion, or these are so frequently induced by the spasm, that the phenomena of these pathological conditions are very commonly combined with those of spasmodic asthma. Hence, in asthmatic subjects, you may have an attack of bronchitis, of dry catarrh, or of humid catarrh, assume in its course a spasmodic character; and you may have a paroxysm of asthma, which came on suddenly as a spasm, terminate by a copious catarrhal secretion. The latter seems to be a common course of the asthmatic paroxysms, which are sometimes associated with organic diseases of the heart. The congestion which these determine in the membranes and structures of the lungs exalts their sensibility and irritability; and where the circular fibres are naturally disposed to spasm, this most readily excites it; and this spasm may not be entirely relaxed until the congestion is relieved by a free secretion from the bronchial membrane.

Hitherto we have considered only the spasmodic form of nervous asthma, or that dependent on an *excessive* sensibility and contractility of the bronchial tubes; but as, in examining the elements of dyspnoea, we found that a *defect* of these properties would disorder the process of breathing, we are led to inquire whether there may not be a nervous asthma or dyspnoea of this kind, from weakness, or a *paralysis* of the circular fibres, or of the nerves, whose sensibility guides their contractions? We have parallel affections of the alimentary and urinary passages, when, from local or general causes, their moving fibres become torpid or paralyzed; and if I am right in supposing that the action of the circular fibres, and the elasticity of the longitudinal fibres of the bronchi, are essential to the effectual performance of the act of expiration, defects of the properties of these tissues must cause a proportionate imperfection in this act. There are some facts which seem to me to bear directly on this point. I mentioned to you before, that Mr. Swan found, that in animals in which the par vagum had been divided in the neck, the act of inspiration became imperfect, and the lungs permanently distended. Laennec remarked, that the lungs of persons who died from suffocation in sewers, appeared, on opening the bodies, uncommonly distended, and did not collapse as usual; and he proposes it as a query, whether this may not be from a sudden dilatation of the air-cells. Now, sulphuretted hydrogen gas, which is a chief component of the exhalations of sewers, is remarkable for its power to destroy muscular irritability; and it seems very probable that its direct paralyzing effect on the bronchial fibres may be the cause of the distension

remarked by Laennec. We shall have occasion to return to this subject, in connexion with the lesion *dilatation of the air-cells*, termed by Laennec, *emphysema of the lungs*; and we shall then advert to the view of Dr. W. Stokes, which embraces a similar pathological notion. The phenomena of impaired contractility of the bronchial fibres would be the converse of those of spasmodic asthma; the chief difficulty being in the act of expiration, which would be performed imperfectly and with much wheezing and effort, whilst inspiration might be short and comparatively unembarrassed. Now we do meet with many instances of dyspnoea, generally with old bronchitic affections, but occasionally in cases more of a generally nervous character, and in hysterical females, in which this difficulty of expiration is the prominent feature. So, also, we see the defective action of the contractile fibres of the intestinal tube arise sometimes from previous over-irritation, and sometimes from more directly weakening or paralyzing causes, and sometimes from that irregular distribution of the nervous influence that produces the phenomena commonly called hysterical. Nay, if we consider that irritations and inflammations first exalt, and afterwards injure the contractile properties of hollow organs or tubes, and that these irritations or inflammations affect successively different parts of the same tubes, we can see that spasmodic and relaxed asthma may co-exist in the same person, one part of the bronchial tubes being unduly contracted, and another unduly relaxed, from an irregular distribution of the property of irritability. We have not time to pursue this subject further at present, but we may revert to it by and by in connexion with dilated bronchi and pulmonary emphysema; and, in the meantime, I recommend you to bear it in mind when cases of asthma or dyspnoea come under your notice.

The treatment of spasmodic asthma may be considered in relation to the paroxysm, and to the general state of the body in the intervals. One point is to counteract the exciting cause of the spasm; the other, to remove or destroy this cause altogether. To relax the spasm of the bronchial tubes, various measures may be suited, according to the immediate cause of the spasm. When this is purely nervous, with little or no bronchitic or catarrhal complication, such antispasmodics as aether, valerian, asafetida, opium, belladonna, and the fumes of stramonium or tobacco, will sometimes succeed, and each one of these has proved more successful than the others in particular cases, but seldom retains its efficacy long. A more generally and per-

manently successful remedy is strong coffee, made by infusion, long ago recommended in this country by Dr. Bree, and much extolled by Laennec. I have known some asthmatic persons who relied so much on its efficacy, that the very idea of being out of the reach of it would be enough to bring on a fit; and they most scrupulously avoided using coffee as an ordinary beverage, lest this should impair its efficacy as a remedial agent. This was a good rule, for even this is not free from the tendency of antispasmodic and narcotic remedies in general, to lose their power by frequent repetition. In some cases, sudden strong impressions on the system, such as by dashing pails of cold water on the body, or passing moderate electric shocks through it, have been known to stop a paroxysm of asthma; and their mode of action must be referred to the principle of which I have spoken before. I know of one remarkable case, in which there is apt to come on quite suddenly a loss of voice, and even of the power of articulation, from a spasm of certain laryngeal muscles, and to some degree of the bronchi also. The subject is a lady of strong mind, and by no means fanciful, or (according to the general application of the term) hysterical. For a considerable time relief was instantaneously given merely by her taking a few electric sparks with her fingers. This remedy afterwards lost its efficacy; and even shocks failed to relax the spasm. Subsequently it was found that holding a lump of ice in the back part of the mouth was as effectual in loosening the tongue and the breath as the electric spark had been. This affection was purely nervous; it could be excited at any time by a strong mental emotion, or a slap on the back, and always ceased as suddenly as it came on.

If the asthmatic spasm be complicated with bronchitic or catarrhal affections, which is very frequently the case, the remedies recommended for these may often be advantageously combined with some of those just named; and when the nervous affection does not form the chief part of the complaint, it is probably dependent only on the altered condition of the membrane, which is either inflamed or congested, and to which, therefore, the remedial agents must be chiefly addressed.

The fulfilling of the second indication, to diminish excessive irritability of the bronchial muscles, or to remove the causes of irritation by which they are excited, will be best aimed at by various means which tend to restore a proper balance of the functions of the whole system, and to improve its general health. Of these the most effectual are those of diet and regimen.

Particular rules can scarcely be laid down, as the proper measures will vary greatly, according to the circumstances; but the experience of the patient will generally give a clue to the most eligible plan. The shower-bath, and moderate exercise in the open air, avoiding walking against a strong wind, are very beneficial in most cases. Of medicinal agents, besides those necessary to regulate the secretions, the metallic tonics sometimes do good, by diminishing the morbid mobility of the bronchial muscles, or the sensibility of the nerves that influence them; and I have known, in various instances, the sulphate and oxide of zinc, the subnitrate of bismuth, the nitrate of silver, and the sulphate of copper, severally beneficial in diminishing the tendency to the recurrence of the paroxysms. Probably these remedies act through the nerves of the stomach (the *par vagum*), which are so closely associated with those which influence the bronchial fibres; and they may do this directly, or indirectly, by improving the condition and function of the stomach, disorders of which, in some form or other, are so commonly associated with spasmodic asthma. It has often occurred to me that *bad*, which is known to exert such a paralyzing influence on the muscles of both animal and organic life, might be capable of lowering their irritability when excessive and excited to spasm; but its administration would require much judgment, and I have not had an opportunity of trying it.

The signs of improvement are (besides the less frequent occurrence, diminished severity, and shorter duration of the paroxysms), a freer state of the respiration in the intervals, so that the vesicular murmur is pretty audible, without much admixture, throughout the chest, and is increased in loudness by quicker and deeper inspirations, not stopped or impaired as during the continuance of the asthmatic tendency, when additional effort will often at any time excite the spasm. In the cure of this, as of other spasmodic disorders, it is very necessary to watch the circumstances that excite the paroxysms, in order to be able to avoid them; for the frequent occurrence of spasm increases the chance of its recurrence, until it becomes habitual, and may be excited under almost any circumstances. The evil of an habitual asthma is not only the inconvenience and distress occasioned by the paroxysm itself, but also the permanent changes which it may induce in the structures of the lung—such as contraction and rigidity of the air-tubes, congestions and other lesions of the parenchyma, diseases of the heart, &c.

I have little to say on the treatment of

the dyspnœa arising from paralysis, atony, or weakness of the contractile and elastic fibres of the air-tubes. Depending, as this affection usually does, on previous inflammatory lesions, the remedies generally useful at the decline of those lesions are such as may be supposed to act, in some measure, by stimulating or giving tone to the bronchial fibres. Thus ammoniacum, myrrh, benzoin, the balsams of copaiba and Peru, and the inhalation of tar and other stimulating vapours, besides their operation on the secretory function of the air-tubes, may probably have an influence of this kind on their moving fibres; and they may thus improve their condition, in relation to the act of both expiration and expectoration; the difficulty of which often forms the most prominent feature in many protracted cases of inflammatory and congestive disorders of the air-tubes.

Most commonly, when the sensibility of the bronchial tubes is increased, their contractility is so likewise; when the inhalation of cold air is painful, it also seems to take away the breath: but I have before hinted, that the animal sensibility and organic contractility may not always be in proportion to each other. Thus spasmodic asthma may be unattended with any other pain than that common to dyspnœa; and the relaxed state of the bronchial tubes, marked by difficult or imperfect expectoration, is sometimes accompanied by an increased sensibility of the bronchial membrane, so that the breathing of cold or irritating air becomes unusually painful. In a few such cases, I have known relief to be afforded by the inhalation, twice or three times a day, of the vapour of hot water, to which a few grains of camphor have been added. When this fails, I should be disposed to try other narcotics, such as hyoscyamus, or conium; which may be diffused through the water, in the form of recent extract, or saturated tincture, rendered more volatile by a small addition of liquor potassæ. The proportions must be determined by experience, beginning with small quantities. In these cases, and others in which soreness, or rawness, of the stomach is complained of, much comfort may be derived from the use of *Jeffreys' Respirator*; or if the patient do not choose to be so muzzled, some of the same benefit may be obtained by tying a porous silk handkerchief, or a piece of fur, over the mouth; or, in the case of ladies, even by wearing a thick veil.

LECTURES ON TUMORS;

Delivered at St. George's Hospital,

BY CÆSAR HAWKINS, ESQ.

Definition of Tumor.—Modes of Formation.—Causes.—Inflammation of.—Destruction by Ligature of Vessels.—Rapidity of Growth.—Texture influenced by Situation.—Analogous and Heterologous Formations.—Physical Characters.—Malignancy.—Classification.

I. Order, ENCYSTED TUMORS.

I. Genus, *Sebaceous Encysted Tumors.*

I HAVE now to bring under your consideration the subject of *Tumors*. But what, in surgical language, is a tumor? Strictly speaking, it may be, perhaps, defined as a new formation—an addition to some part of the body of a substance organized, or partly organized, and not the result of inflammation only. A tumor is not a mere swelling, you will observe, however large. I have seen the breast enlarged so as to weigh more than eleven pounds; but this is hypertrophy only. I have seen the scrotum immensely enlarged; it has been removed, in fact, when of the weight of 100lbs.; but this, too, is a kind of hypertrophy of the skin and subjacent textures. You may here see the tibia twice as large and thick as usual, but this growth is only the enlargement of inflammation; by the side of it is a preparation of the humerus, with some exostoses upon it. Now these, however small, constitute a form of tumor, according to the definition just given.

There is, however, a great difference in the mode in which tumors originate.

1. A tumor is, at one time, a *simple addition* to the original texture: such is sometimes a fatty tumor; such are some forms of exostoses, in which the natural bone is unaltered, and the new formation possesses the same structure nearly as the bone to which it is attached; such is sometimes a cancerous tumor, when attached to the side of the breast, or other organ. And these new formations, you will observe, may sometimes be similar, or at least analogous, to the tissue in which they arise—as the exostoses, or fatty tumor, to the natural bone, or fat—or they may be entirely dissimilar from every natural texture, and not present even an analogy in their structure to any normal part of the body; as in the instance of the cancerous tumor just alluded to. Hence arises the division which has been made, of new or accidental formations, into *analogous* or *heterologous* structures, accord-

ing as they resemble or are unlike any of the natural textures of the body.

2dly. A tumor is, at another time, the conversion of an original tissue, or structure, into a new one. A gland inflames, and is enlarged by the usual deposits of inflammation; it may, however, have a new action established in it, its natural textures may be absorbed, and a new substance deposited in their place, and it will then constitute a tumor; it may be of a carcinomatous nature, or a medullary structure, and so on. Such conversion of one substance into another is generally a change of the natural textures of the part into something not known before in any part of the body—i. e. the tumor formed by change of structure, instead of by simple addition, is generally, though not always, a heterologous tumor. You will perceive, moreover, that, commencing in this manner, a tumor may actually be less in size than the organ whose place it has usurped.

3dly. A tumor may be formed thus: simple enlargement has taken place (in the breast, for instance) in consequence of inflammation; lymph has been organized, so as to leave a swelling for twenty years perhaps: then a new action ensues; there is a deposition of new structure, fungous or scirrhous, and it grows rapidly, and the mere swelling becomes a tumor.

Thus, then, a tumor may originate in three different ways, all differing from inflammation. This distinction was first made, I believe, by Mr. Abernethy, and it is of great importance in practice. For the most part, all simple enlargements, or mere swellings, are more or less under the control of remedial agents, and seldom require a surgical operation. A gentleman, for instance, under my care, had a swelling of the testis, which was at least eight inches long, ulcerated, and with large fungous projections, like those of a malignant disease: but by a course of mercury of six weeks' duration all this was cured. On the other hand, almost all new formations resist treatment, and most of them require the removal or destruction of the tumor.

Many speculations have been entered into with regard to the causes of the growth of tumors. Mr. Hunter and Mr. Abernethy supposed that they began by the organization of a clot of blood accidentally effused, or of lymph deposited by inflammation. A preparation is seen in the museum of the College of Surgeons, to show the first organization of a coagulum in this way; but it is to me any thing but satisfactory, and is probably a mistake altogether; and certainly there appears, in the majority of cases, no proof of either circumstance, and in many the tumor has

clearly not originated in these ways. With regard to the organized lymph as a cause of tumors, we see constantly the thickening around the joint, or the hardness in the breast, produced by lymph, but it is only now and then that a tumor originates in this thickened part. It has been well remarked by Mr. Lawrence, that if the conversion of either blood or lymph were the general cause of tumor, we ought to be able to see its several stages; whereas a tumor of the size of a pea is as distinct and well defined, in many cases, as one of 20lbs. weight. Something more, then, is necessary to make the organized lymph a tumor, and we are, for the most part, ignorant of the ultimate cause of their growth, whether it be in the state of the part or the condition of the general system.

Inflammation is, in fact, an occasional cause only of the growth of a tumor; and the effects of inflammation are a kind of excitant: a tumor grows in the inflamed part from some peculiarity (generally a constitutional peculiarity); and the inflamed and thickened texture is selected for the situation of the tumor, as the weakest; just as if a tendency to ulceration is induced by depression of the constitution, a cicatrix, or other newly-formed part, will usually be the seat of the ulceration.

Sir Edward Home imagined that an injury was always the cause of the growth of tumors; in which injury there was an action more than enough to repair the injury. But an injury, also, is only an occasional cause. A person received a blow on the femur, and this cartilaginous exostosis was the result; but a hundred other persons would only have inflammation established by the blow. A groom, in catching a horse, ruptured a few fibres of the pectoral muscle, and this large tumor of fungus hæmatodes appeared in the part in a short time; but how many persons will rupture their muscles without any such consequence!

Although, then, inflammation, or an injury, will now and then be a local cause for the formation of a tumor, yet, in the greater number of cases, with all the fondness of our patients for assigning a reason for their diseases, no evident cause can be detected. They grow for some time before they are discovered, and no pain, nor redness, nor other sign of inflammation, is perceived; they may increase to 20lbs. weight, and yet no symptom whatever of inflammation is shown during the whole of their steady growth. They produce pressure on the surrounding parts, and its usual effects, condensation of the cellular texture, and consequently, in most cases, a cyst, more or less perfect, around them; absorption of the neighbouring substances, even of the bones which are in contact

with them in the interior of the body; stretching of the skin which covers them, and attenuation of its substance, till it at last gives way by ulceration; and yet, perhaps, no inflammation will have been brought on.

Generally, however, there is a period in the growth of every tumor when inflammation is established, and at this time a sudden increase of the growth of the tumor is observed with all the usual signs of inflammation, and the occurrence of further changes in the new textures—ulceration, suppuration, and sloughing. The disposition to such alteration depends partly on the original texture of the tumor; it takes place early, and pretty certainly in cancer, for instance, while a fatty tumor may have shown no tendency to inflammation when it weighs 40 lbs. It depends, however, partly on the situation of the tumor, and its power of obtaining skin from the contiguous parts. A tumor on the hand would, therefore, generally ulcerate sooner than one on the thigh or shoulder; and one behind the jaw can scarcely gain so large a size without ulcerating as another situated low down in the neck. You must not, on this account, reckon ulceration over a tumor as a certain sign of its malignancy, or of its fatal tendency.

However they are originally formed, tumors are supplied with blood from the vessels around them; sometimes one or two arteries only enter at the base of the tumor, and it increases uniformly towards the surface; at other times vessels enter the tumor in every direction, and every cut of the knife, in an operation, induces great hæmorrhage. Attempts have been made by Maunoir, and other persons, to cause the destruction of tumors by tying the principal vessel which supplies them, and thus deprive them of blood altogether, or to such a degree as to stop their growth. The effect, however, has usually been only temporary, just as when this operation has been done for bronchocle; you close one vessel, but others very shortly increase in size, so as to supply the loss. Sometimes, again, changes are produced by the operation, making the tumor ulcerate and slough, from its possessing less vitality than the original textures of the body; but a successful result from this method of treatment is very rarely met with, and in most instances no difference at all is produced by it; the new action once established, goes on nearly uninterruptedly, since the original cause is uninfluenced by a diminution of arterial supply. The rapidity with which they grow is, however, very various. I have seen a tumor in less than ten weeks increase to a greater bulk than that of two persons' heads joined

together; while another, at the end of twenty years, may not be larger than a pea. Most tumors increase with moderate rapidity for a certain time, and then suddenly enlarge in a much greater ratio, so that a few weeks will make a greater difference in their size than as many preceding years.

The tendency to the formation of tumors arises in part from original texture; thus, glandular organs, such as the breast or liver, are more liable to them than the heart or lungs; but such a rule is not universal, for the salivary glands are scarcely ever thus diseased; the more vascular tissues, such as the skin, are also more disposed to the formation of accidental growths than simple parenchyma.

I have explained to you the meaning of analogous and heterologous tumors. Mr. Hunter's definition of a tumor is, "a circumscribed substance produced by disease, and different in its nature and connexions from the surrounding parts." Now this is true—but in a limited sense. For it is curious that most tumors are assimilated to a certain extent to the organ or tissue in which they reside; thus the same cause in action upon the bone will produce some form of bony tumor, which, influencing the adipose tissue, will cause the new structure to assume the nature of fat. Thus it happens, that certain structures are confined to certain situations; polypi to the mucous membrane; epulis to the gums, and so on; so that I shall leave these special diseases to be described when we speak to you of the diseases of such parts in subsequent lectures. So, also, many of the analogous formations are so from their situation, such as this mass of bone and cartilage which was attached to the femur; but in other cases their structure does not depend on any local cause, such as this cartilage from a gland, or this mass of bone from an ovarian cyst. The heterologous formations are more universally alike, and present nearly the same structure wherever they are situated, whether in the breast or arm. Whether you examine a fungus hæmatodes tumor in the lungs or kidney, or brain, there is no great difference; it is not only unlike the texture in which it grows, but like nothing you will observe which is met with in any natural part of the body: such, for instance, is this melanosis of the lungs. Even these tumors, however, are modified slightly by the textures around them, and fungus hæmatodes of the bones, or of the lungs, presents some points of dissimilarity. Of course, two exactly similar structures will occasion various symptoms and appearances of form and size, according to the organs they reside in, and whose functions they interfere with, whether it

be the lungs or brain. I shall, therefore, confine myself at present to a general description of such tumors as will require, hereafter, a more minute account, from the several organs in which they may be met with; and most of what I have to tell you will apply to such formations wherever they may be found.

New structures situated in the internal organs for the most part affect the form of tubercles, and these are generally of a defined circular form, e.g. fungus hæmatoles, or scirrhus of the lungs or liver, in the cellular tissue of these organs, where they fall under the care of the physician; in external organs, on the contrary (with which we have chiefly to do,) from obvious reasons, such as pressure, and so on, tumors are more frequently irregular in figure, of indefinite size, and with various relations to other parts. Observe, for instance, this cancerous tumor of the breast, and these cancerous tubercles in the lungs of the same individual. These, however, are trifling distinctions compared with other circumstances. A great difference between analogous and heterologous tumors arises from the latter being frequently more universal in the several parts of the body; frequently appearing in several organs nearly at the same time, or in some parts in consequence of their formation elsewhere. With analogous structures, on the contrary, this is never met with; though they may be fatal, it is from local circumstances; and though they may have taken place in several parts at once, yet none are affected by absorption from the first.

This brings us next to the most important of all distinctions between different tumors; the separation of those which are innocent from those which are malignant. What then, you will ask, are we to understand by malignancy? Mr. Hunter says, a malignant disease is one in which "the destructive action overbalances the restorative;" and such is the common sense in which the term is employed; as synonymous, in fact, with an incurable ulcer. Thus lupus, or the corroding ulcer of the uterus, are often called malignant. But it seems to me that something more is necessary to constitute a malignant disease, than its being incurable, or proceeding rapidly to a fatal termination. I would limit the term malignancy to such diseases as are *incurable from their possessing a new formation, capable of generating the same or an analogous disease elsewhere*. This contaminating property is exerted in several different ways. 1st. The new structure produces a similar disease in the surrounding textures; 2dly, the absorbent glands are affected by absorption from the new substance, so that similar tumors are formed

in them; 3dly, both these influences may be going on at the same time; 4thly. Without any apparent alteration in the absorbent glands, the whole system becomes contaminated by the influence of the disease; doubtless by a poisonous effect upon the blood, so that tumors of the same kind as that first formed appear in other organs or distant parts of the body; or lastly, all these effects may be produced at the same period. By the limitation I have laid down, then, lupus cannot be considered as a malignant disease, since there is no new formation independent of the deposits of inflammation, and therefore the disease may be arrested or cured sometimes, and there is no contamination of the absorbent glands, nor of the whole system; even if half the face is destroyed by the ulceration, yet there is no evidence of any poisonous influence upon the constitution.

Mr. Lawrence says that "tumors which in their regular progress destroy life by the changes occurring in the affected parts, such as ulceration, bleeding, sloughing, or by causing similar productions in other parts of the body, more particularly in important internal organs, or by both together, are considered malignant." Now this definition also, you will observe, is less precise than I could wish, unless the word *or* were changed into *and*. A tumor is not malignant, in my sense of the term, unless, besides its power of destroying life by the local changes which take place in it, it is also capable of inducing contamination in other textures, either around it or in the glands connected with it, or elsewhere. Observe the broad distinction this makes in your practice; you remove a tumor which is about to become fatal, by bleeding, sloughing, and so on, but your patient is perfectly safe after the operation, and you have no fear of any return; but not so if it be malignant. There may be no evidence of contamination, and no ulceration or sloughing of the tumor, and yet the blood may be already poisoned, though you cannot detect it, and you cannot be at all confident that the patient will not die from tumors in other situations, of the same character as that you have entirely removed from the part first attacked.

It is, indeed, sometimes difficult to decide, from appearances, if a tumor be malignant or not—whether a crop of warts, for instance, are of the common kind or are cancerous warts; and in diseases really malignant, and apparently alike in appearance, there may be a considerable variety in the degree of malignancy.

1st. I have described a disease in the 19th vol. of the Medico-Chirurgical Trans-

actions, under the name of the verrucous tumor of cicatrices, which resembles in some respects the cancerous warts of the penis, but they are of a very different degree of malignancy; the former being so in the very lowest degree, semi-malignant, as it is sometimes called, affecting the neighbouring skin only with the same new structure, and not contaminating the glands, and therefore capable of being removed with almost a certainty of success; while, on the other hand, the operation is very precarious when performed for cancer of the penis.

2ndly. Cancer of the scrotum is a malignant disease in a more extensive sense, since it does contaminate the glands, and is followed by the formation of cancerous tumors elsewhere, and yet the system may be uncontaminated 40 years after the disease first showed itself. I have seen it thus in an old chimney-sweeper, who was in the hospital at the same time with his son for this disease, who had had a cancerous tumor removed three times, and yet not even then were the glands in the groin affected. So that in tumors even of this degree of malignancy an operation offers a very fair prospect of permanent success.

3rdly. Look to the progress of cancer of the breast, on the other hand, and you will almost always find the glands contaminated, and the whole system affected by the poison, so that an operation for cancer, which is malignant in this high degree, presents a very feeble chance indeed of a successful result.

And yet, 4thly. Even the most malignant tumors, which spread their contaminating influence in all three ways, seem to be very different from one another; some passing their whole progress in the course of a few months, while I have seen other cases in which several parts, including the glands, have been at once affected, and yet little suffering had been occasioned to the patient in more than 20 years from the commencement of the disease.

There is such great variety in the structure of tumors, that I can only lay before you the leading facts concerning them in the description which I shall attempt, and any kind of arrangement of them must be imperfect. The classification proposed by Mr. Abernethy, and which has been most followed, is founded on the internal structure of tumors, and it has been much objected to, because the diagnosis can only be verified after death. In a very recent work by Dr. Warren, an American author, he has adopted a classification founded on the organ or texture in which the tumor originated—tumors of the skin, muscles, arteries, and so on—which to me appears

much more objectionable, since the same kind of tumor must thus come under notice many different times, as they occur in the lungs, liver, or uterus, though they are exactly of the same nature, such as cancer, fungus hæmatodes, and such like, in each part. I must say I think a division founded on their anatomical nature is the best, which will also sometimes designate their origin. It is true we cannot be quite positive of the nature of a tumor till we have dissected it, or examined the whole body; but such is also the case with regard to ulceration of the bowels, or disorganization of the kidney; and yet, who scruples to speak of such diseases as if he knew their existence, and to give his prognosis accordingly? In the same manner I think, with care, we may generally be right as to the nature of tumors, if we attend accurately to the history of their occurrence and growth, to their form, colour, size, weight, solidity or fluidity, and the symptoms they occasion, or are accompanied with. To borrow the mercantile phrase, no one can pretend to be infallible, but I think we may generally be right, errors excepted. I shall select also, as far as possible, the terms already in use, though unfortunately the same term is sometimes employed in totally different senses: mammary tumor is, for instance, meant to designate an innocent tumor in the breast, by Sir A. Cooper, while others, following Mr. Abernethy, intend by this name to describe a kind of malignant fungous tumor like the breast, and situated any where. In fact, it is so difficult to describe accurately in words, or to delineate by drawing, the appearances of different tumors, that it is not easy to know what various pathologists are discussing in the classifications hitherto followed.

The class of tumors may be divided, then, into three orders:—

I. Encysted tumors.

II. Osseous tumors.

III. Sarcomatous tumors.

The latter term was invented by Mr. Abernethy, and is intended to designate not tumors resembling flesh, but tumors more or less solid, in which neither cysts nor ossific matter form the chief characteristic. Each of these orders, again, contains several genera, and some of these may be divided into distinct species, and occasionally we shall find more than one variety of the same species. But although some tumors possess so well-marked a structure, that their genus and order become at once apparent, yet all tumors are so far allied that the several structures are sometimes intermixed; some tumors, called sarcomatous, have cysts mixed with the solid substance, either surrounding it,

or connected with it; and so some osseous tumors are mixed with cysts occasionally, or with solid substances not osseous; and some genera are, of course, still more like one another, and pass insensibly into each other in appearance. We shall find that this circumstance is especially the case with malignant diseases, so that tumors belonging to two or three genera are often seen at once in the same person, or the same tumor may, in different parts, have a mixture of two or more kinds of structure—of cancer, with fungus hæmatodes or melanosis; or a tumor of one kind having been removed, of the nature of cancer, may, on returning in the same part, exhibit an alteration of its character to fungus hæmatodes, and *vice versa*.

Some tumors, lastly, may possess such distinct characters that their place is evident; others, on the other hand, may be of so ill-defined or uncertain a structure, that you may be obliged to place them under the head of tumors to which they bear most similarity, without being quite confident of their real nature. Any division that I could form, must, in fact, in the present state of our knowledge, be an approximation only to the truth, for the purpose merely of assisting your diagnosis, and guiding your practice.

I. The first order of tumors, then, is that of *encysted tumors*, by which I mean not merely the condensed cellular tissue that may give a covering to any tumor, or to an extraneous body, but a cyst which has a secreting internal surface, by which it is filled with various contents, for the most part fluid and unorganised. They may be divided into five distinct genera, that are not always sufficiently distinguished from each other in practice.

1. The most common genus should be called *sebaceous encysted tumors*; they are situated immediately under the skin, are globular, or oblong and flattened, elastic, seldom fluctuating (even when fluid), from the thickness and distension of the sac, but more elastic than sarcomatous tumors. The species are named from the nature of the contents.

a. Milicerous, or like a mixture of honey and wax.

b. Atheromatous, a half-fluid substance, unctuous, like pap in consistence, sometimes rancid and offensive.

c. Steatomatous, or more of the consistence of fat than the rest, and almost solid in appearance, till it is pressed out and found to be unorganised.

These three species, which are most common, are all of the same nature, and originate in obstruction of the sebaceous follicles, and the consequent retention and alteration of the natural secretion. The

cause of their formation was first ascertained, I believe, by Plenck, in his *Systema Tumorum*, and has more recently been pointed out by Sir Astley Cooper, not aware probably that it had been previously described. You will constantly see little black specks arising from partial obstruction, from which you can press out the thick oily substance designed to lubricate the skin. A gentleman, whose sister had died of cancer of the breast, came up to town from Oxford, and begged I would immediately visit him; and I found him in a great fright from the discovery of a blue tumor of the size of a nut on the skin of the abdomen, which he thought was cancer; but I was able to relieve his fears by opening the orifice with a probe, and picking out the hardened matter contained in the cyst, which was thus seen with its duct on a magnified scale. And if the opening is distinguishable, as it occasionally is in this condition, you may palliate the complaint by giving exit to the contents of the tumor from time to time. Sometimes the contents are different from those of the three species already mentioned.

d. Hair is occasionally found rolled up to a great length, and generally without the bulb of ordinary hair, though formed, no doubt, by the hair having been obstructed in its passage through the cutis, at the same time that the atheromatous sebaceous matter with which it is generally mixed became confined.

e. At another time horns are formed by the hardened sebaceous matter projecting through an enlarged follicle or ulcerated opening, to the length of several inches, occasionally by the recently secreted matter pushing out that which had previously been formed. These horny sebaceous tumors are often seen on the forehead, where no one, I presume, would wish to exhibit them openly, however quietly such appendages are sometimes worn in private.

f. Sometimes, again, the interior of the cyst ceases to secrete, and becomes lined with cuticle, so that a large orifice is thus left leading into the cavity of the former tumor, below the level of the skin.

Sebaceous encysted tumors are, of course, most common where the follicles abound, especially on the head and face and back. Numerous hard little bodies are met with on the penis, and in the eyelids, which originate in the same way; and there are often a considerable number in the same person, as in this plate of Alibert's*, or in a patient of Mr. Keate's, whom you have lately seen operated on.

* Most of the circumstances described in these lectures were exhibited by preparations and drawings; but, to avoid repetition, we shall not often allude to them.

These tumors often grow to a considerable size, and exist many years, before they occasion such pain or inconvenience as to lead to any surgical assistance being applied for. When large upon the head they will sometimes produce headaches, and by their pressure have more rarely still led to the absorption of part of the bone below them. Occasionally, also, when rubbed by the hat or otherwise irritated, they inflame and increase in size; and then the fluid is partly absorbed again, and they return to their former bulk; or the orifice opens, or ulceration ensues at the apex, and the contents are partly discharged, as from an abscess, but with a small quantity only of pus mixed with the greasy secretion of the cyst. Sometimes there is more severe inflammation still, and the sac sloughs away, and the ulcer heals, so that a natural cure is effected.

It is wrong, however, to allow this, if the removal of the tumor is permitted, as the ulceration is sometimes very troublesome, and produces severe irritation. It is wrong also to attempt to imitate this process, and to open the cyst with a lancet, or pass a seton through it, or destroy it with caustic. If, indeed, the tumor is small and uninfamed, and the patient refuses to have it removed by the knife, you may puncture the cyst, and let it heal, from time to time.

But the removal by the knife is the best and safest method of treatment, before the tumor has attained any great size, and before inflammation and ulceration have taken place.

The incision is generally very easy, when the tumor is of a moderate size, if it is done in this manner:—Make an incision through the skin rather longer than the diameter of the tumor, down to the surface of the cyst, but without wounding it; then with your thumb-nails press back the skin on both sides from its surface, and insinuate them under it, when it will start out like this, which I thus took away from the head of a lady; or this larger one, which I have subsequently opened to shew the cyst. There is little bleeding, and the incision heals by the first intention, so that you need not with small ones have the hair shaved off, but make a little pressure with lint after oozing has ceased. A large one will more probably suppurate, so that you have to open the wound again; and therefore it is better to shave the hair previous to the operation. If you accidentally open the cyst, then squeeze out the contents, and with a pair of forceps tear out the cyst from its cellular bed, the edges of it being easily seen, and if the cyst is thin or large, the best way is not to try and remove it whole, but cut at once through the skin and the front half of the

cyst, and then drag it out in the same way. If the skin be adherent, or the cyst has inflamed so as to adhere at its base, which is less common, a little dissection becomes necessary; but take especial care not to cut into the occipito-frontalis tendon, lest you produce a troublesome and dangerous form of cellular inflammation. With this tumor, which I removed after a very successful operation for cataract, in an old man of 75, I was unlucky enough to have an attack of erysipelas, which you must sometimes expect, and endeavour to guard against, by looking to the condition of the system before this apparently trivial operation.

In the cheek or temple the cyst is almost always very thin and transparent, so that you need seldom try to dissect out the cyst entire, but divide it partly in the way I before mentioned; or if it is very small, you may divide the skin, and raise the tumor with a tenaculum, and cut it out along with a little fat around it; recollecting, of course, the situation of the parotid duct, and facial nerves.

When the part has inflamed and suppurated, you may lay the cyst open; and if it adhere so as to render the dissection difficult, you may rub the interior slightly with potassa fusa, or nitric acid, and leave it to slough. The great point in any plan of treatment is to leave not the least portion of the cyst behind, since it will then return again. A gentleman, for instance, had an encysted tumor removed in Dublin, and it came again in the cicatrix a few months afterwards; it was of small size indeed, but being on the back of the neck it inflamed after hunting one day, and I dissected it out while suppurating, notwithstanding which the wound healed by the first intention. When situated on the back or limbs, pressure will almost always have produced adhesion, so as to render dissection of the skin from it necessary.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

Treatment of Cholera.

No. VII.

THERE has been, as we have seen, a very general agreement in the experience of all countries with respect to the natural course of cholera, and an almost universal admission that its ter-

mination is always fatal when it appears as an epidemic, unless medical treatment is resorted to. The recoveries, it is true, which occasionally took place in this country, sometimes under the most inert, sometimes under the most contradictory treatment, seemed more reconcileable with the supposition that nature had, in these instances, effected the cure, than that any disease could be amenable to so many different plans of management. But this difficulty may be explained by simply retracing the natural progress of the disease through its consecutive stages. Cholera has always, at least in this country, been preceded by premonitory diarrhoea*, which, if left to itself, ran, in the majority of cases, into the confirmed disease, characterized by rice-water vomiting and purging. When once this confirmed disease commenced, it invariably ran on to pulseless collapse if unimpeded by remedies, but in the great majority of instances was arrested under judicious treatment. When once collapse had taken place, and the pulse had ceased at the wrist, all treatment was apparently useless, and sometimes worse than useless. If the patient was let alone, reaction took place by the unaided efforts of nature in from three to five cases out of ten—that is, from five to seven died in the state of collapse, while from three to five revived and ran into consecutive fever. In those who had, previous to the cessation of the pulse, been judiciously treated, the state of collapse was generally less deep or prolonged, and a greater number of such persons (probably seven out of ten) revived, to encounter the after-dangers. This was the state to which, from the frightful phenomena it presented, public attention had been chiefly rivetted, as if it formed the whole of what was called cholera; the state in which the most inert or the most opposite modes of treatment appeared to be equally successful; and after all our experience of the disease, it remains to be proved what plans or remedies, or whether any, possess an effective influence in altering its natural results up to the period of reaction.

When reaction had commenced, when consecutive fever had begun, the patient became again susceptible of the influence of remedies. These could not, perhaps, effect much, but they effected

something, and without them *all died*. There were many natural recoveries from collapse—that is, from three to five revived out of it, unaided by any remedy, but there was no natural recovery from consecutive fever,—I mean while cholera was epidemic. To sum up the natural history of the disease, all cases of cholera, not subjected to treatment, run without exception into collapse; out of the collapse, three, five, or perhaps seven, revive and run into fever; and if no judicious treatment be still instituted, all these die. There is, therefore, no recovery from cholera when epidemic, unless medical treatment be resorted to.

I cannot help thinking, that the variety of opinions as to the proper treatment of this disease, the diversity of remedies, the indefinite and perplexing conclusions to which all our experience has led, may be attributed almost as much to the scientific zeal and efforts at unattainable perfection in a very talented portion of the profession, as to the indiscriminating empiricism of the remainder. All the pathological investigations which have taken place, either in India or in Europe; all the minute examinations of morbid appearances in the military hospitals at Calcutta or Madras, or at the Hotel Dieu in Paris, or at the Drummond-street hospital in Edinburgh, while they speak highly for the industry and zeal of the medical men engaged in them, have contributed less to any immediate improvement in practice, than some of the simplest prescriptions which have reached us from the unlettered Hindoos. It is far from my wish to slight or undervalue the labours of zealous men, prosecuted at no common sacrifice; I believe those labours may hereafter bring forth abundant fruit for science, and that in one instance at least they have already led, by chemical examination of the blood, to the application of a remedy as successful as it was daring—the injection of the veins with saline fluids. But in new and obscure diseases, implicating almost every part of the system, it is not to be expected that pathological researches can lead to satisfactory inferences in one age or country, or that we can turn to any successful account the mere conjectures to which they give rise. Our practice in such cases must be pure empiricism—not so to say in the ordinary use of the term, but empiricism founded on

* The Cholera of French writers.

analogy, and applied with skill and discrimination. It is on such grounds, in fact, that half the therapeutic doctrines of the present day, which are looked upon as most conclusive, are based; and even those which are strictly connected with pathological discovery, and appear to have grown out of it, will be found, I apprehend, on inquiry, to have for the most part preceded the connexion. Empirical inferences are always of immediate practical application, while those deduced from morbid appearances, at least in diseases which either originate in the nervous system, or are protracted in their course, or affect many organs simultaneously, are of the most doubtful and suspicious character.

I have offered these observations from a conviction that if half the enthusiasm evinced by scientific men in studying the pathology and originating theories about the nature and cure of cholera, was directed to determine the treatment, by careful and logical deductions from the empirical method, we should long before now have arrived at some definite system, and not be left as we have been, should the disease again visit us, uncertain, perplexed, and as liable to be "blown about by every wind of doctrine," as when our experience began.

In reviewing or comparing the chief remedies, or most popular means of cure, which have been resorted to, I regret to say I can only give a partial illustration of the method by which we might arrive at some degree of certainty in our inferences. It is a very imperfect adoption of the numerical method of induction before alluded to, which has been so admirably applied to the investigation of the proper treatment of thoracic inflammation by M. Louis. At the time cholera commenced in this country, I had not seen the account of M. Louis' method, and was led even to the very imperfect adoption of it which I shall describe, by the utter discrepancy of medical opinion with respect to the value of every proposed means of cure, and a consequent anxiety to inquire and determine for myself. The results of this inquiry, imperfectly as it was made, were beyond my most sanguine expectations, and left no doubt on my mind, that if it was similarly pursued in determining the merits of other remedies, as it had been in fixing the pretension of calomel, we should attain

a confidence in our treatment not surpassed by any we possess in the management of more familiar diseases.

In considering the effects of the several remedies which have been employed, it will be convenient to group such of them in classes as seem to be allied in their mode of action. The consideration of sedatives or contra-stimulants, stimulants, emetics, purgatives, astringents, salines, simple diluents, &c. necessarily includes an inquiry into the merits of every reputed specific, and presents readier and more advantageous opportunities for correct comparison. It will also be requisite to discuss the value of every remedy, in reference to its influence in the several stages of cholera, which I have distinguished into three, beside the premonitory one. The latter, or attack of bilious diarrhœa, though almost invariably preceding the disease, and apparently essential to its occurrence, forms no real part of it. There is nothing in its slighter visitations to distinguish it from mild diarrhœa occurring from any other cause, or in other seasons, nor, in its worst attacks, to separate it from English cholera; and when present during the prevalence of the Asiatic disease, it is not, in the majority of instances, followed by it. It is well known, that in every city where the latter has been epidemic, bowel complaints have been general; and yet the proportion of any population which has fallen into cholera under such circumstances has rarely exceeded a twentieth of the whole. The commencement of epidemic cholera should be dated from the occurrence of rice-water vomiting and purging, with suppression of bile, and perhaps urine. This is the first or true primary stage of the disease, and it is, sooner or later, unless interfered with by the influence of medicine, succeeded by another — the second, or stage of collapse, equally well marked in *the absence of the pulse at the wrist*. I have fixed on this symptom of *absence of the pulse* as characteristic of *collapse*, to get rid of the indefinite notions attached to that word by some, and to engage medical men in the use of terms in the publication of their reports, about the precise application of which there can be no doubt. The collapse is followed by a third stage, or that of consecutive fever; distinguished as essentially from the second as either is from the first. These are

the distinctions to which I have adhered in the previous reports, when discussing the mortality of the disease; and the reader will readily perceive, not only the advantage of considering the influence of remedies separately, with reference to each, but the total impossibility of forming a comparison of any one medicine, or plan of treatment, with another, without the strictest observance of them. In the distinctions drawn by Dr. Mackintosh and others, the premonitory is regarded as the first stage of cholera, and their second, or stage of collapse, is strangely enough made to include the true primary stage above described, though the latter often exists for many hours without an appearance of those symptoms which characterise collapse. From reports drawn up with such vague distinctions, in which every medical man is at liberty to class cases of premonitory diarrhœa with true cholera cases, and those with firm pulses, but who have a little blueness or sinking about the eyes, with true cases of collapse, what can one learn, or what compare, or infer? The value of the distinctions I have drawn will be more fully appreciated in the sequel.

It would be needless waste of time to make any particular reference to the effect of remedies in the premonitory or simple diarrhœal stage. The usual treatment for the suppression of ordinary diarrhœa, or that recommended in the circulars issued by the Board of Health, or, still more simple, the exhibition of crude opium in grain or two-grain doses, is always capable of controlling it; and, as far as my experience has gone, I believe the lapse of simple premonitory diarrhœa into spasmodic cholera is always attributable to the neglect or mismanagement of either patient or doctor, and not to the inefficiency of medicine. The pure opium treatment may not be strictly applicable to every case, but it is so to the great majority; and the ill consequences that follow its use, when misapplied, do not, at all events, include the occurrence of cholera. The misapplication of purgatives, on the other hand, however mild they may be, is frequently irremediable; the patient, after their operation, running rapidly into collapse before we can arrest the mischief. The use of purgatives when cholera is threatened, requires, indeed, at all times the utmost caution; nor are they often required

even in those instances where the opium treatment has confined the bowels for two or three days, their natural action eventually taking place before any disturbance of the system is occasioned. I am most confident, that if the public at large was made familiar with the use of opium wherever cholera was present, and it was customary for each person to carry a piece in his pocket, so that no time should be lost in suppressing attacks of diarrhœa, more would be effected in arresting the progress of the epidemic than by the most expensive hospitals, or the most rigid sanitary regulations. It is, in fact, a question with me, whether those who are apprehensive, or constitutionally disposed to the complaint, might not take small doses of opium daily, with advantage, as a preventive, in the same manner as belladonna has been used to prevent attacks of scarlatina.

[To be continued.]

SOME OBSERVATIONS ON THE PATHOLOGY OF STAPHYLOMA.

To the Editor of the Medical Gazette.

SIR,

THE term *staphyloma* has been applied, by writers on the diseases of the eye, to various prominences on the surface of that organ, produced by a partial yielding of its coats. But that form of projection to which the name *staphyloma* was originally given, and for which it is still most commonly employed, occupies the place of the cornea, and is, according to the opinion of all authors (I speak under correction), the cornea itself, degenerated and distended, together with the iris, which has become adherent to it throughout its whole extent; the anterior chamber being, of course, annihilated. The following words of Mr. Lawrence * express, I think, very clearly and fairly, the generally received opinion as to the mode of origin of *staphyloma*:—"In order that the state of *staphyloma* should be produced, there must be severe inflammation of the eye, involving the entire cornea, and rendering its texture opaque; that inflammation must also have extended to the iris, and caused it to adhere to the cornea; and there must be increased

* Treatise on the Diseases of the Eye, p. 373.

secretion of the aqueous humour, to push these unnaturally connected structures forwards."

This form of staphyloma is usually called *spherical staphyloma of the cornea*, and it may be either *partial* or *total*. In the following remarks, every other form of staphyloma—such as conical staphyloma, staphyloma scleroticæ, &c. is excluded. What is known by the name of *staphyloma iridis*, will be shown to be merely a stage of the disease under consideration.

The structure of the cornea is changed, the iris adheres to it, surface to surface, and the two together are distended into a staphylomatous projection. Such, in a few words, is the commonly received opinion regarding the formation of staphyloma. I have examined many cases of inflammation of the eye—inflammation of the cornea, inflammation of the iris, inflammation of the membrane of the aqueous humour, &c.; but never observed adhesion between the two membranes take place in the manner described. In penetrating ulcer of the cornea, and prolapsus iridis, of course the prolapsed part of the iris adheres to the cornea at the one point, but though the two membranes have come into contact in their whole extent, in consequence of the escape of the aqueous humour through the opening in the cornea, made by the penetrating ulcer, and though, in consequence of the attending inflammation, the circumstances favourable for adhesion exist, still the iris does not adhere to the cornea surface to surface, as the pleurapneumonalis does to the pleura costalis; on the contrary, as soon as the ulcerated opening in the cornea closes, so that the aqueous humour is allowed to accumulate, the iris recedes from the cornea, and the anterior chamber is re-established. The only adhesion between the iris and cornea is at the one point where the prolapsus iridis took place. Again: cases of penetrating ulcer of the cornea occur in which, the aqueous humour having escaped, and the iris come into contact with the cornea, but no prolapse of the former having taken place, no adhesion at all between the two ensues, but the iris recedes from the cornea as soon as the opening in it from the ulcer closes, and prevents the farther escape of aqueous humour. One should suppose that if adhesion between the

anterior surface of the iris and inner surface of the cornea was a thing prone to take place, that it should have been observed in those cases of inflammation of the membrane of the aqueous humour in which the operation for evacuating the latter has been performed; but I apprehend no one ever saw such an event ensue. In the operation for the extraction of the lens in cataract, the aqueous humour having escaped, the iris comes into contact with the cornea, and continues so for a considerable period; but if there be no prolapsus iridis, adhesion never takes place. If the iris does not adhere to the cornea when these two parts come into contact, from the escape of the aqueous humour, and while in a state of inflammation, much less do they adhere, independently of the removal of that fluid*.

But it may be said, it is not in consequence of such inflammations of the eye that staphyloma occurs, but that "purulent, gonorrhæal, and variolous ophthalmia, are the most frequent causes of staphyloma." True; but under what conditions does staphyloma occur in those diseases? Not by adhesion of the iris to the cornea, surface to surface. Mr. Wardrop says, "as far as I have been able to observe, staphyloma never occurs unless the cornea has been previously ulcerated, and unless the ulcer has penetrated into the cavity of the aqueous humour and destroyed the cornea as deep as the internal tunic." I apprehend it would have been nearer the truth to have said, that staphyloma never occurs without more or less extensive destruction of the cornea. Purulent, gonorrhæal, and variolous ophthalmia, are the diseases of the eye, in consequence of which staphyloma most frequently occurs, and these are the very diseases in which the cornea is more or less extensively destroyed.

The only mode of formation of staphyloma which I could ever trace is the following:—

If, in scrofulous, catarrhal, or catarrho-rheumatic ophthalmia, there be a penetrating ulcer of the cornea, the aqueous humour escapes, the iris falls forward into contact with the cornea, and a small part of it is perhaps prolapsed through the ulcerated opening. The progress of the ulceration being stopped by the yielding of the

* Middlemore on Diseases of the Eye, vol. 1, p. 512.

inflammation, the prolapsed portion of iris, and the ulcerated part of the cornea, are involved in one cicatrice. The opening in the cornea being thus closed, the aqueous humour again collects, and the anterior chamber is restored, though somewhat diminished, in consequence of the partial adhesion between the iris and cornea (*synechia anterior.*) There is no prominent distension on the front of the eye in this case, because, as the inflammation subsides, the small protruded portion of iris shrinks and flattens; but if the destruction of the cornea has gone on farther, either by ulceration or the giving way of an onyx, and considerably more of the iris has protruded, the prolapsed portion of the iris does not shrink when the inflammation begins to abate, as in the former case, but remains, and forms a projection at one part of the cornea, generally the lower or lateral. This projection is at first merely a bag of the iris distended by the aqueous humour; but by and by its exposed surface becomes covered by an opaque firm tissue, of the nature of the *tissue of cicatrices*, and this tissue is incorporated at the base of the tumor with the sound cornea. The projection, the mode of origin I have just described, is a *partial staphyloma*; it is not a distension of the cornea itself, but a protruded portion of the iris covered by a *new tissue*, intended to supply the loss of substance which the cornea has sustained. The mode of origin of a *total staphyloma* is essentially the same, but differs only in degree. The whole or greater part of the cornea being destroyed, as occurs in gonorrhœal, purulent, and very often in variolous ophthalmia, as also that of new-born infants, the whole iris falls forward, the pupil becomes closed, and the aqueous humour being thus allowed to accumulate in the posterior chamber, the iris is kept distended in the form of a tumor on the front of the eye. Its surface gradually gets covered with an opaque cicatrice-like tissue, or pseudo-cornea, which assumes a greater or less degree of thickness, and a total staphyloma is the result. Sometimes the central part of the cornea only is destroyed, a ring of the circumference still remaining; the staphylomatous projection has then the form of a small globe stuck on the front of a larger.

In 1834, when in Glasgow, I directed the attention of Dr. Mackenzie to the subject, and he adopted my views so

far as to admit my description of the origin of staphyloma into the second edition of his work, then in preparation (p. 602). Subsequent and more extensive experience and observation have convinced me more of the correctness of my views, and induce me to speak more decidedly on the subject than I did at that time.

Founding my reasonings on those views, I conceived that the supply of aqueous humour in the still-existing posterior chamber was what kept up the distension of the iris, and the consequent moulding of the pseudo-cornea on its surface in the form of a round prominence on the front of the eye. If, therefore, it was natural to infer the source of the aqueous humour could be destroyed, we should not have the development of the staphylomatous projection, or, if already formed, it would disappear. For this purpose puncturing the tumor is not found to answer well. To break in upon the integrity of the posterior chamber, I conceived the simplest and most effectual plan would be to extract the lens,—an operation which I put into practice in the following case.

A young man about 22 years old came to me labouring under the effects of severe purulent ophthalmia of both eyes. In the right eye I found the cornea destroyed, and the iris protruding and distended with aqueous humour, the pupil being closed. The left eye had also suffered very much; there was penetrating ulcer, prolapsus iridis, and consequently considerable distortion and contraction of the pupil. Both eyes were still affected with the inflammation, and it was very doubtful whether the left eye could be prevented from getting worse, especially as it was evidently kept in a state of additional irritation from the presence of the staphyloma in the right. By an incision with a Beer's cataract knife in the protruding and distended iris, the lens was extracted. Severe re-action followed; less perhaps in consequence of the operation, than in consequence of the patient not having been in a situation to take proper care of himself. The iris did not again become distended; on the contrary the eye shrunk, and irritation being thus removed, the left eye progressively improved, as far as the organic changes it had already undergone allowed, and farther than there had been previously reason to hope for, as vision was pre-

served sufficient to enable him to resume his employment as a porter.

In those cases in which the eye is destroyed by purulent ophthalmia, whether of adults or new-born infants, gonorrhoeal ophthalmia, variolous ophthalmia, &c., and in which staphyloma does not form, but the eye-ball shrinks and becomes atrophic, I suspect (though at present I cannot adduce any direct proof) the lens has escaped on the giving way of the cornea.

The conclusions, then, which I draw from my observations are the following:—

That the iris and cornea do not unite surface to surface, and if they unite at all it is only partially, and that in consequence of penetrating ulceration of the latter, and prolapse of the former.

That the tissue composing a staphyloma is not degenerated and opaque cornea, but a *new tissue*, of the nature of the tissue of cicatrice, developed on the anterior surface of the iris exposed by the destruction of the cornea itself.

I am, sir,

Your obedient servant,

T. WHARTON JONES.

PLASTER OF PARIS IN FRACTURES.

To the Editor of the Medical Gazette.

SIR,

In my note-book I find the following extract; it must have been written many years since, as I have no recollection from whence I made it. The plan has frequently presented itself to my mind as worthy of trial, and I am happy to find my opinion, that it might be turned to good account, verified by Mr. Sweeting. The extract is headed, "Arabian Mode of Curing Fractured Limbs."

"The Orientals will never consent to have a limb cut off. Their practice is to lay the limb upon an oiled mat, after reducing the bones, and then inclose it in a case of gypsum, or plaster of Paris; an operation which they perform much in the same way as is practised by statuary to take the cast of a limb. They first pour the plaster of Paris under the limb, until it rises to such a height as to touch the whole lower sur-

face, filling up all inequalities, so as to form a sort of bed, placing at the same time a few hollow reeds at proper distances, and in such positions as to serve to conduct away through the plaster any fluid that might collect in the gypsum case, from the wounds, &c. When this becomes firm, which it does in a very short time, the limb is next covered with the same plaster of Paris, so as to inclose it completely, and, on hardening, to form a light case or plaster boat, to keep the parts in as natural a position as possible. They next make a sort of furrow or channel in the soft plaster, on the upper surface, to receive such vulnerary fluids, during the treatment, as they think conducive to the cure, and which filter through the gypsum to humect the leg at pleasure. To render this upper shell more easily removed or changed during the cure, if necessary to examine the state of the parts, &c., they make deep incisions into the soft plaster, both lengthwise and across, though not quite through, by means of which the upper case is removed without disarranging the limb. The firmness of the lower part, or bed, makes the removal of the whole boot practicable, should such a measure at any time be found expedient."

I have not seen Mr. Beaumont's pamphlet, and he may have possibly made mention of the practice being followed among the Arabs and eastern nations: if, however, it has not been noticed, it may probably be interesting to him and Mr. Sweeting to read the above.—I am, sir, with much respect,

Yours obediently,

THOMAS INGLE.

Lyme Regis,
Feb. 7th, 1835.

CASE OF BLACK VOMIT IN AN AFRICAN.

To the Editor of the Medical Gazette.

SIR,

In reference to some valuable remarks on the "Malignant Fever of British Guiana," by Dr. William Fraser, contained in a late number of your journal, I would request your insertion of the following case, one of many which no doubt can be produced in answer to that part of Dr. Fraser's letter where, in

speaking of Africans, he says, "I have heard it stated that the black vomit is unknown among the sable race; but whether this is true or not I cannot, from my own experience, attest or contradict*.

Your obedient servant,
J. MACDIARMID.

February 7, 1838.

Sierra Leone, 1837. — J. Richards, African private, 2d West India Regiment, was admitted into hospital May 11th, with slight febrile symptoms; bowels constipated; tongue furred. On the 13th, reported as "making no complaint;" skin cool; bowels regular; tongue, however, still furred. On the night of the 15th, patient was suddenly seized with vomiting of coffee-ground matter, mixed with blood. Morning visit reported, "Patient in a low typhoid state; pulse weak and thready; extremities cold; smell of the body cadaverous." Lingered till 10 A.M. of the 16th.

Sectio cadaveris, four hours after death. — Conjunctiva deeply tinged with bile. Thorax: Lungs on the right side adhered extensively by pretty strong bands to the parietes; superior portion of the right lung, and numerous patches of both, presented a dark spotted appearance, and, when cut into, sanguineous engorgement in a great degree, fluid blood flowing out profusely without the slightest pressure. A small quantity of serum in the pericardium. Abdomen: Liver about the natural size, pale, and somewhat condensed in structure; tinged yellow. Gall-bladder contained an ounce and a half of a dark fluid resembling liquid tar. Stomach filled with a dark fluid to the amount of a pint, similar to that vomited before death; portions of its serous surface, especially towards its cardiac extremity, dark and congested; the lining membrane in the same situations corresponding in appearance. Spleen slightly enlarged, dark, and semifluid, giving way under the finger. Bladder contained a pint of fluid similar to that found in the stomach, but thinner. Intestines generally presented nothing remarkable. Membranous textures of the body throughout deeply tinged with bile.

ON THE
CEREBRAL EXTREMITY OF THE
OPTIC NERVE.

To the Editor of the Medical Gazette.

SIR,

I AM desirous of putting upon record, through the medium of your valuable journal, a fact regarding the cerebral extremity of the optic nerve, which I do not find noticed in any author on this subject. It may be interesting to many, inasmuch as it appears to afford additional evidence of the important office of the cineritious neurine; especially when taken in connexion with those views of the function of the grey matter which Mr. Grainger has lately so materially elucidated by his minute dissections of the central extremities of the spinal nerves, and the deductions which he makes in confirmation of Dr. Marshall Hall's views of the spinal cord as a true centre of power. I will also take this opportunity of bearing my testimony to the accuracy of Mr. Grainger's statement regarding the roots of the spinal nerves.

I traced fasciculi of both the anterior and posterior roots of the spinal nerves, into the grey matter of the cord, in presence of Dr. Todd, at King's College, on a dog which he had procured for that purpose; since which, I have seen them exposed by Mr. Grainger himself, at his school in Webb-street.

The connexion of the optic nerve with the brain itself has been variously described by different authors; by some it has been described as arising only from the thalami nervorum opticeorum; by others, only from the optic tubercles; and by most, in latter days, from both of these bodies, "by a flat band of white fibres*." These fibres, which come from the surface of the thalamus and the optic tubercles, are well known and easily demonstrated; but they are not the only fibres of communication between this nerve and the brain.

If the optic nerve is carefully traced from its commissure backward, it will be found to be connected to the tuber cinereum, as described elsewhere; after crossing the crus cerebri, to which it is connected with membrane, it divides into a superficial and deep layer: the superficial layer is that which is

* MEDICAL GAZETTE, Jan. 20, p. 641.

* Mayo's Physiology, 4th edit. p. 450.

described in most anatomical works; the deep layer, which is thin and flat, plunges partly into the substance of the thalamus and partly into the corpus geniculatum. Those fibres which go through the corpus geniculatum are separated into delicate threads by cine-ritous neurine, as the motor tract of the spinal cord in the corpus striatum. These fibres which plunge into the thalamus are stronger and more distinct, and after spreading into rays are lost in its substance.

This arrangement may be seen after raising the nerve from the crus cerebri, either by tearing its fibres very carefully in a brain previously hardened in alcohol, or by making a longitudinal perpendicular section of the optic nerve in a recent brain, right through the corpus geniculatum and thalamus; when one layer of white neurine will be seen on the surface of the corpus geniculatum, and another just passing through its anterior part, but principally through the substance of the thalamus, separated from the first by the posterior and superior portion of the grey matter of the corpus geniculatum.

I remain, sir,

Your obedient servant,

SAMUEL SOLLY.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

DR. ELLIOTSON

ON THE PROPOSED

LECTURES ON PATHOLOGY.

WE suppose that a certain portion of *amour propre* is common to all men; but in some the quality is so superabundant, that it betrays itself when they least intend it, and often when they are quite unconscious of it. The learned Professor of Medicine in University College stands in this predicament. In his edition of Blumenbach, recently published, he lays claim to almost every important improvement

made in physic during his time; and in a printed letter now before us, he modestly expresses his opinion that all teachers of medicine should be made by authority to take his lectures as their model.

The occasion which has given rise to this very curious document is the real or supposed intention of the University of London to insert a course of pathology in the curriculum, for the guidance of aspirants to degrees in physic. Dr. Elliotson disapproves of this, and so do we; but the worthy professor, in adopting the arguments already repeatedly urged by us, contrives to place them in such a light as to make the measure against which he argues appear to be imperatively required. He informs the Senate that he teaches medicine in such a manner as to render a separate course on pathology and morbid anatomy unnecessary; but as he more than implies that this mode of proceeding is peculiar to himself, his argument goes to shew that a change in the method of teaching generally adopted is absolutely requisite. The medical Faculty of the London University have no power to compel lecturers on medicine to teach morbid anatomy; and thus Dr. Elliotson's epistle, so far as it may be supposed to influence them at all, is calculated to confirm them in the propriety of remedying the supposed evil in the only way which is open to them—namely, by decreeing that aspirants for their honours shall have attended an *ex professo* course upon the subject in question; a proceeding which they are well aware would be followed by the announcement of abundance of such lectures.

That there may be no mistake, however, as to Dr. Elliotson's mode of conducting either his course or his argument, we shall give his own account of it:—"I commence," says he, "with an account of what is meant by disease." "I examine the nature and operation

of the various causes of disease in general." "I then proceed to the history, nature, and treatment of general diseases." "I arrive at the diseases of individual parts." "I proceed through the head, chest, and abdomen." "I illustrate by individual diseases all the general principles." "I exhibit all the morbid preparations," &c. &c. &c. All this information, with *I, I, I*, in the van, would naturally lead any one to suppose that the plan described was something absolutely novel, and totally different from the system adopted by others. Now, from the document before us, we have no doubt that Dr. Elliotson is firmly persuaded of this, and implicitly believes that no one in the three kingdoms but himself knows that a course of lectures on the theory and practice of medicine ought to comprehend the pathology and morbid anatomy of the diseases treated of. The same general observations have been made in his introductory lectures, and on a variety of other occasions, by the learned Doctor, but perhaps never so very broadly as now; for all this preliminary setting forth of methods generally adopted, as if they were peculiar to himself, is followed up by the modest and unassuming recommendation to the Senate of the University, as the simplest mode of getting over all their difficulties, "*That it should be declared that the course on the principles and practice of medicine must comprehend the subjects treated of in mine*"!!! Such are the words contained in a printed letter addressed to the Medical Faculty of the London University, bearing the signature—J. ELLIOTSON*.

The simplicity with which this re-

* The sentence, as printed in Dr. Elliotson's letter, contains a parenthesis, which we have omitted, because it separates the first and second clauses too far from each other. It runs thus:—"That it should be declared that the course on the principles and practice of medicine (which is, in truth, a course of general and special pathology in all its branches of pathogeny, etiology, semeiology, and therapeutics), must comprehend the subjects treated of in mine."

commendation is made cannot fail to be appreciated by all; but we take leave, in justice to other lecturers, to add, that it is not necessary for the Medical Faculty to issue the proposed mandate; and for this reason—that the courses of lectures on the theory and practice of physic, delivered in London, and probably every where else, with few if any exceptions, do already contain what Dr. Elliotson so gravely recommends as something new.

As to the general question of the expediency or in expediency of establishing separate lectures on Morbid Anatomy, we take the opportunity of repeating the sentiments we formerly expressed (see Leading Article, August 19th, 1837,) namely, that such a proceeding is wholly uncalled for, and inexpedient; the only example in this country of attendance on such lectures being rendered imperative, occurs in Edinburgh, where the arrangement was notoriously the result of a desire to serve Dr. Thomson; and the medical faculty of the University of London may rest assured that if a similar regulation be adopted by them, it will be regarded as a job to serve the interests of Dr. Carswell. By the way, neither he nor the Professor of Materia Medica is much beholden to their colleague for writing such a letter as that which has called forth these remarks.

PRESENTATION OF SIR CHARLES ALDIS.

It was announced in the Court Circular, a few days ago, that Sir Charles Aldis had been presented, at the Levee on the previous day, by Sir Henry Halford. May we ask, does the learned Baronet know the history of Sir Charles's knighthood? Is the President of the College of Physicians aware that the name of the party in question has been omitted from the list of mem-

bers of the College of *Surgeons*, in consequence of the transaction alluded to? To make the affair still more complete, the book which Sir Charles presented to his youthful Queen on this occasion, was nothing less than an exposition of his method of *curing* cancer without the knife, and on the abuse of mercury in the treatment of—certain diseases. *Proh pudor!*

MILITARY PUNISHMENTS.

IN our articles upon Military Flogging (vol. xx. p. 277 and 596,) while we condemned the inhuman manner in which it has hitherto been practised in our army, we ventured to express a doubt whether there was any thing objectionable in the punishment itself when restrained within the bounds of reason and humanity. In other words, though the old punishments of 800 or 1000 lashes were substantially death with torture, and the modern *mitigation* to 200 or 300 is still utterly indefensible, the philanthropist cannot make any valid objection to punishments of 40 or 50 lashes—punishments which are found in various countries to be perfectly efficient in repressing crime, without the disgraceful necessity of making the surgeon an aid to the torturer, while he stands by and carefully computes how much more suffering the sinking culprit can endure.

We will now proceed to a further consideration of this painful subject, following as our guide the spirited treatise of General Napier, to which we have been already indebted*.

Picketing is a species of torture which has happily grown obsolete. It consisted, we believe, in making the offender stand for a given time upon a pointed stake, where he could relieve himself from the pain endured by the

foot only by a forced position or violent exertion of the arms; and when the continuance of this exertion became impossible, the foot could no longer be relieved. General Napier thinks, that if torture is to remain as a military punishment in time of peace, the picket is preferable to the cat-o'-nine-tails; because he supposes the former to be attended with no danger to life, the culprit being well the moment his punishment is over, and no marks being left. To this it might be answered, that under proper regulation there would be no danger from the lash; that it is a doubtful advantage for torture to leave no mark; and that it is highly improbable that prolonged picketing is unattended with danger. Hence we cannot join in the regret that this species of torture has been disused.

To flogging itself, the General makes eight objections, namely, that it is torture; that it is torture of a very unequal infliction; that the culprit may have more or less obtuseness of feeling; that the infliction may vary, not only according to the will or strength of the drummer, but also according to the temper of the commanding officer and drum-major; that the state of the man's health cannot always be ascertained at the time when he is punished; that the danger to life is greater in a hot climate than in a cold one; that the first punishment is the most cruel, as the back of one who has been frequently flogged gets callous; and, lastly, that the lash brands the sufferer with indelible marks.

These objections are very forcible when urged against the enormous punishments of the old school, and those unjustifiably severe ones which are still allowed to take place; against those which we propose they would be comparatively feeble. The inequality of the punishment would still remain, it is

* Remarks on Military Law and the punishment of Flogging. By Major-General Charles J. Napier, C.B. London, 1837.

true; but this inequality exists in all other punishments. Thus we learn from Mr. Malcolmson's account (*MED. GAZ.* vol. xx. p. 279), that many men, particularly those of indolent habits, endure solitary confinement for four or six weeks, on bread and water, without injury; while in others a shorter period is ruinous to the health. In like manner fines, transportation, working on public roads, &c. &c., are unequal punishments, and are borne with more or less difficulty according to the means, temper, and stamina of the offenders.

Nevertheless some of the inequalities in the infliction of flogging, such as those resulting from the kind of instrument employed, and the duration of the infliction, might be abolished by proper regulations. This would put an end to all refinements of vengeance; such, to give an instance, as we find in the letter of Colonel Arthur to Major Bradley, dated Belize, July 15th, 1818:—

"In carrying the punishment awarded against the prisoner Reeves into execution, which I desire may not be hurried, but most impressively inflicted," &c.

General Napier says—

"I never would admit that drummers were to decide whether a culprit should be flogged with more or less severity; there is a certain degree of severity in the blows given by drummers, any great deviation from which an experienced eye can discover at once; and I always endeavoured to prevent the drummers from being more or less severe than this medium. If the soldier to be punished be not a favourite, if his crime have disgraced the corps, the drummers are oftentimes very savage, and more often they are so much the contrary as to deprive the punishment of its due effect, and almost to provoke the commission of crime."—*Remarks on Military Law*, &c., p. 172.

Hence it is clear that it would be necessary not merely to limit the lashes to a reasonable number, but also to fix most rigorously the manner in which

they are to be inflicted; otherwise your disciplinarians, looking back with a longing eye to the good old days of a thousand lashes, would use some instrument of prodigious power, a cat-o'-ninety-tails, or a scourge fit for the Furies, and make mince-meat of their victims in a few minutes; just as they tell us in books of travels, that a Russian hangman can kill a criminal, when it is thought desirable, by three or four blows of the knout.

It was a shrewd saying of Dr. Cullen's, that there are more false facts current in the world than false theories, and this is singularly exemplified in the present discussion. We showed in our last article on the subject, that authorities differ as to whether a general court-martial is limited to the infliction of 200 lashes, or not limited at all; in India it would seem, at any rate, that there is no such limitation. By a general order, dated Head Quarters, Camp, Moodkee, April 4, 1837, Robert McKin is sentenced to 500 lashes, for having struck Serjeant Winter*. General Napier, again, is very indignant at the practice, which he supposes to exist, of flogging women, in England†, and says, "It is surely high time to abolish this remnant of barbarism;" when the fact is, that it has been abolished nearly eighteen years‡.

Another strange fact relating to this subject is, that Lord Wm. Bentinck, then Governor-General of India, abolished flogging among the native troops on the 24th of February, 1835; thus paying a compliment to the easy *corrigibility* of the Hindoo, at the expense

* *Morning Herald*, Nov. 6, 1837.

† *Remarks on Military Law*, &c. p. 157, note; and p. 201-2.

‡ "The punishment of whipping has been long recognized by the English law, the statute of 22 Hen. VIII., c. 12, directing all vagabonds taken begging to be whipped. But by 1 Geo. IV. c. 57, this punishment is very properly abolished with respect to females, and imprisonment to hard labour, or solitary confinement, is substituted in its stead."—*Drakon's Digest of the Criminal Law of England*, p. 1376.

of the Briton. Lord William, in his evidence before the Commissioners appointed to inquire into military punishments, states his belief that this difference will not create any jealousy on the part of the European troops; he probably thinks that the British soldier will cry out, like the swain in Virgil, *Non equidem invideo, miror magis!*

There is no doubt that one of the chief difficulties in the way of the abolition of flogging is the indifference to it which habit has produced in the minds of military men. On this point we have General Napier with us; for he says, "it is to be observed, that when men are charged with the infliction of any punishment (no matter how revolting it may be in its nature), they generally become desirous of adding to its severity: their minds grow hardened by seeing such punishments inflicted, and they erroneously believe that the bodies of their fellow-creatures grow equally indurated. To correct this horrible disposition to cruelty, which seems inherent to our nature, reason must interfere, or the heart becomes steeled through the eyes*."

And after telling the story of the old woman skinning the eels, he adds—"Those who are accustomed to see and inflict horrible suffering, as the old woman was, lose the power of feeling for their victims, and fancy the infliction not to be sufficiently severe, because it has ceased to excite their own sensibility†." Yet, at p. 140, the General asserts, that it would be utterly false to say that those who are in favour of

military flogging advocate its continuance from want of feeling!

Nil fuit unquam
Sic dispar sibi!

General Napier thinks, on the whole, that it may be safely dispensed with in time of peace, and that it is better to shoot, hang, or transport, a soldier-thief, than to habituate troops to the sight of flogging; but on a campaign, "the army cannot afford to lose the bayonet even of a thief."

ON ANIMAL MAGNETISM.

No. II.

FROM the theories we proceed to the facts, real and false, of this art, and these we shall consider in the order of their importance. We shall endeavour to show that there is not a credible effect said to be produced by animal magnetism, which does not occur under certain other circumstances, from causes of which one or more is in operation during the supposed exercise of magnetic influence. As the causes to which we shall ascribe the different symptoms act alone, and certainly, in many cases, there can be no reason why in others in which magnetism is employed in conjunction with them, their action should be denied, and all the effects ascribed to the other agent, whose presence and nature are altogether hypothetical. A sufficient cause for the production of any phenomenon being proved, it is contrary to all reasoning to ascribe the same phenomenon to any second cause, unless the operation of the first be clearly disproved, or *à fortiori*, while the first is acting.

Of the slighter effects produced by animal magnetism we have but little definite account, authors having generally related only the more extraordinary of the results obtained. On the majority of persons no influence whatever is exhibited; on those least affected a number of anomalous slight symptoms are produced; a sensation of heat or of coolness in the part operated on, which sometimes appears to follow the hand of the magnetizer; a feeling of creeping or trembling over all the body, or wherever the influence is said to be most

* As an instance to show how the bystander becomes hardened as well as the inflicter, we may mention the celebrated proposal of Paley, in his *Moral Philosophy*. He lived in hanging days, when there were two hundred capital offences on our statute-book; and imagining, therefore, that the eels had become used to skinning, he puts forth a suggestion, that some criminals should be thrown alive into dens of wild beasts. Yet Paley was at bottom a mild, good-humoured man.

† Remarks on Military Law, &c. p. 146.

strongly exercised; a slight increase in the frequency and fulness of the pulse; the respiration somewhat hurried; occasional blushing; restlessness, or rather the feeling vulgarly called the *fidgets*, or the *vapours*; slight twitchings of the muscles of the face, or of the part operated on; or yawning and sighing; calmness and quietude, followed by slight drowsiness and desire for repose; heaviness of the eyelids and the limbs; apparent fatigue; dozing; and at last more or less sound sleep, with or without dreams.

Assuredly, none but magnetizers could have thought of ascribing such common things as these to any uncommon cause. The feelings of heat and cold, and those of creeping and trembling, for example, which they would have to result from the entrance or exit of the magnetic fluid, are to us only the usual imaginary feelings which most persons have if their attention be strongly directed to any particular part of the body, more especially if (as is generally the case with magnetic patients) something is expected to occur. Our reader may at once experience this: let him direct his attention to one of his feet, steadily and intently for a few minutes, keeping it all the time quite unmoved; he will very soon perceive sensations of restlessness, or slight itching in it, and if at all nervous he will find the muscles begin to twitch, or cramp come on, so as to oblige him to change its position. Every one must have felt the painful tickling of the palms of the hands, or other parts of the body, during anxiety, or when awaiting something that will at last come suddenly as an electric shock. Long before the knife, or other instrument expected to produce pain, has touched the body, a shivering *retreating* sensation is felt or imagined in the part; and hence many may really be said to cry out before they are hurt, from feelings for which there was no external cause; and so when a blow is suddenly struck at a person, although contact does not take place, he perceives an evident sensation.

The approximation (without contact) of the tips of the fingers to the secretive part of the body, as to the space between the eye-brows, the spot selected by many magnetizers, gives rise to a slight tickling sensation, which produces annoyance and restlessness in some, and

tranquillity in other persons. It may depend in part on the transmission of heat from one to the other, but its more especial cause is shown by this—that if a healthy person who has perceived the sensation when his eyes were open, be made to close them, he can no longer tell with accuracy whether the fingers are approximated to his face or not.

These and the hundred similar instances of subjective sensations which we might quote, are sufficient evidence that the slight sensations experienced during magnetic manipulations *may be* imaginary. M. Bertrand says, that the effects he has produced have always been proportionate to the conviction of the patient. In all these cases, there is attention strongly directed to different parts of the body; an expectation of something occurring; anxiety, or even fear, any one of which is cause sufficient, and in other similar cases actually efficient. Why seek for another in pure hypothesis?

The same explanation is sufficient for the slight disturbance of the circulation and respiration, which indeed are rarely undisturbed by impressions on the mind, however slight, and are sometimes so affected by the more powerful feelings of fear and joy, that death itself is produced.

For the other slight symptoms of *vapours*, drowsiness, and at last natural sleep, no other cause need be sought than the tediousness and *ennui* of passing the hands for more or less than an hour over the most sensitive parts of the body. This is only an instance of the well-known effect of weak monotonous impressions on the senses inducing sleep; analogous examples are found in the soothing influence of a body seen slowly vibrating, or of a distant calm scene, or the motions of the waves, or of quivering leaves; or in impressions on the sense of hearing by the sound of a water-fall, the rippling of billows, the humming of insects, the low howling of the winds, the voice of a dull reader; or on the nerves of common sensation by gentle friction of the temple or eye-brow, or any sensitive part of the body; the rocking of a cradle; any slow and regular motion of the limbs, or trunk;—all these instances show that the effect of monotonous impressions on the

senses is to produce, in most persons, tranquillity, or drowsiness, and ultimately sleep. In some, indeed, they produce another magnetic symptom—restlessness, malaise, or the *vapours*; and this is especially the case with those on whom magnetism is said to act most powerfully—viz. the nervous and sickly, in whom the same monotony that more commonly favours sleep, is sufficient to maintain all night in restless watchfulness.

For the production of some of these symptoms, too, we may suspect the influence of imitation, which possesses a power clearly seen in producing sleepiness; as when the figure of a gaping man is shown to one slightly fatigued, or when one person in a company yawning, all the rest follow; or in the trick of slowly opening the hand before the eyes of an irritable person.

Here, then, for all these slight symptoms we have causes more than sufficient; for many of these will produce them on all persons, of whatever temperament, while they follow magnetic manipulations in only a portion of those submitted to its influence. Indeed, if there be any thing remarkable, it is that any body can sit for an hour unmoved, while another is, with all gravity, looking him intently in the face, and *pawing* over him. Human patience can scarcely endure to *think* of the dulness of such teasing.

Now one or more of the causes we have mentioned—either fixed attention, imagination, anxiety, fear, ennui, fatigue, the influence of monotonous impressions, or imitation—is present in every instance. It is *certain* that the effects *may be* the results of these, and it is therefore quite irrational to suppose them to depend on the superadded influence of animal magnetism, which is entirely hypothetical, and of the existence of which we have no evidence except from those facts which are clearly explicable by the analogy of similar phenomena.

The next effect which we shall notice is the state of *crisis* which Mesmer was in the habit of producing. The symptoms observed in this state were violent convulsions, constrictions of the throat, with sensations of suffocation, as if a ball were lodged there; spasms of the abdominal muscles, pain at the epigastrium, crying, laughing, and hiccup; spitting of a thick, viscid, and sometimes bloody

fluid; flushings of heat and sweating, or sensations of chilliness. As soon as one was seized, another followed; and, before long, nearly the whole of the patients were similarly affected; while the sight or a movement of the principal magnetizer seemed sufficient at once to calm them, or a word from him would give a different appearance to their symptoms.

Now we would refer to the judgment of any man of average ability, who is in the habit of seeing many persons affected with hysteria, whether these symptoms are not daily under his observation—nor these alone, but others far more extraordinary, and to non-professional persons even frightful. It would be difficult indeed to say what symptoms *never* occur in this disease. Sydenham said that, at various times, they “resemble most of the diseases wherewith mankind are affected;” and it is unfortunate that, amidst such a choice as he might have produced, Mesmer should have presented only those which are, as it were, its generic characters, and present in nearly all cases.

The symptoms, then, of the *crisis* are those of hysteria; the causes, too, are alike in both. It is well known that the hysterical paroxysm is very generally produced by fear, or anxiety, or anger, or vexation; that talking about it, or thinking intently on it, will often bring it on; above all, that imitation is an almost irresistible cause of it; while among the most strong predisposing causes is an excited state of the animal passions, the presence of the opposite sex, and an habitual desire of attracting attention. Now of all these Mesmer took advantage; they were his real apparatus, which the tubs and pipes so often described only served to conceal, by giving an appearance of a really active electricity; for few, if any, of his patients were of a class who could know the impossibility of disturbing the electric equilibrium by glass bottles and water. All Mesmer's arrangements were well adapted for producing a powerful impression on the minds of his patients. They were all assembled in one large apartment, and seated around an impressive-looking apparatus, while a dim mysterious twilight only was shed upon them from without, or from a few lamps; notes of soft music were heard from a concealed corner; and young men, selected for their beauty

and robust forms, began to perform the various manipulations of the art, passing their hands over the face, bosom, body, and limbs, of each of those who sat around, in silent expectation of some extraordinary sensation, of which they had heard from Mesmer or their friends. Is it wonderful that ardent and voluptuous French girls should blush, or that their pulses should quicken, or that their breathing become rapid, under such excitement as this? or that a worn-out old *debauché* should perceive unusual sensations? or that the nervous and debilitated should tremble at such treatment? When all that excitement of the animal passions—imagination, anxiety, love and lust—could accomplish, then Mesmer himself entered the apartment, habited in delicately-coloured silk, and wearing an air of deep gravity and importance: walking about as if endowed with magic power, he presented to each in turn a rod, or his hand, which *they were told, and believed*, was charged with the magnetic virtue. Some of them were then at once seized with hysterical fits, and all the others, by imitation, followed them. “As soon as one began,” says the first report, “another succeeded.” “The convulsive state,” says M. Du Potet, “once excited in a patient, never failed to manifest itself in all the others.”

Here, then, we have every circumstance pointing out the true nature of the crisis. The patients were nearly all women, and these the most frivolous of the voluptuous court of Louis XVI., during the most licentious period of modern France; there was therefore the favourable predisposition in ardent animal passions, in a superficially cultivated intellect, in a body weakened by dissipation, and a mind yearning for some new and powerful excitement; there were expectation, anxiety, and perhaps some fear of strange and novel feelings—for Mesmer never failed to let his patients know what might (and *therefore would*) be the effect of the magnetic influence: there were the awe with which ignorance looks up to one supposed to possess supernatural power, the heated passion excited by the meeting and the contact in no decent degree of the opposite sexes, and perhaps some modest fear. With these it would have been more remarkable if the patients had not been affected with hysterical paroxysms; but these once excited, the most powerful of all their exciting causes, imi-

tation, at once came into force. The influence of this is estimated only by those who have seen it. It is but a short time since we saw nearly every woman in a large surgical ward in hysterics, the example for which had been set by one who saw a slight operation performed on another patient. Dr. Bright mentions a similar case. Dr. Darwin speaks of a number of nuns who were successively afflicted with hysteria, and amongst other symptoms, an anxiety to imitate the squalling of cats. Dr. Whytt describes a disease common in the Island of Zetland, which affected a number of young unmarried women, and some few of the opposite sex. There were violent palpitations, convulsions of the limbs, and difficult respiration. If one was seized in the market, or at church, all who had ever been affected before directly followed the leader, and each such general disturbance was sure to increase the number of convulsionnaires. Boerhaave had a similar case in a number of boys and girls in a charity-school at Haarlem, and Dr. Haygarth another in Anglesey, where in two or three months 18 girls were affected with pains in the head and side, convulsions, and other symptoms, which magnetizers would have called magnetic. In short, the acquirement of even severe hysterical affections, if not of epilepsy and other nervous disorders, by imitation, is well known, and its occurrence guarded against by every practical physician, and even by the public.

We lay the more stress on this as a cause of the supposed magnetic symptoms, because it is one that the magnetizers themselves (very few of them being practitioners) cannot know the importance of, and because its influence has been evident in the account given by every one of them, however different the effects they produced. Thus, all Mesmer's patients had the commoner form of hysterical fits, and *all were affected alike*; the same was the case with Deslon's. Puysegur discovered somnambulism, and immediately he had few but were somnambules (a state unknown to Mesmer), and he said that every patient was affected according to the system and wish of the magnetizer: he himself desired somnambulism, and all his patients had that affection. M. Petetin wished for cataleptics, and in less than two years he had in the then small town of Lyons eight cataleptic cases,—a greater number we believe than has occurred in

all England during the same period. And thus it has continued. The series of symptoms which each magnetizer induces may, as Puysegur said, be whatever he pleases: he has but to make one case for a model, and this he may shape and frame by descriptions of desired results, before exciting the mental feelings, and all the rest will at once accurately imitate it. We have no doubt whatever—for from what little has already been seen or published it is even now nearly evident—that the generic character of all cases of magnetic hysteria produced in this country will be the easy sleep of M. Du Potet, and the raving, abusive, and convulsive form of Dr. Elliotson.

If further proof of the hysterical nature of the crisis were wanting, it may be found in the cessation of these symptoms when the causes to which we have referred them ceased to be made use of. It would be difficult else to explain why the same state never occurs now; for the magnetic agent must be the same, and therefore why not the effect? We can easily imagine that it was *advisable* the crisis should be given up; it was too violent, and not marvellous enough; at times too painful to the patient, and alarming to the by-standers; not to add that it had been made the means on no few occasions of gratifying the passions whose exaltation had favoured its production. The twilight chamber, the large assemblies of both sexes, the mystical apparatus, the magic dress, and the awful appearance and gestures of the arch magnetizer, were therefore given up, and the common form of hysteria which they had produced was exchanged for the mild and comparatively pleasing somnambulism which the philanthropy of M. Puysegur engendered.

It may be said by a few that the fact that the *crisis* occasionally occurred in men, disproves its hysterical nature. But this is an error; though more rarely, it is well known that symptoms precisely like those of hysteria in women occur in the opposite sex, especially among those who present the same peculiarities of temperament and external characters as the females subject to it—who are easily excited to grief or joy—who are of irritable or variable temper, and of weak or moderate intellect, of generally delicate health, or debilitated by disease—and who are what is loosely but expressively called *very nervous*. These are the *only* individuals of the

male sex who are obnoxious to hysteria or to the influence of magnetism—a fact which, while it assists in proving the correctness of the view which we have taken of it, disproves completely any theory that has yet been invented.

REPORT

LAID BEFORE

THE GENERAL COURT OF GOVERNORS
OF THE

Small-Pox and Vaccination Hospital,
1st of February, 1838.

BY GEORGE GREGORY, M.D.
Physician to the Hospital.

My Lords and Gentlemen,

I BEG to place before you a statement of the principal occurrences within the Hospital during the past year, and this I do the more willingly, from a conviction that the facts I have to adduce are calculated, by shewing the great utility of the institution, to attract towards it that share of public patronage which it enjoyed in former times, before vaccination shrouded it in a measure from the public notice.

The hospital received within its walls, during the year 1837, 251 patients, of whom 12 laboured under eruptive diseases, not of a variolous character. There remain 239 cases of true small-pox, who here found a refuge, relieving thereby numerous families from extreme inconvenience, and withdrawing from the crowded population of this metropolis so many sources of infection and danger. Of the 251 cases admitted, 94 were females, and 157 males.

There were admitted,

Under seven years of age	29
Between the ages of seven and fourteen ..	27
Of fourteen years of age and upwards ..	195
Total	251

Of these there were received,

With letters of recommendation from individual governors	16
With letters of recommendation from parishes	101
On payment of one guinea (chiefly servants in gentlemen's families ..	41

As objects of charity,

From the several hospitals and public asylums of London	29
On their own application, and without any recommendation but their sickness and poverty	61

Total 251

I would beg to invite the particular attention of the governors to the fact, that nearly two fifths of the patients, during the past year, were admitted without any letters of recommendation, and simply as objects of charity; and to add my belief that this may be assumed as the average practice of the hospital for a long series of years past.

The admissions were very far from being equally distributed through the several seasons of the year. The accompanying Table will shew, that during the first three quarters they were comparatively few. About the middle of October small-pox began to prevail as an epidemic in London, and increased to such an extent, that 70 patients were received in the course of one month (December), a circumstance hitherto unparalleled in the annals of the hospital. This epidemic still continues.

Table of Admissions into the Small-pox Hospital during the year 1837.

January	5	25
February	8	
March	12	
April	8	12
May	11	
June	20	
July	11	44
August	14	
September	19	
October	27	140
November	43	
December	70	
Total	231	

The general character of the disease, during the past year, has been mild. The deaths have amounted only to 46, equivalent to 19 per cent., which is an unusually low rate of mortality.

The number of cases subsequent to vaccination, has been considerable, amounting in all to 95, or 40 per cent. of the total admissions. Of them, nearly one-half (46) had small-pox in that peculiarly mild form, called the varicelloid. These cases are devoid of all danger, and are sent into the hospital chiefly for the security of others. The remainder (49) took the small-pox in various degrees of intensity. Many were for a time in danger; but of the whole number one only died. The records of the hospital, this year, corroborate the important principle, that the susceptibility of small-pox increases with the interval from the date of vaccination. Eight children only (of ages varying from seven to fourteen years) were received having small-pox after vaccination; while of adults (between the ages of fourteen and thirty-five) the number admitted having small-pox after vaccination, was 87.

It further appears, that not only the fre-

quency but the severity of the disease increases with the distance of time from the period of vaccination. The eight children, just mentioned, had each the disorder in the mild or varicelloid form. The severe cases of small-pox after vaccination occurred exclusively among the adults.

In these facts there are still abundant sources of consolation. While we acknowledge, on the one hand, that the security which vaccination affords against the inroads of small-pox is neither so uniform nor so permanent as had been anticipated, we see, on the other, that vaccination can, in a measure, strip small-pox of its malignity, and reduce it to the character of a mild, and comparatively harmless disorder.

The bills of mortality announce only 217 deaths by small-pox, in 1837. Owing to the recent law of registrations, these documents are avowedly much less to be depended on than formerly. Making all due allowance, however, the past year appears to have given the fewest victims to small-pox of any year which has elapsed since the bills of mortality were established in London. The number of cases may have been as great as in former years, but the difference is in the rate of mortality.

I shall next advert to the vaccination department of the hospital, which this year presents a novel and interesting feature. The number vaccinated during the year amounts to 3,078. Besides which, lymph has been supplied to 1,013 medical practitioners and others.

The lymph in use at this hospital had been preserved, in uninterrupted descent, for a very long period of time; but for three or four years past, I had noticed that its intensity was diminished, and that eight or ten incisions produced not more irritation than the three to which I was accustomed fifteen years ago. In March last, Mr. Marson, the resident surgeon, employed lymph obtained from a different source. This new lymph was found to be far more intense and active than the old lymph. Three or four incisions were now found amply sufficient; and so satisfied was I of the superior quality of the new lymph, that, after a careful trial of about two months, the old lymph was suffered to die out, and for the last six months we have vaccinated exclusively from the new stock. These facts have convinced me, that vaccine lymph, by passing through the bodies of many persons, loses, in process of time, some essential portion of its activity. It follows from this, that an occasional resort to primary lymph from the cow becomes a matter of great importance, perhaps even of indispensable necessity.

Through the kindness of Mr. Sewell, of the Royal Veterinary College, I have re-

cently obtained fresh matter from the cow, with which trials have been made. Although these have hitherto been unsuccessful, I shall pursue them, as opportunity offers, and avail myself of all favourable occasions for trying new varieties of lymph. The existence of two forms of vaccine virus, possessing different grades of intensity, is now clearly established. Others may possibly exist. At any rate, the selection of an active virus is a matter of such obvious importance to the successful practice of vaccination, that I shall continue to direct my earnest attention towards it.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

Saturday, Feb. 10, 1838.

EDWARD COCK, ESQ. IN THE CHAIR.

MR. DENDY read a paper—

*On Effusions into the Membranes of the Brain
and Spinal Marrow.*

He referred briefly to the discrepancy of pathologists regarding the origin of these effusions, Cheyne, and Goelis, and Abernethy, having asserted that hydrocephalus may usually be traced to ramollissement, or hyperæmia, or effusion of lymph in the alimentary canal; while Spurzheim and some of his disciples, in reference to cause and effect, affirm that the cerebral is always the primary, the intestinal the secondary disorder.

He then alluded to the varied situations of the effused fluid, beneath or within the envelopes of medullary matter, and to the extensive intercommunication, which often reduces the ventricle and spinal sheath to one cavity.

"In the description of acute and chronic effusions into medullary membranes, authors have employed a latitude of expression, as if they consisted but of one serous tissue, like the pleura or peritoneum, and as if the fluids were all alike, and poured into one cyst.

"The minute anatomists have, on the contrary, differed as to this locality. Bichat, and indeed the majority of pathologists, fixing on the serous bag of the arachnoid, while Andral, Magendie, and Dr. Green, have decided on the subarachnoid tissue, or pia mater."

"The effusions may be referred to two principal divisions:—

"1. As the result of abnormal or dis-

eased action—the acute, or inflammatory, or febrile forms—the deposit of fluids and films morbid in their nature.

"2. An excess of normal secretion—the conate or chronic forms—resulting from intra-uterine derangement.

"The termination of the acute forms, hydrocephalus and inflammation of the spinal membranes, in limpid effusion, were most strongly marked in the puerile stage, when the balance of circulation between the sanguineous and absorbent systems is in constant danger of disturbance.

"In most cases there is an essential proneness or predisposition, closely allied to struma."

Mesenteric disease, conjoined with hydrocephalus, and the acute disorder attacking one child after another, had been observed by the author. In one family six were snatched away by rapid effusion—the water stroke.

"It is in these cases that our plans of treatment are so constantly inefficient."

"When meningitis occurs in children of a different temperament, the fatal termination is marked by other characters.

"We have in these membranes two species of inflammatory action—the phlegmonous and the erythematic or tubercular.

"In the first there is more combination of arachnitis with the diseased action of the pia mater, and it is marked by a rapid course; while in the second, it is either the sequela of a subacute form, or comes on by stealth.

"The morbid products of the two forms are usually different. In the first, lymph, false membrane, or purulent deposit; in the latter, generally serous effusion.

"Probably these results may be also influenced by the nature of the membranes on or by which the fluids are poured out. Cases have occurred where aqueous fluid has been found on the pia mater, and a purulent deposit within the cavity of the arachnoid."

The author considered it a question to be decided whether the usual termination of subarachnoid meningitis and arachnitis were essentially different in their character, but thought it probable that medullary ramollissement and granular deposits depended essentially on the former, while thickening and films of lymph were chiefly confined to the latter.

The second part of the paper was devoted to the excess of the normal secretion or cephalo-rachidean fluid, cases widely different from the sequela of encephalitis, and to which alone the term hydrocephalus should be applied.

The observations of the author related to two points interesting both in an anatomical and pathological sense.

The situation of the cerebro spinal fluid, and the origin of conate hydrocephalus and spina bifida.

The first were adduced with a view of testing the opinions of Magendie regarding the seat of the fluid.

It was found that the analysis of the fluid did not yield the constituents of serum, which we might expect if it were contained in a serous bag. Then, regarding the distribution of the arachnoid, it had been a subject of dispute, whether the arachnoid passed into the ventricles by the veins of Galen, as Bichat states, or not.

"Magendie asserts that it does not line the ventricles, but that their cavities communicate with the subarachnoid tissue, and in this is the cerebro-spinal fluid seated. Were this so decided, it would refer the pathology of the conate hydrocephalus, as well as the effusion of granular meningitis, to the pia mater instead of the arachnoid, and might explain the comparative results of our treatment in these cases. In illustration of Magendie's views, it might be difficult to explain the intricate insinuation of the fluid among the convolutions, and also the facility with which sanguineous effusion from the vessels of the pia mater communicates with the surface of the brain and the ventricles, and even descends to the sacrum, the arachnoid remaining *entire*."

Regarding the conate effusions, Mr. Dendy argued, that they might not always depend on osseous deficiency, but that the bifid spine, as well as the enclosed sutures and enlarged crania, might be the result of the pressure of the cerebro spinal fluid from within outwards. "We know that excess of this fluid will stunt by compression the growth of medullary matter, keeping down the cerebral mass to a mere tubercle, consisting of olfactory nerves and corpora striata, and checking the development of the spinal medulla. Thus, I believe, will the centrifugal tendency, or determination outwards, often induce the non-coalescence of osseous sutures. In one case, in which I operated repeatedly, the base of the tumor was a shut lateral ventricle, the fluid having pressed upwards, carrying with it the ceiling of the ventricle, and bulging through a fissure of the parietal bone. May we not, indeed, sometimes regard these openings as the modes of nature to avert the dangers of compression from fluid excess? In the acute disease, where we may have, indeed, absorption, and a renewal of ossific deposit, we have seen re-excitement produce fresh effusion, the sutures have again expanded, and the disease has been re-established for a time.

If ossification had been in these cases complete, the subjects would have probably died with symptoms of compression: this,

indeed, is very speedily the result of hydrocephalus and hydrorachitis, when the cranium and spinal canal are shut.

In the course of the discussion which followed the paper, a difference of opinion arose as to whether the cerebro-spinal fluid was contained within the arachnoid or in the sub arachnoid tissue. Mr. Hilton, on being requested to give his opinion, said, he had no doubt that the cavity of the arachnoid contained it, and disagreed with Magendie, who had asserted, that the ventricles were not lined by that membrane. The chairman, on being particularly called upon by Mr. Dendy, expressed his full concurrence with Mr. Hilton; he quite believed that the cerebro-spinal fluid was contained within the cavity of the arachnoid.

At the next meeting of the society, February 24th, Dr. Guy in the chair, Mr. Birkett will read some cases of syphilis, with observations.

In-Patients 16

Out-Patients 41

Total 57

Two cases of strangulated hernia were operated on: the subject of the first was a female, aged 45, who had been labouring under the severest symptoms of strangulation for a week. There was a very small femoral hernia on the left side. The operation was immediately performed, and the intestine, which had completely lost its natural appearance, was returned. She recovered without a bad symptom.

The second case was that of a young man, who had had an inguinal hernia for some time, for which he had worn a truss; this, however, he had ceased to do for the last year, in consequence of a portion of the hernial tumor remaining constantly in the sac. Symptoms of strangulation had

existed for thirty hours. After unsuccessful attempts at the taxis, whilst in the warm bath, and the application of ice, the operation was performed. The stricture was formed by the neck of the sac, which had become much thickened; the intestine, dark in colour, but not in the least disorganized, was returned, and a portion of adherent omentum was excised.

The man died on the ninth day after the operation, without any relief from the bowels.

It was found, on examination, that the portion of intestine, about five inches in length, had never recovered its proper appearance, but although not sphacelated, yet was dark and contracted, and seemed incapable of transmitting onwards the contents of the bowels above. There were two lines of ulceration of the mucous membrane in the situation of the stricture, as if nature had commenced a separation of the useless part. There were traces of peritonitis, but by no means intense.

CHOROID GLAND OF THE FISH'S EYE.

To the Editor of the Medical Gazette.

SIR,

IN my recent communication on the so-called choroid gland of the fish's eye, I mentioned that its real nature was still very much misconceived by anatomists. I was not then aware of Mr. Owen's observations on the subject, which show that the vascular structure of the body had not escaped him, otherwise it would have given me great pleasure to have adduced such an authority in confirmation of my description.

Mr. Owen's remarks contained in the 3d volume of the Physiological Catalogue of the Hunterian Museum, 1836, are the following:—

"1656, Parts of the sclerotic coat, membrana argentea and choroid gland of the Moon-fish, to show the structure of the latter substance, which is peculiar to osseous fishes. It is always situated between the silvery membrane and the true choroid, and is extended more or less, and in different forms, about the termination of the optic nerve, which is here preserved. In the present species it almost completely encircles the nerve in the form of an oval ridge, and its structure appears fibrous, whence it has been considered muscular; but the fibres consist in reality of minute parallel and closely disposed vessels, which in the recent state are of a bright red colour. The use of this part has not been determined."—Your obedient servant,

T. WHARTON JONES.

TRIBUTE TO MR. EARLE.

To the Editor of the Medical Gazette.

SIR,

PERCEIVING by the MEDICAL GAZETTE of last week that a number of the pupils of the late Mr. Earle, residing in London, have expressed a wish to mark, in some appropriate manner, their sense of his worth and talents, I beg to suggest that the definite object of such meeting be made generally known by circular or advertisement, and that the subscription list be kept open for some little time, in order that the numerous though scattered pupils of that excellent surgeon and most estimable man may have an opportunity of assisting to render as emphatic and suitable as possible the deserved tribute to his memory.

Your obedient servant,

RICHARD MIDDLEMORE.

Temple-row, Birmingham, Feb. 20, 1838.

COLLEGE OF SURGEONS.

MR. TYRRELL has been elected a member of the Council, in the room of the late Mr. Earle.

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine,

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE IX.

Change of Colour in the Cineritious Substance of the Brain. — Change in Consistence. — Laceration. — Ulceration. — Scrofulous Tubercles. — Change of Colour in the Medullary Substance. — Ecchymoses. — Cloudiness. — The Medullary Substance of a Grey Colour. — Ramollissement. — Diffuse Suppuration. — Encysted Abscess. — Induration. — The preceding Changes sometimes unattended with any appreciable Symptoms during Life. — Effusion of Serous Fluid, Coagulable Lymph, Purulent Matter, and Blood, into the Ventricles. — Apoplexy. — Premonitory Symptoms.

Change of colour in the cineritious substance of the brain.—The cineritious substance of the hemispheres of the brain presents various morbid appearances, sometimes the result of natural disease, and at other times produced by external violence, with which it is highly important, in a judicial point of view, that you should be familiar, and able, in any given case, promptly and accurately to refer to their proper cause.

The cineritious portion of the cerebral substance is often the seat of inflammation, acute or chronic, and of congestion, active or passive. These affections are indicated by a change in the colour of the cineritious substance, which, from its natural grey colour, may vary from a rose red to a bright crimson, or from a dusky brown to a deep violet, or purple. The

brighter and the more intensely red the colour, the greater the evidence that it is the result of recent acute arterial action. The more dusky or purple the colour, the greater is the probability that the change is connected with interrupted circulation of the venous capillaries, constituting the state of venous congestion. When the arterial capillaries give to this portion of the cerebral substance a crimson colour, and when this colour extends over a large portion of the hemispheres, you may in general consider it as evidentiary that inflammation has been induced by some natural cause; but in proportion as this red or crimson colour is limited in its extent, and is distinctly circumscribed, it should beget suspicion that it has been produced by some cause acting specially on this particular portion of the brain—as a blow, a fall, or some other form of external violence. When the dusky or purple colour indicates congestion of the cerebral vessels, you should examine whether this state of congestion be confined to the blood-vessels of the brain, or whether it be connected with obstructed circulation in some distant organ, or have been produced by some external agent. You may find reason to conclude that the congestion is confined strictly to the cerebral blood-vessels; or you may discover in the lungs, in the heart, in that peculiar condition of the different viscera which accompanies fever, the true source of the congestion in the brain; or, on the contrary, this condition of the cerebral blood-vessels may afford one evidence of poison, or of death, from some form of external violence—as suspension, or drowning.

Change in consistence.—When the change of colour in the cineritious substance is the result of natural disease, its consistence is generally equally altered. It becomes more soft and pulpy than natural, and is either torn away from the convolutions, with the pia mater, on the slightest

touch, or, when that membrane is removed, is capable of being scraped away with the greatest ease.

Laceration.—But instead of a change in the colour and consistence of the cineritious substance, you may find it actually lacerated. This, of course, can result only from the action of some violent agent. You will, in general, have little difficulty in determining what that agent is. The effusion of blood may have broken down the cineritious substance. Then you will find the clot probably at the surface of the convolutions, and, on searching farther, you will discover laceration in the medullary fibres also, or some other evidence of an apoplectic seizure. But if you cannot succeed in tracing this event to any natural cause, you must bear in mind that it may have been occasioned by external violence (as concussion), for the evidence of which you will then seek.

Ulceration.—The cineritious portion of the brain, as well as the foliated surface of the cerebellum, is occasionally the seat of ulceration. This is not a common occurrence, but you may meet with it. On different parts of the hemispheres appear spots of various extent, with ragged edges and sensible loss of substance. On the ulcerated spots the pia mater and arachnoid are commonly destroyed: sometimes the spot presents the appearance as if a clean excavation of the cerebral matter had been made, and the excavated surface is covered either with bloody or with purulent matter. From this condition of the brain, taken alone, you can determine nothing as to the cause of death. It is sometimes the result of natural disease, but it is often the consequence of mechanical injury; and when you meet with it, you must search for other indications of disease, or of violence, before you can determine the true nature of the case.

Serofulous tubercles.—The cineritious substance is the common seat of those depositions of adventitious matter which are called serofulous tubercles. These bodies are often wholly confined to the cineritious substance, until by their increased growth they pass, on the one hand, into the white matter, and on the other, become adherent to the pia mater and the other membranes.

They vary greatly in size, from that of a millet-seed to that of a pea, and sometimes they attain to the magnitude of an egg. Like the tubercles of the lungs, they appear sometimes to remain perfectly quiescent for a long time after their formation, but at length they begin to soften in the centre, and then constitute a kind of abscess surrounded by a firm cyst, very analogous to that of the softened tubercle of the lungs. While quiescent and of small size, they may occasion no appre-

ciable inconvenience; but when at length they become active, grow, soften, and form cysts of purulent matter, they produce violent irritation. This irritation often manifests itself quite suddenly in some severe form of cerebral disease which proves rapidly mortal. A child may be in apparent health. Stopping suddenly while at play, or waking up in the middle of the night from sound sleep, with a scream, it may complain of violent headache; or without any pain, it may suddenly become pallid, faint, and perfectly prostrate, and from that moment with appalling rapidity may supervene the most urgent symptoms of acute hydrocephalus. On examining the brain, you may find different portions of the cineritious substance studded with tubercles, in a state of softening, with or without serous effusion.

Change of colour in the medullary substance.—Notwithstanding the countless number of blood-vessels with which the medullary substance of the brain is pervaded, it is when perfectly sound almost a pure white. On a circumscribed spot, or over an extended surface, you may find this substance changed from a white to a pink or a deep red colour: a change which you may regard as evidence of active inflammation of the brain, even though there be not the slightest appreciable alteration in the consistence or structure of the cerebral matter. This evidence you may consider as greatly strengthened when on making a section of the brain you find the points of blood from the cut surface increased in number; when the points themselves are larger than natural, forming blotches rather than minute points; and when, as the scalpel passes over the cut surface, drops of fluid blood ooze from the vessels. You are called to examine a case of very rapid death. On inquiry into the history of it, you find that the person was attacked suddenly with headache; that the headache was followed quickly by delirium, delirium by coma, and coma by death; or to the headache succeeded violent convulsions, in a paroxysm of which the patient expired. On examining the brain, you find no appearance of disease whatever excepting this red tint, which is restricted to a circumscribed spot, or which pervades in a greater or less degree the whole extent of the medullary matter. Here is an adequate cause of death, and whether the redness be limited or circumscribed the cause may be natural disease. Nevertheless, whenever the redness is distinctly circumscribed, search diligently for evidence of mechanical injury, because inflammation thus limited in its extent is very frequently the immediate consequence of external violence.

Echymoses.—If, instead of red points or

blotches, you find numerous minute ecchymoses, like petechiæ, of the medullary substance, you may consider this appearance as unequivocal evidence that the circulation of the cerebral blood-vessels has been from some cause or other greatly obstructed; obstructed to such a degree that some of the capillary branches have given way, and allowed the escape of minute portions of blood. This can scarcely happen from any natural disease seated in the brain itself; but it may result from great obstruction to the circulation, in consequence of disease in some distant organ, as the lungs or heart. Often, however, it is entirely the result of mechanical violence. One characteristic mark of severe concussion is the appearance of little round spots of ecchymoses, the result of ruptured vessels; the spots varying from the size of a pin's point to that of a pea, and situated in different parts of the brain.

Cloudiness.—But instead of blotches or ecchymoses you may find the clear white substance of the brain clouded, as if from staining; and the cloudiness may be either of a pink or of a purple colour. When it is of a pink colour, it indicates acute inflammatory action; when of a purple colour, retardation of blood through the cerebral vessels. Such retardation of the blood is the constant consequence of disease in some distant organ, as the lungs or heart; but on the other hand it is often the attendant on death from asphyxia, and more especially of death from suspension.

The medullary substance of a grey colour.—Sometimes as the result of natural disease, apoplexy, paralysis, convulsions, dark-coloured blood is accumulated in the minute vessels to such a degree that the medullary substance of the brain is changed from a pure white to a grey colour: an approach to this may also be the result of death from suspension.

Ramollissement.—Such are the changes of colour in the medullary substance to which it is important that you should direct your attention; but you will often find not merely the colour, but the consistence of this portion of the cerebral matter, essentially altered. By far the most frequent morbid change of this kind is that termed softening (*ramollissement*) of the brain. A part of the medullary substance becomes broken down into a soft pulpy mass, which at first retains its natural colour, and is without fœtor; but as the process goes on, the colour changes to a yellow, or grey, or greyish brown, and sometimes it acquires a reddish hue from the admixture of blood. The degree of disorganization varies from a slight diminution in the natural consistence of the medullary substance to a semi-fluid mass, which often presents the appearance of a

curd. The softening may affect any part of the brain; the surface or the substance of the hemispheres, the corpora striata, the optic thalami, the crura cerebri, any portion of the apparatus of union, and the cerebellum. It varies greatly in extent, being sometimes confined to a very minute space, and at another involving the greater portion of one lobe, or even of one hemisphere. It appears to result from two different causes. The evidence is indubitable, that in a great number of cases it is the direct result of inflammation, acute or chronic; but in some cases it would appear to be the consequence of a diminution in the supply of arterial blood to the part affected, from the operation of some cause which obstructs the circulation, and which thus produces a species of gangrene. Dr. Abercrombie suggests, that when any portion of the brain is deprived of its proper nutriment, in consequence of the nutrient arteries being from any cause rendered incapable of supplying it with the requisite quantity of arterial blood, it may lose its vitality or become gangrenous, just as any other part of the body.

Diffuse suppuration.—Sometimes the softened cerebral substance is evidently mixed with purulent matter, affording decisive evidence that the process of inflammation has been going on. Sometimes the inflammatory action being diffuse, and having no tendency to limit its progress by the effusion of lymph, or the formation of a vascular cyst, there is formed a large ragged undefined cavity, filled partly with purulent matter extremely fœtid, and partly with broken down cerebral substance, the surrounding medullary substance being soft and disorganized.

Encysted abscess.—But on the contrary, you will often find a well-defined regular cavity, filled with purulent matter, lined by a soft and vascular cyst, and surrounded by medullary matter in a healthy state. This constitutes the encysted abscess, the *apostema cerebri*. Collections of this kind appear often to have their origin in the development of the serofulous tubercles already described, which slowly grow, soften, and suppurate; but in other cases they seem to consist merely of a portion of cerebral matter itself, indurated by inflammation, and subsequently surrounded by a cyst of coagulated lymph, and deriving its vascularity from the fine vessels of the pia mater. Cysts of this kind appear to be readily formed in the brain during the slow process of inflammation, and they often arise spontaneously from internal causes; at the same time, however, it is important that you should bear in mind, that it is often possible distinctly to trace their origin to external violence.

Induration.—But inflammation, instead of softening, may indurate the brain. It is by no means uncommon to find the cerebral substance in general preternaturally firm and unyielding; at other times the hardening is partial, extending only to a small circumscribed portion; and this hardened part is often surrounded by a portion in a state of softening. When the induration is limited in its extent, you may succeed in tracing it to a blow or fall, or some other form of mechanical violence; but it may have its origin purely in internal causes, and a careful examination of all the circumstances of the case will often enable you to ascertain the true cause.

These changes sometimes unattended with any appreciable symptoms during life.—In general, inflammation of the brain, and the several morbid changes in the cerebral substance produced by the inflammatory action, are attended with such manifest disturbance of the functions of the organ, as to leave no doubt that it is the seat of serious and alarming disease. But this is not invariably the case, and it is of the last importance, in a judicial point of view, in all your examinations of the cause of sudden death connected with cerebral disease, that you should bear this fact in mind. Instances without number occur, in which decided inflammation of the brain, extensive softening, diffuse suppuration, encephalitis, abscess, and preternatural induration of the cerebral substance, exist during life without being discovered, or even so much as suspected. Persons in apparent health, but really labouring under one or other of these forms of disease, are seized so suddenly with violent symptoms, and die with such extreme rapidity, that the suspicion is actually excited that they have been destroyed by poison. An elderly sailor for months before had done duty, eaten his rations, and drank his grog, as usual. One day, while in the act of pulling his oar, he suddenly dropped down, and died at once. On examining the body after death, there was found in the middle lobes of the brain an extensive abscess, which had made its way to the surface. You can readily conceive of circumstances under which such a case of sudden death might give rise to the suspicion of the administration of one of the most powerful poisons; but the inspection of the brain would at once decide the question. Dr. Christison records a remarkable case, which actually did give rise to a strong suspicion of poisoning.

A man who had previously enjoyed excellent health was found one morning in a low lodging house, in the Lawnmarket, at Edinburgh, comatose and convulsed; he died several hours afterwards.

The neighbours spread a report that the woman of the house had poisoned him, with the view of selling the body for dissection. By an odd coincidence, it happened that the police, when they went to apprehend the woman, found an anatomist in the house concealed in a closet. The body was examined judiciously. An ulcer was found on the fore part of the left hemisphere of the brain, and a small patch of softening on each middle lobe. These appearances declared the true nature of the case, and were quite sufficient to decide that the death arose from a natural cause.

But you must bear in mind that softening of the brain, when not far advanced, is very apt to escape notice, because, as has been already stated, it is not necessarily attended with a change in the colour of the diseased part. There is reason to believe that it has been often overlooked, and that the death which it has occasioned has been erroneously attributed to simple apoplexy. Whenever you meet with a case apparently of simple apoplexy, search carefully through the substance of the brain, to see if you can find no point of softening in it.

Effusion of serous fluid into the ventricles.—The circumstances connected with the effusion of a preternatural quantity of fluid into the ventricles of the brain, occasionally present questions of considerable interest in a judicial point of view. The moisture which lubricates these cavities during life would appear to condense after death, so that in the healthiest condition of the brain they always contain some portion of fluid; but the quantity seldom exceeds a drachm in each lateral ventricle, and that contained in the smaller cavities is scarcely appreciable. In certain states of the system this quantity may increase somewhat during the process of death, or shortly afterwards; but when it exceeds two or three drachms, you may generally regard it as the result of some morbid action, the true nature of which it may be of great importance that you should clearly ascertain.

That a preternatural quantity of fluid may accumulate in the ventricles of the brain, as the result of acute inflammation, the evidence is indubitable. The inflammatory action may come on quite suddenly from a great variety of natural causes, and terminate in effusion with great rapidity. In a case of this kind, with febrile and inflammatory symptoms highly acute, death may take place in a few days or even hours. On examining the brain, you may be able to obtain from all its cavities not more than half an ounce, or six drachms, of fluid; yet this may have been a case of inflammation ter-

minating in effusion—a case of hydrocephalus in its most acute form.

The more intense the inflammation, and the more rapid its progress, in other words, the more acute the hydrocephalus, the less the effusion. The intensity of the inflammation extinguishes life before the fluid has time to accumulate in any considerable quantity; and the small quantity which is poured out, from the suddenness with which the effusion takes place, produces more violent irritation than a much larger quantity slowly deposited. Suspicion arises that a child has been put to death by violent means. Two or three days before its death it was in perfect health. It was attacked suddenly with the most violent symptoms, for which no probable cause can be assigned. You find in the brain manifest traces of inflammation; you find a quantity of fluid effused into its cavities, the amount of which, when all of it is carefully collected, scarcely exceeds half an ounce. You inspect the chest and abdomen; you find all these organs free from disease. You are now in possession of evidence sufficient to warrant you in deciding that the death in question has arisen from a natural cause, acute hydrocephalus, arising as an idiopathic disease of the brain.

All the other forms of hydrocephalus will occasion you less difficulty. When you find an accumulation of three or four ounces of fluid, with the indications of recent arterial action in the brain, you cannot for a moment doubt the nature of the disease. Still less can you be in doubt when you find the accumulation to be, not in ounces, but in pints; when, instead of two or three drachms, the quantity condensed when the brain is perfectly sound; or half an ounce, which, as we have seen, may be all that is effused when the disease exists in its intensest form; or from three to four ounces, the quantity accumulated when the disease is moderately acute, you find from eight to ten pints; and when, as the necessary consequence of so large an effusion, the whole shape of the ventricles is lost, and the convolutions form little more than a lining to the skull. Such an accumulation of fluid can have taken place only by the gradual and very slow deposition of it, a deposition often congenital, and, when it begins in infancy or childhood, not infrequently the immediate consequence of a high degree of congestion, induced by an enfeebled state of the system.

Coagulable lymph, or purulent matter, poured into the ventricles.—When, instead of serous fluid, you find coagulable lymph or purulent matter poured into the ventricles, in the absence of all evidence of violence, you may consider these undoubted results

of inflammation as induced by some natural cause; but you should always bear in mind that these results are very commonly the immediate consequence of inflammation induced by external violence.

Effusion of blood into the ventricles.—And so also is the effusion of blood into the ventricles, which may happen from a violent blow, and which is the frequent result of concussion. But the effusion of blood into the ventricles is intimately connected with the consideration of apoplexy, which, of all the diseases of the nervous system, is, in relation to forensic medicine, the most important.

Apoplexy.—Apoplexy consists in the abolition of sensation, and the loss of motion. The extinction of these faculties may be complete or incomplete, and may be with or without convulsions.

Premontory symptoms.—Should you be called to ascertain the cause of death in a person who has died suddenly of apoplexy, alone and in the midst of strangers, and of whom no one can give any account, of course you can obtain no light from the existence of any symptoms that may have preceded the fatal event. All the knowledge you can gain in this case you must derive from the inspection of the body. But if the deceased have been struck with this disease in his usual abode, and in the midst of his companions and friends, whatever apprehensions or suspicions may have arisen, you may sometimes obtain so much light on the case, merely from the previous history of the symptoms, as to render any inspection of the brain needless—needless, that is, as the means of affording evidence that the death in question has resulted from a natural cause. But, of course, however complete the evidence of this may be to your own mind, you would never fail to examine the body carefully in all cases, to ascertain with certainty the exact cause of death.

Apoplexy often appears to come on quite suddenly, without giving the slightest indication of its approach, while, in reality, the premonitory symptoms are abundantly obvious to a careful observer. Its voice is not heard or not regarded; but it not the less sounds the alarm of the coming evil. By giddiness, headache, a sense of weight in the head, dulness of mind, a momentary loss of consciousness, peculiar noises, as ringing in the ears; depraved vision, slight defect of sensibility in particular parts of the body, frequent irregular or convulsive actions, stupor; palsy, partial perhaps, and slight, but not the less significant, it announces that it is at hand. It is true that severe, and even fatal, attacks do occur without any previous symptoms which have excited alarm. It is even stated by Rochoux, a

writer of authority on this disease, that out of sixty-three cases which came under his notice, only nine had distinct premonitory symptoms. This is a vastly greater proportion of perfectly sudden attacks of apoplexy than occurs to the observant practitioner in this country, who finds that, in the great majority of cases, some one or more of the premonitory symptoms which have been mentioned existed before the attack. You must not, then, attach too much importance to the absence of these premonitory symptoms; but if you find that they have been present, you have obtained one fact evidentiary that the death has arisen from a natural cause.

No age nor sex is secure from this disease, but it is more frequent in the male than the female; and it chiefly attacks persons advanced in years. You may meet with it in the infant, but this you would note as an extraordinary occurrence, whereas you would expect it in the old. A case recently occurred in this city in which it attacked a child two years and a half old, and on examining the head there was found a large extravasation of blood at the surface of the brain. I have myself recently met with three cases of it in my own practice in persons all of whom were under thirty, and one scarcely twenty. Dr. Craigie observes, that of eighteen cases described by Bonetus, five occurred in persons above sixty, and six in persons below forty. Morgagni relates the cases of thirty apoplectic persons, seventeen of whom were above the age of sixty, and five below that of forty. Of thirty-one cases of bloody extravasation in the ventricles or the substance of the brain recorded by Lieutaud, one was at the age of twenty-five; eight between the ages of thirty and forty-one; eleven between forty-one and fifty-one; six between fifty-one and sixty-one; two between sixty-one and seventy-one; two between seventy-one and eighty-one; and one only above one hundred. Of twenty-nine cases seen and dissected by Portal, two were between nineteen and twenty-three; four between thirty-one and forty-one; seven between forty-one and fifty-one; eight between fifty-one and sixty-one; four between sixty-one and seventy-one; and the same number between seventy-one and eighty-one. Of six cases of cerebral hæmorrhage given by Cheyne, three were between thirty and thirty-five; two at fifty; and one at sixty-three. Of the sixty-three cases given by Rochoux, two occurred between the ages of twenty and thirty; eight between that of thirty and forty; seven between that of forty and fifty; ten between that of fifty and sixty; twenty-three between that of sixty and seventy; twelve between that of seventy and eighty; and only one between

that of eighty and ninety. According to this view apoplexy is extremely rare before the thirtieth year; from that period to the fiftieth it is not common, but may occur; after fifty it becomes more common; between sixty and seventy is more frequent, becomes of the same rate of frequency after seventy as before sixty, and is very rare after the eightieth year. Of the cases given by Lermier and Serres, though two are between thirty and thirty-five, the greater part are between sixty and seventy-five. From the whole, then, it is plain that apoplexy is rare in the young, and common in the old. If, therefore, the person be of advanced age, you have obtained another fact evidentiary that the death has arisen from a natural cause.

It is also certain that there is a close connexion between corpulence and apoplexy; for the same circumstances predispose to both conditions of the system—a vigorous constitution and good digestive powers. The stout and close-built frame, the broad chest, the short neck, the large head, the full and florid cheek, the brawny limbs, have been so often found in connexion with this disease, that they have been conceived to form the apoplectic constitution. Apoplexy may, indeed, attack the tall and thin, but the pletoric frame is much more predisposed to that irregular action of the arterial system on which this disease essentially depends. While, then, you must not attach too much importance to the absence of the apoplectic conformation, yet, if it be clearly and strikingly present, you have obtained a third fact evidentiary that the death has arisen from a natural cause.

The immediate cause of apoplexy is often a full meal; consisting, perhaps, of indigestible food and stimulating drink. Articles of food and drink, which may be taken with impunity, and even advantage, by those in sound health, may prove highly dangerous, nay, even instantaneously fatal, to those strongly predisposed to apoplexy. If the death in question has occurred after a full and stimulating meal, and more especially immediately after, or even during such a meal, in a person accustomed to habitual indulgence amounting to intemperance, you will have obtained a fourth fact evidentiary that death has arisen from a natural cause.

Great anxiety of mind, violent emotion, whether depressing or exciting, and severe long-continued and uninterrupted mental exertion, to the exclusion of physical exercise, lead to such a derangement in the circulation of the blood-vessels of the brain, as to prepare the way for apoplexy. If, then, you find that circumstances of this kind have existed in a powerful degree for a considerable time, and more

especially that they have concurred in a person in other respects predisposed to apoplexy, you will have obtained a fifth fact evidentiary that the death has arisen from a natural cause.

Severe blows inflicted on the head, the immediate effect of which may have ceased for a long time, and have been forgotten, sometimes lay the foundation of apoplexy, and must be regarded as an occasional very powerful predisposing cause of the disease.

Much importance cannot be attached to one of these circumstances alone; but the presumption will strengthen as the number of individual facts concur in the same subject, according to that cumulative power which I have already shewn to be characteristic of evidence.

But whatever force there may be in these predisposing causes, and however they may assist the diagnosis in certain difficult and doubtful cases, still the only absolutely certain signs of the existence of this disease, and the operation of it as the cause of death, are to be found in the morbid conditions of the brain; and with these it is of the last importance, in a judicial point of view, that your knowledge should be exact and complete.

LECTURES ON TUMORS,

Delivered at St. George's Hospital,

BY CESAR HAWKINS, ESQ.

I. ENCYSTED TUMORS, *continued.*

2. *Serous or Aqueous Encysted Tumors.*
3. *Hydatid Encysted Tumors.*
4. *Congenital Encysted Tumors.*
5. *Bursal Encysted Tumors.*

I.—2. *Serous or Aqueous Encysted Tumors.*

THE second genus of encysted tumors may be called the aqueous or serous encysted tumors, and they consist originally of a thin delicate secreting cyst, containing a transparent fluid, like water in appearance, and composed of pure water, with a small quantity of animal matter, which Dr. Marcet has termed muco-extractive matter. This fluid is not coagulable by heat, since it contains no albumen, as serum does, and therefore the term *serous* has been given, you will observe, not to the secretion, which is aqueous, but to the cyst, which is like the serous membranes in appearance, especially the arachnoid membrane, which, you are aware, secretes scarcely any albumen naturally. You will find a minute account of these tumors, especially as to the liver and kidney, in a paper of mine, published in the 18th vol. of the *Medico-Chirurgical Transactions*. These cysts have also been called *hydatids*.

but very erroneously, since they are fixed, and attached to, and nourished by, the vessels of the surrounding parts, and are not parasitic animals, which will be hereafter described to you. They are termed *spurious hydatids* by Mr. Hunter, but I think either of the names I have mentioned is better.

It is conjectured by Dr. Hodgkin, that they originate in the obstruction of excretory ducts, and Sir A. Cooper assigns the same origin to an analogous disease of the testis. Now there is no doubt that cysts of fluid are often formed in some glandular structures, such as the breast and kidney, in this manner, and in the same way also in the ducts of the salivary glands, and I believe the mucous follicles are obstructed so as to form similar tumors about the vagina and elsewhere. It may be objected, perhaps, that tumors thus formed should be termed *mucous encysted tumors*; but, in fact, their secretion, when thus confined and changed, is no longer mucus, but the cysts become exactly like serous membranes, and the secretion from them is often transparent water. All this is no more than we should expect *a priori*, as analogous to the origin of the sebaceous encysted tumors. But we must not forget that this will only account for some such tumors, and that serous encysted tumors are met with in the cellular tissue of organs that have no secreting property, and no ducts to be obstructed. Look, for instance, at this plate of Dr. Hooper's, of cysts of this kind in the brain, or at a preparation from a patient of Dr. Macleod's recently, in which you may see two large serous encysted tumors in the same organ. Here, then, they must arise in a different way; possibly by enlargement of the cells of the cellular tissue: whether the fluid secreted in them is first prevented by some peculiarity from being absorbed, and the cyst subsequently condensed, or whether the secreting cyst is first organized in a peculiar way, may admit, indeed, of dispute.

After a time, changes often take place in the cyst and in its secretion, altering the appearance of the disease. The fluid becomes more mucous and tenacious, but still transparent, or brownish and opaque; or some albumen is deposited, generally sinking to the bottom, or lining the cyst; or the fluid is mixed with blood, though still transparent, or dark and thick, like currant jelly; or green, or black, like ink; or sometimes mixed with pus. So also the cyst sometimes loses its delicacy and transparency, and becomes thick and opaque, like the reflected pericardium, or tough and fibrous, like the capsules of some of the joints; and sometimes, also, the cysts become partly ossified.

Both the names given to this genus be-

come, therefore, inapplicable to every stage of the disease, and a new one would be necessary for every change in the fluid, or in the cyst; we may, however, without much impropriety, retain the name for every encysted tumor, which probably consists originally of a simple serous cyst, secreting an aqueous fluid.

You see the disease before you in various organs, in these preparations from the brain, ovary, liver, lungs, testis, breast, spermatic cord, neck, thigh, and so on; in fact, scarcely any part seems exempt from their formation.

Examine these tumors in the living person, and you find a smooth, firm, elastic, rounded tumor, in which fluctuation is very evident when you tap it, unless the sac is very small and much distended, in which case they sometimes feel very solid and hard. You find them of every size; from that of a pea to a sac containing several gallons of fluid, and yet still retaining its original appearance. If, however, the sac has become very thick and fibrous, the diagnosis between a tumor of this kind and a solid tumor becomes more difficult, though with care you will seldom fail to distinguish the fluctuation of fluid even when they are deeply situated, as in the abdomen, in which situation they acquire the greatest size; probably from the inferior degree of pressure to which they are subjected. Their deeper situation will almost always distinguish them from the last genus (the sebaceous encysted tumors), which can, of course, only be formed beneath the skin. Their general freedom from inflammation, and its attendant symptoms, will usually distinguish them from abscesses, although, if they grow very rapidly, they sometimes occasion a good deal of pain, and even considerable constitutional irritation; and they are most like the two next genera of tumors, from which, in some instances, there can be no means of distinction till they are dissected.

The treatment of serous encysted tumors must depend partly on their size and situation, partly on the condition of the sac and the nature of its contents.

1. If they are superficial, and the sac thin, and the fluid watery, or nearly so, you will sometimes succeed in producing absorption of the fluid and obliteration of the cyst, by external stimulation. You may try this lotion:—

R. Muriat. Ammoniacæ, ʒij.; Aceti, ʒix.;
Sp. Vini Rectif. ʒiiij. M. ft. Lotion.

If this excoriates the skin, the following may succeed:—

R. Liqueur. Plumbi Subacet. ʒj.; Sp.
Camphoræ, ʒviij. M. ft. Lotion.

By something of this kind, assiduously

applied on linen, even large tumors will sometimes be cured, when near the surface.

2dly. They may be sometimes cured by puncturing the cyst, and evacuating its contents by means of a grooved needle, or a trocar. On the exterior of the body this plan will generally be a palliative only. A girl was under my care for a long time, with a tumor at the side of the neck, who was unwilling to have measures adopted for its perfect cure, but was relieved from the inconveniences of its pressure upon the larynx and œsophagus, by evacuating about eight ounces of aqueous fluid, from time to time, by a small trocar. In the interior of the body a single puncture will very often obliterate the sac, probably because very effectual pressure can be made, so as to keep the sides in contact. You have very lately seen me evacuate twelve pints of pure water from the abdomen of a young woman in whom the tumor had existed four years, and did not appear to be connected with the ovary, though I cannot say to what part the sac, that no doubt contained the fluid, was attached, unless it was the liver, as Dr. Chambers believes. A few years ago I saw Sir Benjamin Brodie puncture a cyst of this kind, in the liver of a boy of 12 years of age, a patient of Dr. Chambers, and let out a pint and a half of pure water; and the boy seemed to be cured when he left the hospital. In another case, Sir B. Brodie had an opportunity of seeing a young lady five years after the same operation for a serous encysted tumor of the liver, and no return of the disease had taken place.

3dly. Although you cannot at once procure the absorption of the fluid by external irritants, nor by simple evacuation of the contents of the cyst, yet you may succeed by using both means; the secretion of the cyst, when it fills again, being sometimes different from what it had been before the puncture (just as you will find to be the case with regard to enlarged bursæ), and yielding to the lotions you had employed without success before the puncture. A woman had a good deal of inconvenience from a tumor, the size of an orange, in front of the trachea; and having punctured it with a needle, and let out four ounces of dark-red fluid, I applied an irritating plaster of ammoniacum, with a little powdered cantharides sprinkled on it. The cyst partly filled again, but then became smaller, and entirely disappeared in five or six weeks. These simple means may then always be tried before having recourse to the more severe; and if they fail, they do not at all interfere with what I have next to recommend.

4thly; Then if adhesive inflammation is insufficient to cause the obliteration

of the sac, suppurative inflammation will probably succeed, which may be excited by making a moderate incision into the tumor, and dressing it lightly with lint to the bottom; or by means of a seton through the longest diameter, as recommended by Maunoir, of Geneva, and by Dr. O'Beirne, of Dublin, for what the former terms hydrocele of the neck, *i. e.* an aqueous encysted tumor in that situation, where it is not uncommon, as you will already have seen.

Both these methods are often employed for encysted hydrocele of the spermatic cord, which is this disease of that part. The unfortunate Delpach, whose tragical end by the hand of one of his own patients excited so much sympathy a few years ago, cured some very large ones in the orbit and neck by dressing with lint, one containing as much two pints of fluid; but I should tell you that one patient died from the sac passing through the orbit into the cranium. For a circumscribed and accessible tumor I like free incision, and dressing with lint; for a large and irregularly-shaped tumor among muscles, the seton is to be preferred, as the irritation sometimes requires to be continued for several months before the sac contracts enough to be finally obliterated; and you must be prepared in important situations, such as that in the neck, for a good deal of local irritation and severe constitutional disturbance, from either plan of treatment; and if small and not inconvenient, and not growing, you should not unnecessarily expose your patient to risk. If you use a seton, you may make an incision at one part, and through this introduce a long straight or curved trocar, and pass it out in the opposite direction; and through the canula some silk may be passed.

But 5thly, you can scarcely hope that a tough fibrous cyst, or one mixed with bone, will be removed by absorption, or filled up by granulation; and therefore it must either be destroyed by caustic, or removed. Having, therefore, opened the cyst freely, you may rub the interior with strong nitric acid, applied by means of some linen tied on the end of a small piece of wood. A man, 55 years of age, had a tumor in the neck, divided by the sterno-mastoid muscle into two portions, one of which was situated in the triangular space between the mastoid and the trapezius muscles; the other projected on the inside of the sterno-mastoid muscle, pushing the larynx to the right side, and making him disturb every one by his snoring at night, and interfering much with the functions of the parts. It was dark-coloured, and seemed disposed to burst. I punctured it, and let out ten or twelve ounces of transparent fluid, and a

second time a thicker fluid, mixed with blood. As it filled again rapidly, I made an incision into it, and rubbed the inner surface with nitric acid, the inside being irregular from bands of ligamentous structure in several directions. I felt the scaleni muscles behind, on the outside of the sterno-mastoid, and other muscles from the sternum in front; the larynx and trachea were attached to the cyst at its inner extremity, and I could feel the vessels at the back part in contact also with it. By the fourth day the cavity had contracted to a small size, and the sloughs had almost separated without much inflammation, when he was unfortunately attacked with fatal erysipelas. This circumstance might, of course, follow any mode of treatment; still you should reserve this plan to the last, as attended with greater risk than the preceding methods of treatment.

Lastly, you will see here some cysts which have been entirely dissected out; and it accessible, and the sac be fibrous or osseous, this operation is to be preferred to the caustics; but it is often quite inadmissible. A young child was a patient of Mr. Keate's in this place, with a cyst, which I saw him puncture, in the nates, which evidently came out of the sciatic notch, beyond reach of the knife; a child, two years of age, was a patient of Mr. Babington's, with one or several cysts, reaching from the axilla to the neck, through all the vessels and nerves of that cavity; and the case I have just now mentioned shews you what you would meet with in the neck. Here is a preparation of a cyst in the neck, mixed with the solid matter of fungus hæmatodes, and which I therefore only punctured to let out the fluid; but observe what I should have encountered if I had tried to remove it: here is the jugular vein in front, the nerve at the side, and behind it; three inches from the vein, is the carotid artery, and all closely attached to the cyst. Even if not mixed with malignant substance, be very cautious how you remove these serous encysted tumors in the neck. Dr. Warren, in the work I have before alluded to, well remarks, how tempting they sometimes look, as if quite detached, while in reality processes of the tumor may dip into very important situations; and he relates two cases, in one of which he tied the internal jugular vein, held aside the par vagum, and dissected off the common carotid artery; and in the other, the internal carotid artery and jugular vein were both left insulated, after a difficult dissection, in the upper part of the neck. He very properly thought the operations, when he had completed them, scarcely justifiable with his knowledge of the connexions of the cysts; and very likely the cases might

have been cured by the other means which I have described. In all operations on the neck for tumors, you will do well also to recollect, that air may get into the veins, and cause an instant death.

All these operations, however, are occasionally liable to be attended with dangers. Having punctured the cyst, it may inflame, when you do not wish it to do so, as when situated in the interior of the body, especially if growing rapidly before the puncture. A little boy had a tumor on the right side of the abdomen, occasioned by a blow six weeks before his admission into the hospital, under the care of Dr. Seymour and myself. As he was suffering very much, I punctured it, and evacuated eighteen ounces of water, shewing, therefore, that it was one of these cysts, the nature of the case having been previously obscure. When he died from the rapid growth of the tumor afterwards, I found it nearly filling the abdomen, and even projecting below Poupart's ligament. I gave an account of this case, along with the description of these tumors in the liver, in the *Medico-Chirurgical Transactions*; but you may see in this preparation the thinness of the cyst when containing five pints of water mixed with pus, and the curious circumstance of there being a separate kidney removed from the right, and both attached to the cyst.

Here is another of these serous encysted tumors from the neck, which was punctured, but bled so largely, from an unhealthy state of vessels, that it was obliged to be removed by Sir Benjamin Brodie; but the patient died of sloughing. Occasionally when opened a peculiar action takes place, and a fungus arises, sometimes called malignant, though erroneously. In a patient of Mr. Walker's in the hospital, with a cyst of this kind in the breast, a large unhealthy fungus, three inches in diameter, with great pain and excessive factor took place, requiring the amputation of the breast; the case did well, however; nor, as far as I know, is there any reason in such cases to expect a return of the disease from any thing malignant in its nature. Perhaps this fungous growth is more likely to ensue when only a small puncture is made and left open, or when the cyst is thick and fibrous, than when it is freely opened, and the sac still thin.

A man was admitted into the hospital, with a tumor of the liver of some standing, lately attended with increase of suffering, which I punctured, and let out a good deal of fluid, consisting of pus mixed with watery mucus, and tinged with bile. He was relieved for some time, and the cavity was nearly filled up, when it began to bleed a good deal, the edges ulcerated, and an unhealthy bleeding and sloughing fungus took

place, very much like the appearance of a malignant disease, and attended with so much pain, that his sufferings were hardly alleviated by six grains of acetate of morphia daily. He became gradually emaciated, and died five months after the puncture, at which time the sloughing ulcer was fourteen inches broad by ten in its shortest diameter. Here is a preparation and a cast taken from a patient of Mr. Babington's, who died exactly in the same way, though the disease was of smaller extent. The ulceration here was so very like that of fungus hæmatodes that Mr. Babington could not help suspecting it was of that nature, though he was acquainted with my previous case. Now here there was no disease in the substance of the liver, and no hardness like that of an abscess of this organ, but only a little body of the size of a nut, that I am inclined to believe was an encysted tumor obliterated after the puncture, but assuming an unhealthy disposition analogous to that previously mentioned in the breast.

There is a variety of tumor described by some persons, in which a cyst at first appearing to be of the kind we are discussing, becomes filled with solid matter growing from one side of the cyst, and ulcerating and projecting through the opposite side. Mr. Abernethy describes one such case, where the cyst was cut across in amputating the arm, where the fungus grew again, and destroyed the patient. I cannot say I have seen any thing of this kind in an encysted tumor of the kind I have placed before you, and I suspect the cases in question are instances of cysts with fungus hæmatodes, and not of serous encysted tumors. Here is a little preparation said to be of this sort, however, but I do not know its history.

Such is a brief account of this kind of tumor, but when situated in important situations other mischiefs may be produced. In the chest they induce oppression of breathing and suffocation;—in the brain fatal irritation of that organ;—in the liver they may give rise to anasarca and ascites, and occasion the death of the patient from their immense size, as much as twenty pints of liquid having been found in them, besides the fluid in the peritoneum. In one case I recollect a man being brought into the hospital in consequence of a fall from a waggon in which a basket struck him and ruptured one of these cysts of large size in the liver, and occasioned his death in a few hours, much of the substance of the liver having been absorbed by pressure.

1. 3. *Hydatid Encysted Tumors.*

The third genus of encysted tumors is composed of hydatids, and they may be

found in many of the situations in which the serous encysted tumors occur. We have seen that the serous cysts are sometimes called hydatids, but erroneously, because the cysts are nourished by the vessels of the surrounding part; the hydatid-cysts, on the contrary, contain parasitic animals, zoophytes, which are nourished by imbibition only, by means of their own coats, from the fluids of the part in which they are situated. They are for the most part mere globular bags, situated in some cavity of a living animal, and are the *trachia hydatidea* of Linnaeus. In the lower animals they generally have a distinct head, sometimes elevated on a kind of neck, with an opening through it into the great bag; they are found in immense numbers in sheep, sometimes in the liver, in what is called the rot, or in the brain in the disease termed the staggers, and they are often accompanied by the flat worms, the flukes; placed in warm water they evidently appear to have a kind of voluntary motion, and power of changing their position. The human hydatid has less evidence of distinct vitality, being seldom possessed of more than a contractile property by which it rolls up in a curious way, as you may here see; it is the *hydatid accephalocystis* of Rudolphi, scarcely ever being seen with a mouth or head; but occasionally the more perfect animal, the *hydatid cysticercus*, is found in the human subject mixed with the accephalocysts. The parent hydatid appears to have a power of generating others, which are attached at first to the interior of the original one, covered by a fine membrane, whence after a time they drop off, and float in a kind of aqueous fluid which fills each bag, of which there are sometimes an immense number, as you may see in these preparations. The smallest of them, when formed in this manner, are less than the globules of the blood, while others, as you see, are an inch or two in diameter.

Around them there is generally formed a cyst of cellular structure, like the serous cysts in appearance, which, like them too, becomes thick and fibrous, or even osseous, as in this example; but occasionally there is scarcely any thing that deserves the name of cyst around the hydatids. The cellular cyst secretes a fluid that sometimes becomes thick and adhesive, and even purulent, in which case the fluid within the hydatids still remains thin and transparent, being changed by the independent vital properties of the coats which compose them, and undergoing a kind of assimilation. Sometimes, where the parent hydatid is large, the cyst is lined by a thick unctuous secretion instead of fluid, and occasionally it becomes quite filled

with hydatids, broken down, and pressed together into a mass of the consistence of isinglass-jelly.

Even the largest hydatids have no attachment to the cyst in which they are contained. Here is a part of one, for instance, removed by Mr. Keate from the breast, where three pints of fluid were evacuated by a puncture, and this single large bag was easily pulled out from the cavity in which it lay quite unattached. The cellular cyst in which these globular bodies are contained is often mistaken for the parent hydatid; but you will recollect, from the name I have given you of hydatid encysted tumor, that there is the *attached cyst*, containing loose hydatids and fluid.

How they become developed in the living body in such enormous quantities is a curious subject of inquiry—whether by spontaneous generation, as some persons imagine, or whether (as is more probable) the germs are conveyed by the mucous membranes or blood-vessels, through the textures of the body, till they meet with some appropriate nidus, in a frame fitted by ill health, or disease of some kind or other, to favour their retention and growth.

The hydatid tumor is most common in the liver, in which situation most of these preparations were found, but they may be met with elsewhere, and I have already mentioned their occurrence in the breast and the brain; in fact, there is scarcely any part of the body in which they have not been seen by some person or other. The diagnosis of these tumors will be much influenced by the thinness or solidity of the cyst, and by the quantity and consistence of the fluid in which the hydatids float, and by the number and size of the hydatids themselves. The cyst will sometimes fluctuate distinctly, if the number of hydatids is small compared with the fluid, or if the hydatids are themselves large, so as contain much fluid; at another time it vibrates rather than fluctuates, when the hydatids are very numerous and small, or the fluid of the cyst is scanty, or thick and gelatinous; sometimes, again, the cyst may be so firm, or so filled with hydatids, as to appear almost solid, especially when deeply situated. Sometimes they produce little inconvenience, even when of large size, so as to be distinguished by this circumstance from a collection of fluid pus; but on the whole they occasion more pain and impediment to the functions of the parts in which they reside than serous encysted tumors, which also generally fluctuate more distinctly than the hydatids. Sometimes they inflame and suppurate, but even then the

existence of the semifluid tumor, for a definite time, before symptoms of suppuration shewed themselves, will serve as a guide to the probable nature of the disease.

In parts of the body which have an external communication, they occasion little disturbance of the general health. I have seen them discharged by the bladder from the kidney for a great length of time, with only occasional inconvenience from their obstructing the urethra. Not a very uncommon situation for their growth is, however, behind the bladder, where, having no exit, they have produced fatal pressure upon this organ, with consequent disease of the kidneys. So, also, in the brain or heart, although they have been found, when unsuspected during life, they can scarcely increase much without serious consequence. Sometimes it would seem that the containing cyst in the liver or spleen bursts, and some hydatids escape into the peritoneum; sometimes a vast number of separate cysts of hydatids are found in various parts of the abdomen, amounting to many pounds weight, in which case an irregular surface of vibrating tumors would be a diagnostic sign. What are called hydatids are often found in the uterus, as in these preparations; but I doubt their nature, since you may see an attached surface from which they grow, and they are fixed to one another like bunches of grapes, so that they must have a different mode of generation, and are, in fact, all attached intermediately or directly to the uterus. These tumors grow to a large size, and are the result, as it appears, of conception with disease of the membranes of the ovum; and although discharged from the uterus by means of its external opening, the disease is frequently fatal, by the severe symptoms occasioned by their propulsion.

Occasionally it would seem as if the hydatids cease to increase, and the cyst remains stationary, or contracts upon the dead animals. More commonly their death induces inflammation and suppuration in the containing cyst; and I have seen several pints of broken down hydatids, mixed with semi-purulent fluid, evacuated by the trocar. Sometimes, even after pus has been formed, a natural cure has been effected by the tumor ulcerating towards one of the surfaces of the body. Mr. Keate mentioned to me the case of a gentleman who was for a long time ill with some obscure disease, who suddenly had a kind of diarrhoea, in which one potful after another of hydatids was evacuated, from some encysted tumor of this kind giving way. A lady was under Dr. Seymour's care with a tumor of the liver,

which disappeared, and the patient recovered, after the hydatids were discharged by stool. Sometimes the tumor in the liver ulcerates apparently into the duodenum, instead of the colon, and these bodies have been vomited as well as discharged downwards. At other times a communication has been established through the diaphragm, and the hydatids from a cyst in the liver have been coughed up for years through the lungs. In all these cases the patient may get well, and has, perhaps, quite as good a chance of surviving as when an opening is formed either spontaneously or artificially, on the surface of the body. Whether opened or not, however, they may occasion death by rupture, or irritation, in the same way as the serous encysted tumors. For a detailed account of them in the liver I may refer you to the same papers I have alluded to in the *Medico-Chirurgical Transactions*.

Next as to the treatment of these cases of hydatid encysted tumors; which, however, must necessarily vary according to their situation or connexion as well as their actual state.

1. Can you check their increase and get rid of the disease without operation? One of these preparations, I believe, is from a patient of Dr. Chambers's, a young woman, in this hospital, whose tumor in the liver very much subsided under the use of iodine in friction. I apprehend, however, we cannot reasonably expect, from any treatment of this sort, more than a temporary diminution of the size of the tumor from absorption of its fluid part; at least I conceive it can scarcely kill the hydatids, or if it did so, leave them quiet afterwards. I should expect to see what took place in this case, namely, that having some relief for a time, the patient was obliged to return to the hospital, and died of the disease about a year afterwards, with suppuration in the sac. It can do little harm, however, to try for a time the stimulant lotions I before spoke of, as sometimes curing the serous encysted tumors. In some internal organs we can do little more than administer those medicines, such as tonics and alteratives, which are called for by the state of the system, and which may possibly affect the general health so as to retard their growth, or prevent their development in some other situation, or their return, if one such cyst has been cured. Or else we may remedy those symptoms of irritation from pressure which attend their rapid growth, and relieve the further evils which result from their inflammation and suppuration.

2. The tumors may be opened, the hydatids evacuated, and pressure applied, by which means the sides of the containing

cyst will often be made to adhere, so as to become obliterated. This was the case with this large one from the breast, in which Mr. Keate made a puncture with a lancet and drew out the hydatids, and these bodies are so soft and brittle, that a large one, or great numbers of small ones, will come through a small aperture. In some situations, however, as in the liver, or other internal or deep situations, a trocar is preferable to the lancet, from the canula preventing the alteration of position of the textures through which the puncture has been made, from closing the opening. It has been recommended by Recamier, and some other persons, to make an opening by means of an eschar, successively destroying the skin and the subjacent parts, till the sac is reached, both for the aqueous and hydatid encysted tumors, the object of which mode is to procure adhesion of the peritoneal surfaces, and thus prevent extravasation into the cavity of this membrane. I presume, however, the operation will not lightly be performed in the liver or other important viscus, so that adhesion will generally have taken place before the operation; and extravasation is not very probable, even if it has not done so, since the cyst must at least be in contact with the parietes, or we could not make the puncture, and in that case pressure, by means of bandages, and long straps of adhesive plaster, would almost certainly keep them in contact after the puncture. I cannot approve of this caustic mode, if no inflammation has taken place, since its adoption under such circumstances wholly precludes any chance of the sac being obliterated by adhesive inflammation after the puncture, and the chance of mischief from the open suppurating cavity, which is, of course, invariably produced by the caustic, is, in my opinion, more dangerous than the occasional probability of inflammation from extravasation of the fluid of the cyst, which is not an irritating fluid, unless it happens to contain bile, when situated in the liver.

As I have only once or twice seen hydatids in the limbs, let me mention a case in this situation, to show you how reasonably we may hope to procure union by the first intention, and obliteration of the sac, when an hydatid encysted tumor requires a puncture, from its size. It is published in the *MEDICAL GAZETTE*, by an intelligent surgeon (Mr. Attenburrow, of Nottingham), whose son was formerly a pupil of mine. A tumor began about the groin, a month after a fall, and in eleven months increased so as to reach from the pubes two-thirds down the thigh, and to measure twelve inches long, nineteen broad, and thirty-three in circum-

ference. So large was it, therefore, that I think much credit is due to the surgeon for distinguishing the tumor from one of fungus hematodes. Mr. Attenburrow punctured it with a trocar, and evacuated seven pints of fluid, with quantities of hydatids; a bandage was then applied, and the cavity became obliterated, and the patient got well.

Such, then, is the simplest mode of proceeding with hydatid tumors, taking care not to produce injurious pressure; and with this view using a cupping-glass sometimes, rather than the hands, to break down and draw out the hydatids, and watching carefully the appearance of the tumor and the condition of the system after the operation; so that if it inflames and suppurates, which it does more frequently than after the puncture of the aqueous encysted tumor, we may directly open it freely, and give exit to the secretions of the inflamed sac.

3. If, then, the sac has suppurated previously to any operation being practised, the same operation becomes necessary, but the orifice should now be left open after the puncture, instead of being allowed to close. If the tumor is easily accessible it should be freely opened, so that no pressure may be necessary; and a small and insufficient opening is more likely to be followed by irritation, and that unhealthy inflammation and fungous growth, which I before mentioned as occasionally following the puncture of the aqueous encysted tumor. In important situations, however, as in the liver, the trocar of some size should be used, through the canula of which a catheter may be passed after the sac has been emptied, and in a short time the orifice may be enlarged, if necessary, when time has been afforded for more extensive adhesion of the sac to the peritoneum; or if you please you may open the suppurating cyst by caustic (if the symptoms are not so urgent as to require a more immediate evacuation), to which method there is not now the objection I formerly made to it in the uninfamed sac.

Can we facilitate the obliteration of the sac by any injections? I have not seen any used myself, for the patients have either died after the puncture, before the period of quiet suppuration has arrived, when the puncture has been made in an important situation, or else, when not dangerous, the cyst has filled up, and contracted readily, without them. Injections have, however, been recommended and practised by Recamier with success as it would appear, nor is there any objection, that I am aware of, to their use, if the sac is quiet, and does not easily contract or adhere, beginning with warm water, and afterwards employing a small quantity of

spirit and water, or a weak solution of chloride of lime, or other mild stimulant. When the diseases of the bones are described to you by Mr. Babington, he will very probably mention a very interesting case of Mr. Keate's, in which he evacuated some hydatids from the diploe of the cranium, by the trephine, with success; and I believe, in sheep, they have sometimes been removed by this operation from within the cranium.

4. Sometimes, lastly, the entire removal of the sac with its contents may be practised, in situations where it is easily accessible, and not of large size, and the sac is thick and fibrous. Here is a sac containing an hydatid removed by Mr. Babington from the cellular texture of the thigh, about three inches in diameter, and the sac something like fascia in appearance. It is only in cases such as I have just mentioned that I should be inclined to remove the whole tumor by the knife, rather than lay it open, and in many cases, even in the extremities, the excision must be quite impracticable, as in Mr. Attenburrow's case for instance.

I. 4. *Congenital Encysted Tumors.*

The fourth genus of encysted tumors I will call *congenital encysted tumors*, by which I do not mean all which are found at the time of birth; for instance, a young infant has recently been under my care for some encysted tumors about the neck and face and tongue, making the side on which they occurred double the size of the other. Several of these I punctured, and let out some fluid of different kinds in each, but for the most part like currant-jelly, and most of these cysts did not fill again, so that comparatively little swelling is left; but these were of the second genus, the serous encysted tumors, developed soon after birth. Neither do I mean that all tumors of the kind I am going to describe are discovered at the time of birth, but only that if formed and developed later in life they are of the same kind as those which are most usually congenital.

There are thin cysts met with, generally in young infants, containing a great variety of substances of a peculiar kind. Sometimes there is a quantity of substance like adipocire. I assisted Sir Benjamin Brodie in removing a large tumor of this kind from the back of the neck, of the most offensive odour, which was situated too deeply to have been a large sebaceous encysted tumor. If I recollect right, a tumor which some of you have recently seen removed from the parotid gland by Mr. Walker contained some substance of this sort. Sometimes there is a quantity of fatty substance of a peculiar kind, which has been termed stearine by Dr. Bostock, which often con-

tains mixed up with it a mass of long hair. There is here a portion of a large ovarian tumor, which I had tapped in this hospital, and evacuated about sixteen pints of dark liquid, and in which, after death, a mass of fat, half a pound in weight, was found mixed with another mass several inches in length, of long rolled-up hair. This is a drawing of it from Dr. Seymour's beautiful work on the ovaries, whose patient she was, while in the hospital. Sometimes the cyst contains some shining micaceous particles, like fat kept long in spirit, which has been called margaritic acid by Dr. Prout and Cherreul. At another time, the contents are very like a ripe medlar, or rotten apple, in appearance.

These tumors occur in various situations. Here is a small tumor of fat and hair from the orbit, which is not an unfrequent locality for this genus of congenital encysted tumors, as well as for both the two last genera, and where the operation is sometimes difficult, from the intricate manner in which portions of the tumor sometimes dip down between the muscles and nerves, and where also the cyst is sometimes found attached to the bone. Another very common situation is a cavity in the ovary or broad ligaments of the uterus. I have had two patients with tumors apparently of this kind by the side of the vagina, occasioning a good deal of trouble and pain. One of these I laid open in a pregnant woman, who was to have returned to me, if the tumor formed again, after her confinement; the other suppurred suddenly, after having been five years at least in forming. The most singular kind of tumor, however, of this genus, is when the cyst contains not only hair and fat, where none is naturally found to determine the peculiar growth by its analogy, but has also in it teeth and portions of bone, especially the jaw-bones, or other parts, of a *fœtus*. They are most frequently found in the ovary, whence this sac with teeth and hair was taken in a patient in this hospital, and of which another instance occurred here very recently, though I know not what became of the preparation, and from this locality they have sometimes been regarded as instances of extra-uterine conception, but on very insufficient grounds, for they are found in other situations also. Mr. Barnes, of Exeter, met with teeth in the orbit, and such tumors have been found in the stomach and bladder; Sir Benjamin Brodie, I think, saw one in this last situation. They are met with in virgins, and in the male sex, and in animals of no sex at all, since Mr. Coleman met with a tumor of this kind in the thigh of a gelding.

Such portions of fetuses in congenital encysted tumors are not so common, however, as the other substances I have alluded to, and I should have little doubt that they are examples of double conception, *i. e.* of an imperfect fetus united with or included in another, of which many instances are on record, from the nearly perfect fetus found in the abdomen of a boy by Mr. Highmore, to the cysts containing one or two teeth, or a little hair and fat. There is here a plate from Cruveilhier of a tumor with hair and fat; the hair is unravelled, and you may see that it has been attached to what seems to be a portion of scalp at the side of the cyst. In other cases you do not find any substance from which the hair grows; and with regard to the other peculiar contents of the cysts which I have placed in this genus, it is possible that I am wrong in classifying them thus, and that they should only be looked upon as some peculiar change in the secretion of the serous encysted tumors. If this be so, of course the genus of congenital encysted tumors must then be confined to those which evidently contain such substances as appear to be part of a fetus. Even in the latter case, however, you will understand that although the rudiments are thus commenced and attached in the fetal state, they need not be large at the time of birth, nor become much developed till long afterwards. Being connected with vessels to the part of the body in which they reside, some accidental circumstances may occasion an increased supply of blood to the part, and cause them to lose their stationary condition, and become rapidly increased in size; such, for instance, as the altered condition of the ovary at puberty or during pregnancy.

Whether I am right or wrong in thus bringing into one group all the kinds of cysts and their contents, which I have now enumerated, is not of much consequence, however, since I know not how you could always distinguish them from the two former genera till after the contents have been evacuated, or the cyst dissected out. You can perhaps ascertain the existence of an encysted tumor; but even this must depend upon the circumstance I have before spoken of with regard to the former genera; the quantity and consistence of the secreted materials—the mixture of solid matter—the thickness and distension of the sac, and so on. Nor is the perfect diagnosis of the tumor of much consequence in practice, since nearly the same circumstances which I formerly dwelt upon should guide us, I think, in our treatment of these. In some few, where the nature of the contents, the thinness of

the cyst, and the connexions of the tumor with the surrounding parts, render it favourable or desirable to do so, we may try the puncture of the sac, with a view to its obliteration by adhesive or suppurative inflammation; but the greater number, where accessible, are best treated by excision of the whole tumor, either entire, or by dissection of the cyst after the previous evacuation of its contents.

In some cases, where excision is unadvisable from the connexions of the cyst, we may, as with the serous encysted tumors, where simpler means fail, attempt to destroy the cyst by nitric acid or potassa fusca. In other cases, again, all operations are out of the question, and we are obliged to content ourselves with warding off as much as possible the consequences of the growth of the tumor, without trying measures which would be impossible, or too hazardous to be thought of with prudence and justice to our patient.

1. 5. *Bursal Encysted Tumors.*

The next genus of encysted tumors on our table are the bursal. These take place sometimes in the bursæ and their secretions, either as the consequence of pressure and inflammation, or else without our being able to trace the cause of certain changes, by which tumors are formed, not curable by the usual means suited to inflammation, but requiring the knife of the surgeon. Instead of synovia and the secretions of inflammation in such membranes, you have semi-fluid matter, like currant-jelly in colour and consistence, or otherwise altered; or masses of solid matter like melon-seeds, as in this preparation; and the cyst, instead of its usual structure, becomes, as you may see here, thick and fibrous, and the cavity is sometimes obliterated, so that a large solid tumor is formed.

In such cases the changes are so considerable, and the treatment required so different from what is necessary for inflammation of these textures, that they may not be inappropriately designated bursal encysted tumors. I shall not at present describe them, however, but leave them to be spoken of with the other diseases of the joints and bursæ, and shall content myself with observing, that when you meet with tumors containing more or less fluid, in the known or probable situation of the bursæ mucosæ, you should generally attribute their formation to these textures; and the recollection will assist your diagnosis in many otherwise obscure affections.

RECOLLECTIONS OF CHOLERA;

ITS NATURE AND TREATMENT.

BY WILLIAM GRIFFIN, M.D.

Limerick.

No. VIII.

*Of Sedatives, or Contra-Stimulants—
Calomel—Opium—Brandy—Emetic
Tartar—Ipecacuanha, &c.*

THE first practice almost universally resorted to in this country was that which came so highly recommended from India—the exhibition of calomel in large and repeated doses. It was adopted at St. Manehin's hospital, in connexion with those other means suggested in the Board of Health circulars—emetics, sinapisms, injections, dry heat, &c.—and the results proving very unsatisfactory, opium stimulants, salines, turpentine frictions, turpentine and tobacco injections, &c., were successively resorted to. These remedies appeared as unsatisfactory in their results as the calomel had been; and after having witnessed or conducted the treatment of 44 cases, of whom 21 died, instead of deriving any advantage from the experience, I only became perplexed and distrustful of every proposed means of cure. In this frame of mind I was transferred to St. Michael's hospital, where the admissions were very numerous, and the mortality alarming. I here found the calomel practice pursued with much more boldness and resolution than any results I had witnessed could have induced me to adopt*. As it was little complicated with the use of opium or any other medicine which could materially interfere with its operation, and I had myself lost all faith in treatment, I determined to become a mere observer for one month, that I might have some numerical evidence, at least, in the cases submitted to the action of one powerful remedy, of the good or evil it was capable of effecting. To arrive at more accurate conclusions, I noted in each case, on admission, the presence or absence of the pulse at the wrist, and

took care that the registrar or apothecary did the same whenever I was absent. I also, in conjunction with the other physicians, endeavoured to prevent, as much as possible, the admission of patients in the mere premonitory stage, which, however, was not always possible. At the termination of the month, I found the gross amount of deaths was 47 out of 165 cases, or less than one-third, which was not far away from the general mortality in most countries. But on casting up the tables, and ascertaining the amount of mortality in the separate stages, I was perfectly astonished to find that while in the primary stage, or that of rice-water vomiting and purging, there were only 5 deaths in 119 cases, there were in those admitted in collapse 42 deaths in 46 cases. I had here at once evidence sufficient to lead me to the most certain and confident conclusions. The calomel practice was clearly capable of effecting a greater number of cures than any known remedy in any other dangerous disease, so long as the patient was placed under treatment before the pulse ceased at the wrist; but after that occurred, it did nothing, or it did mischief, the recoveries being perhaps less than might be effected if the cases were wholly abandoned to nature until the period of reaction. These inferences were afterwards amply confirmed by the reports from other hospitals in which similar notes were made of the stage in which patients were admitted, and the comparative mortality in each; the same treatment, with little deviation, having been at the time pursued in all. The correspondence of these reports is remarkable, and may be looked upon as in itself a proof of the general correctness with which they were kept. I am at the same time ready to admit that they only make an approach in the whole to the accuracy which is desirable for medical induction. The deaths in cases treated before the pulse had ceased at the wrist are reported as 5 in 119 at the most successful period, and at 16 in the 100 at the least successful. I believe, in reports very accurately kept, and from which mere premonitory cases were strictly excluded, the mortality would seldom, under any treatment, be less than the latter amount, and would probably, at the onset of the disease, when cases are

* After the exhibition of an ipecacuanha or mustard emetic, it was given in scruple or half drachm doses every hour until the patient was salivated or died. Cordial mixture, saline draughts, and turpentine and astringent injections, were also employed.

generally of the rapid type, exceed 20. The recoveries reported in cases of collapse varied from 1 in 11 to 3 in 10. I do not believe in any hospital in Limerick they ever exceeded the former amount, and I am disposed to attribute the greater number which took place in the second instance partly to our having tampered less with the patients while insensible to medicine, and partly perhaps to the decreased severity of the disease in the latter months of its existence amongst us. Dr. Mackintosh states the estimate of recoveries in Edinburgh to be only 1 out of 12 in cases in which the pulse was either so weak as scarcely to be felt, or was imperceptible at the wrist; but believes this too high, and that not more than 1 in 20 recovered out of that state. In Paris, at least during the first incursion of the disease, I believe the recoveries from collapse were equally rare. Such reports from cities in which the patients had the advantage of the highest medical talent in the world, joined to the well-ascertained inefficiency of all remedies in those cadaverized cases, leads necessarily to the conclusion, that the greater or lesser success in the results indicated simply a greater or lesser severity of the disease.

To return to the treatment. I had now satisfactorily ascertained that calomel was a most successful medicine if administered while the pulse was perceptible at the wrist, but, on the contrary, detrimental when given in collapse; not that it can then do any immediate mischief, the stomach being apparently insensible to its action, but because it is accumulated to an amount that becomes destructive or injurious as soon as reaction takes place. Another object of investigation arose naturally out of these facts. On first visiting the convalescent wards, after I became attached to St. Michael's Hospital, I was excessively shocked at the appearance of the patients, all of whom were in a state of profuse salivation. Their heads seemed, for the most part, of an enormous size, their faces and jaws puffed out, and shining as if they would burst, their edges sunk in, and their lips disgustingly swollen and ulcerated at the angles; some were sitting up in the bed endeavouring to wash the sloughs from their mouths with the sharp gargles, and complaining

bitterly, others were lying moaning, with their faces on the pillows, which were drenched with saliva, while some hung over the bed-side, dribbling the same glairy secretion, mixed with blood and matter, into tin vessels. The slow recoveries of these—the tortures they went through—the shattered constitutions they often went away with, seemed such a drawback from the benefit which could attend any treatment, that I felt, even after I had convincing evidence of the curative powers of calomel, remedies of less efficacy might be preferable, if not succeeded in the cases of recovery by such protracted suffering and ill health. It became, therefore, at once an exceedingly interesting question, whether the cure of cholera by calomel was to be attributed to the usual influence of mercurials on the system, or to some unknown property which it possessed when given in large doses. The universally received opinion, among the advocates for the calomel treatment, at the time, both in England and in this country, was, that if once its mercurial influence could be established—if once the gums became sore, the patient was beyond danger; and whether they were right or wrong in the presumed connexion between the recovery and the salivation, the facts could hardly be disputed. As a consequence of this opinion no limit was placed to the amount of mercury exhibited until symptoms of salivation set in, and of mercurial liniment rubbed into the skin through every stage of the disease. To the results already described, a protracted convalescence, sloughing ulcerations of the mouth, and torture unimaginable by those who have not felt it, almost invariably succeeded. In reflecting on the rapid manner in which the influence of calomel is evinced in cholera, on the suddenness with which it sometimes arrests both the vomiting and purging days before its mercurial action on the system is perceptible, I strongly suspected the correctness of the prevailing doctrine. Even if it was a fact that persons who were salivated invariably recovered, it could be said to prove nothing, since it was clear, when calomel was administered so profusely to all, no one who recovered from cholera could escape salivation. It

might indeed be said, with great probability, *that they were salivated because they recovered, rather than that they recovered because they were salivated.* To satisfy myself on this point, I immediately sent a set of queries to medical friends in Liverpool, Dublin, and other places, and I found that in several instances, not only had patients in salivation for other complaints fallen into cholera, but some who had been salivated for cholera had, during the salivation, sunk back into collapse and died. I was indeed furnished, soon after, by a medical friend in Limerick, with the details of three cases which had occurred in his own practice, in each of which profuse salivation had occurred, with apparent relief of the choleric symptoms, and subsequently a relapse, followed by the usual cessation of pulse, and sinking, and death. It was obvious, then, that the salivating influence of calomel was not that which tended to effect the cure, but some other of which we are less observant, and consequently that the remedy should be discontinued as soon as there was an arrest of the symptoms. It also followed that the external use of mercury by ointments and liniments should be altogether abandoned, since they could not be supposed calculated to produce that sedative or counter-stimulant effect sometimes almost instantaneously observed to follow the exhibition of large doses of calomel. A third and not unimportant inference finally suggested itself—that if the benefit derived from calomel was to be attributed to its sedative influence alone, as it had been by Annesley and other Indian practitioners, it should always be given in large doses only, and those rapidly repeated. It should be given, in fact, altogether (on Rasori's counter-stimulant plan) to produce an effect on the system and the disease, *entirely independent of any sensible evacuation.*

Having fully convinced myself of the correctness of these inductions at the termination of the first incursion of cholera, I determined, should it return, to test them on as extensive a scale as possible; and this I had soon a fair opportunity of doing. The disease made its second visit in the latter end of August, and being appointed to the care of St. John's Hospital with three

other medical gentlemen, we agreed upon a plan of treatment which altogether excluded the use of calomel during collapse, and the administration of large doses after re-action had taken place. No limit was placed on the amount to be given in the early stage of the disease. There was more than usual care observed in preventing the admission of persons with mere premonitory symptoms, and in noting with accuracy the cases in which the pulse had ceased previous to their arrival at the hospital. The result is already given among the tables of the mortality of cholera. There were admitted within six weeks, 120 cases; 59 in the primary stage, and 61 in collapse. Out of the 59 several ran into collapse in despite of treatment, of whom 8 only died. Out of the 61 in collapse on admission, 43 died and 18 recovered,—a greater number than had previously recovered from that state under the most sedulous medical treatment.

But the most gratifying circumstance of all was, we had few sore mouths, and no very bad ones, such as did occur being slight, and attributable to our occasional perseverance in the calomel from mere apprehension, after the symptoms of the disease were arrested. I had, indeed, numerous instances among the recoveries to convince me that the resistance to the salivating influence of calomel on the system was coexistent with the presence of active cholera, and that the resistance gave way with the disease. This was so strictly true, that one dose of calomel, even a small one, given after the symptoms appeared to be arrested, was found to occasion sore mouth more certainly than an ounce administered while they were violent, or on the increase. The probability of salivation depended not on the quantity of the medicine administered, but upon the non-existence of active cholera at the moment of its administration. As long as cholera existed, none of the usual effects of calomel appeared; it acted neither on the salivary glands, nor liver, nor bowels; I suppose on the same principle that tartar-emetic does not excite vomiting, nor opium narcotize, during the presence of inflammation. I have in several cases given it hourly, in scruple doses, to the amount of two or three drachms, or upwards, without eventual salivation; and I recollect one instance, in particular, in which I gave nearly

two drachms within an hour and a half, with perfect success, and without affecting the system. A tall stout young man was brought into the ward one day, who had been for some hours in the disease. He had most violent vomiting and purging of colourless fluid, with suppression of urine; his look was somewhat sunk and alarmed, and cramps were commencing. He was got to bed, and took an emetic of ipecacuanha; of the advantage of which on all occasions I have much doubt. Sinapisms were applied to the calves of his legs, to allay the cramps, and dry frictions were made use of for the same purpose. As soon as the emetic was thrown off, a scruple dose of calomel was given; after which no drink was allowed for a little while, although the use of cold water, saline draughts, or occasionally of mild cordial mixture, usually formed part of our plan of treatment. In half an hour afterwards, I found all the symptoms continuing unabated; the skin, which was warm on his admission, becoming cool, the pulse more compressible, and the voice weaker. Half a drachm of calomel was instantly given, avoiding the administration of drink after it for a time, as before. On passing the bed when another half hour had elapsed, appearances were still more unfavourable; the pulse manifestly failing, and the countenance indicating approaching collapse. I now gave a drachm of calomel at a dose, and anxiously watched the effect. At the end of fifteen minutes I was glad to find there was no advance towards collapse, and within half an hour there was a perceptible improvement in the pulse and increase in the temperature of the skin. There was from that time forward no troublesome recurrence of the vomiting, or purging; no cramps, no coldness, no sinking. The thirst gradually abated, the natural secretions returned, and, without another grain of calomel, the patient recovered. He was discharged in three or four days, without the slightest soreness of mouth, and I met him in the street, in a week afterwards, returning from his work, stout and well.

It is of course not to be imagined that in using any remedy, however influential, we could feel ourselves warranted in rejecting accessory treatment. Nothing, however, on the whole could be less complicated than the curative

means adopted in conjunction with calomel, consisting generally of dry frictions, frictions with turpentine, or sinapisms to relieve the cramps, or the violent action of the stomach or bowels — of cold or saline drinks to allay the thirst, or of anodyne or astringent injections to suppress the discharges by the rectum. This last became a most important object with us, when we grew familiar with the disease, as we often found that where, from the excessive irritability of the stomach, or the smallness and inefficiency of our doses, no early effect was produced on the choleric symptoms, the patient was usually carried into collapse by the exhausting serous diarrhoea. I have, indeed, not infrequently seen a patient, apparently maintaining his ground for some hours, sink suddenly into collapse after one profuse evacuation, and have been so deeply impressed, by such instances, with the necessity of invariably suppressing the diarrhoea, that I latterly made it a rule to give an astringent injection after each evacuation, however numerous, until my object was accomplished. The injection generally consisted of half a drachm of the acetate of lead mixed with thin starch, to which a tea-spoonful of Linctum was added, either when the injections were repeatedly returned immediately after administration, or the cramps were distressing and resisted other remedies. I always, however, considered the administration of calomel more essential to the permanent suppression of the diarrhoea than any injections. The effect of the latter, even when successful, was often of short duration, and not to be depended on; the effect of the former, when perceptible on the discharges, was in itself a sign that the disease was giving way, and was more steady and disposed to continue. The astringent injections seemed calculated to divert and gain time; the calomel to contest the ground with, and conquer the malady.

Opium was seldom given with the calomel, except perhaps in the earliest periods of the attack, its beneficial effects appearing always proportioned to the earliness of its use; but of this it will be necessary to speak hereafter. The cordial mixture (aromatic spirit, with sweet spirits of nitre and camphor) was latterly given very sparingly, or not at all, in the primary stage; and even in collapse it was employed rather with a

view of giving moderate support, than of hastening the period of re-action. The application of external heat in any shape was latterly almost wholly abandoned, and I believe without any disadvantage.

I have now given an account of the calomel treatment and its results; and if ever any remedy got a fair and full trial—if ever all the good or evil it was capable of effecting was displayed—if ever materials were afforded for absolute induction in medical science, it was in the application of this medicine to the cure of cholera at Limerick. It was tested in 1448 cases treated in different hospitals, at different periods, and with a very close correspondence in the results in all. The quantity of calomel used was enormous, having seldom or never been given in any hospital in less than scruple doses, and these generally repeated every hour or half-hour; half a drachm, and even two scruples, was indeed not an infrequent dose.

I cannot conceive that any one who considers the facts and reasonings here brought forward, can again assert we have attained no valuable knowledge, no successful treatment, from our experience of cholera. It is now at least evident that, by the judicious application of one remedy, we can control the disease, or arrest its progress, in 84 cases out of 100, if the patient be placed under our care before the pulse has ceased at the wrist; and if, after that, no more than two or three can be saved out of ten, it is only to be considered that the stage of collapse in cholera is like the stage of muttering delirium and floccitation in fever, the almost fatal conclusion of the disease. It is our object to prevent the occurrence of these states in either; and surprising though it be, it is much more easy of attainment in the former than the latter. I am far from thinking the tables I have given as evidence of facts were kept as accurately as they ought to be, but I believe that they closely approach the truth, and that they will be borne out by subsequent experience, except, perhaps, their accuracy be tested in incursions of the epidemic of a more rapid and virulent type than afflicted this country. They happily furnish us with evidence of the capabilities of a remedy more popular on the whole than any which has been tried, and enable us to form some estimate of the value of others

by a comparison which has been hitherto impracticable. I regret to say I do not consider the use of calomel free from objection, employed even in the qualified manner I have suggested; but no other medicine has yet been proved to us capable of effecting so large a proportion of cures. I believe, however, there are some which approach it closely in power, but from the want of all accurate classification in the statements respecting them, I can only offer well-considered opinions as to their probable value.

Opium.

No medicine employed in the cure of cholera has been so much praised or abused as opium. It came to us, like calomel, highly recommended from India, where it was extensively used both among the English and native practitioners, but was not long employed in this country when it fell into very general disrepute. Some asserted that it narcotised the patient without relieving the disease; others, that it obstructed the respiratory functions, and hastened the fatal event; a third party, that it insured the supervention of destructive congestion in the consecutive fever; while a few only maintained that its merits had been underrated, and that no remedy was calculated so safely, so readily, and so certainly, to arrest the course of the malady. It need scarcely be mentioned that this extraordinary discrepancy of opinion arose, as we have already pointed out, from the application of the remedy to all stages of the complaint: some, when they found it effecting cures in one stage, extending their faith in its influence to all; and others, when it was manifestly unsuccessful in the state of collapse, in which so many were brought under treatment, assuming it to be at all periods worthless or mischievous. This was very much the case at the hospitals in Paris, where at first opium was employed very extensively. The great majority of persons admitted were unfortunately in deep collapse, to which the warmest advocates for its use consider it to be inapplicable; and the natural result was a total loss of faith, and abandonment of the remedy. At La Pitié, where it was given both by the mouth and by injection, narcotism quickly appeared in the majority of cases, without arresting the unfavoura-

ble symptoms, and so it was laid aside. The physicians of the Hotel-Dieu also, for the most part, discontinued its employment, diminishing the doses considerably even when they did use it, or limiting its exhibition to injections or liniments. M. Bally and M. Recamier asserted that it was absolutely injurious in the blue period, and useless in others. Those practitioners, however, who commenced with its use in the early stage of cholera, do not seem to have been so disappointed with its effects; as I believe it was continued, more or less, throughout the epidemic, by Dupuytren, Chomel, Gendrin, Rayer, Lermurier, and M. Mailly.

I have not had much experience myself of opium in confirmed cholera, but I have now before me the opinions and statements of the principal British practitioners, and, setting aside such as appear to be founded on inaccurate or very partial observations, the conclusion appears to be, 1st, that, like calomel, it is wholly inapplicable to the stage of collapse, hastening the death even where it allays the sufferings of the patient; 2dly, that it is inapplicable to several cases previous to collapse, occasioning narcotism without abating the symptoms or arresting the course of the disease, such cases being usually those of persons with florid complexions and full habits; 3dly, that in the vast majority of cases with pulse distinct at the wrist, it is eminently successful.

It would be exceedingly gratifying to me if I could draw an absolute comparison between the effects of opium and calomel, as, if the former could be proved at all as successful as the latter, I should unhesitatingly prefer it. If, for instance, we could determine the exact average of persons in the hundred who were liable to narcotism, or other evil consequences of the remedy, and that it did not exceed 16 in the 100, who is there that would not consider it a "*heroic*" medicine in so dreadful a disease? If we can venture on a confident inference from the experience of two very observant practitioners, we have their evidence that the fatal cases under the opiate treatment do not amount even to so many. Dr. Brown, of Musselburgh, says, when once a patient is in confirmed cholera, he thinks of no medicine but opium, and no cordial but brandy. He allows no drink after the opiate, merely wetting

the tongue with water*. Then, if the vomiting has not returned, he gives brandy and water. Should the case nevertheless be running on into collapse, the vomiting and purging continuing, he resorts to opiates and stimulant enemata, assisted by pressure. By this plan he asserts that he saves 9 out of 10, or 90 in the 100. Mr. Tweedie speaks, if possible, still more confidently; declaring that, previous to collapse taking place, the disease may be stopped quickly, safely, and with human certainty, by full and energetic doses of opium, proportioned to the age, idiosyncrasy, and condition of the individual. Whether these gentlemen consider any case *in collapse* in which the pulse is distinct at the wrist, I know not; yet much of the value of their statements depends upon the strictness of their definition of the word.

Opium seems to operate in the cure of cholera as calomel does, by some contra-stimulant power, and not by inducing any narcotic or other sensible effect. This power is manifested in certain medicines only, and always in the exhibition of large or extraordinary doses; for in small or ordinary doses their common characteristic effect is more likely to appear. Thus in ordinary doses, in inflammatory disease, calomel will purge or sdivate, opium will occasion sleep, or emetic tartar vomiting, if it be possible to produce these effects by such medicines in the morbid condition of the patient. But, given in large doses for the same disease, neither purging, nor salivation, nor sleep, nor sickness of stomach, follow the exhibition of any of these remedies: all of them in such instances, however different their ordinary influence, operating on one common principle, and producing one common result—an arrest of the malady without sensible evacuation of any kind. It is, then, of some importance to recollect, when giving any medicine with a view to its contra-stimulant influence, that if any of its ordinary sensible effects appear, there exists some idiosyncrasy of habit incompatible with the safe administration of an ade-

* This should be a general rule with regard to every medicine given in cholera, except such as are intended to excite vomiting. Even where drink is allowed *ad libitum*, as it was lately in Limerick, the patient should not be allowed to take any for a quarter of an hour or twenty minutes, at least, after taking medicine.

quate dose, or the disease is on the decline, and does not require so large a one, or was never present at all, and therefore the system is free to the ordinary operation of the medicine.

I believe the failure of opium in the hands of many practitioners has arisen from their not having exhibited it with sufficient boldness or judgment. With some it was administered timidly and faithlessly; with others it was given in cases where it ought not to have been employed at all. It is very possible that those cases of cholera in which, even in its primary stage, a tendency to narcotism after opium is observable, are precisely such as would be benefited by abstraction of blood, and thus probably made tolerant of a remedy otherwise inadmissible.

There is one great and very mischievous error into which the vast body of the medical profession has fallen, in forming their estimate of the value or the danger of remedies proposed for the cure of this disease, and that is, attributing the fatal congestion in the consecutive fever to some medicine injudiciously made use of in the early stage. So long as this congestion was referred to the fatal practice, as it was called, of administering opium and stimulants, and was advanced with sufficient dogmatism, I was myself led away like others; but when I witnessed the same congestion following the cold water treatment, and yet more, when I heard its frequent occurrence attributed to it, I began naturally to consider whether it was not rather a necessary, or almost necessary, result of the mischief or injury sustained by the system during the collapse; and to this conclusion I eventually arrived. I make the observation here, because not only opium, but other valuable remedies, lost reputation, owing to the dreadful fatality of the consecutive fever, with which they had no absolute or direct relation. In the report of the Hôpital St. Antoine, at Paris, M. Kepler is stated to have abandoned opium, because, though effecting speedy cures, it was sometimes followed by violent attacks of cerebral congestion, which rapidly destroyed convalescents. Similar inferences were drawn by practitioners in this country, on as questionable grounds; and it was only after the cessation of the disease that the truth began to dawn upon the profession.

In concluding the subject of opium,

I must acknowledge myself favourable to a further and more full trial of it. Should the opportunity occur, its use should be as little complicated as possible with other remedies, should be limited to the primary stage, and in that stage to those cases in which narcotism is not readily induced. In all new trials, too, of either this or other remedies, it would be interesting to note accurately the amount of cases in which fatal congestion took place in the consecutive fever, so that, after some experience, a comparison (impossible at present) might be instituted between their results in this way. It is just possible such congestions may take place in greater proportion after one mode of treatment than another, but not at all deducible from any facts at present before us.

Stimulants.

The employment of stimulants, especially brandy, in the cure of cholera, appears to have been as general in the East as the use of calomel or opium. They probably operate exactly in the same way, and are influential or useless at the same periods of the disease. In these countries, however, when brandy came to be tried, it experienced the fate of all other remedies for cholera, and lost its reputation with the mass of the public, which is not apt to be very philosophic in its inductions. The testimonies in its favour which have survived its loss of character are, however, far too decided and too numerous to permit us to assent to the indiscriminate censure which has been directed against it. We cannot understand the very strong belief evinced by those who have used this and other stimulants extensively, that it is generally successful in the primary stage of cholera, and especially in those cases in which the employment of opium is admissible or useful, without supposing it to be founded on some very imposing evidence. I do not indeed know of any reports which would enable me to compare its results with those of calomel or opium, but I hold it to be very inferior as a contrastulant to either. There are individual cases to which, perhaps, it might better apply, but these we shall never have it in our power to distinguish until we are furnished with more accurate estimates of its general effects.

I have been here speaking of stimu-

lants given in large doses, with a view to the arrest of the disease. There is, however, a much more general agreement as to the benefit derived from them when given more moderately, and merely with the object of sustaining the circulation. Most practitioners have employed them in the stage of collapse, and if any thing can really be said to assist the occurrence of re-action, it is probable that very mild cordials may, given patiently, and more as a slight stimulus to sustain the sinking powers of life, than to excite them. Even when they were abandoned as a remedy in several of the hospitals in Paris, their use was continued in this way, and apparently with advantage. The same change of opinion with respect to stimulants was observable among the majority of practitioners in this country, but some still continued to employ them confidently as a means of exciting or ensuring re-action; and if we could give implicit faith to the correctness with which their reports were kept, not without good reason. Mr. Stable, of Aldersgate-street, stated that out of 107 cases with the characteristic dejections and collapse, only 23 recovered in 1832, or about 2 out of 10, when treated in various ways; while in 1833, 17 recovered out of 41 treated by stimulants, or upwards of 4 in 10. Mr. Anderson published three cases (two in bad collapse) which were cured by continued doses of brandy with a little laudanum, until warmth was restored—and many others might be quoted. But referring to Mr. Stable's statement, to which, from the number of cases compared, some value must attach, we can only say, the weight of medical opinion is immensely against it. It is, indeed, a very prevalent belief, that excessive stimulants given in collapse have, in general, tended to oppress what little power remained, which, I am convinced, to say the least, has been occasionally the case with that very popular stimulant, the mustard emetic.

There are other popular stimulants, and amongst them, camphor and turpentine, of which I have not spoken. The latter, recommended by Mr. Sawyer, would appear to deserve a fairer trial than it has yet had in this complaint,—I mean in the primary stage. He gave it, he asserts, with considerable success, in doses of from two to four drachms, combined with a little

laudanum, and found it to remain on the stomach when other fluids were rejected.

Camphor was used extensively in India, and in very large doses. I do not think it has been tried uncombined with other equally powerful medicines, in England or Ireland, except in those places in the latter country where it was administered as a popular specific in the form of a spirituous solution, called the Pousonby Drops*. These drops acquired a high reputation among the non-medical portion of the public in Limerick and the surrounding counties, and I have no doubt they effected numerous cures when given early in the complaint, while the symptoms were yet mild; but I believe their fame was chiefly due to the wonderful recoveries they seemed to effect from the state of deep collapse. They were given in the dose of two drops every five minutes, and no drink whatever was allowed during their exhibition, or until the patient's recovery, except cold or iced water. Under this treatment reaction came on in two, three, or four cases out of every ten; in the usual proportion, in fact, in which it comes on when nature is not interfered with in her efforts; and all the credit of their having lived to pass through consecutive fever, and die of it, was attributed to the camphor. The impression created in the public mind by the absolute cures these drops effected in the early stage, and the extraordinary power they seemed to possess of reviving persons out of the deepest collapse, was so favourable, that on a slight return of the disease to Limerick, I believe in September 1832, eight cases were placed (with the sanction of the Board of Health) under the care of a medical man who was a strong advocate for their employment, to test their efficacy. They were all in collapse, or nearly so, when the treatment commenced; and the success, as may be imagined, was not very flattering; six out of the eight died, after having struggled into consecutive fever, when the Board of Health put a stop to the trial. Other remedies were subsequently made use of for the remaining two, but without avail. As well as I can recollect, not one out of the eight finally recovered.

It was the opinion of some physicians

* One ounce of camphor to six ounces of spirits of wine.

here, that camphor certainly evinced considerable power in exciting reaction, but that fatal congestion always followed. As this congestion, however, so frequently follows the cold water practice, as well as the stimulant or sedative, we cannot look upon such opinions as at all conclusive.

REMARKS ON LEPROA VULGARIS.

ILLUSTRATED BY CASES*.

By JOHN BISHOP, Esq.

Surgeon to the Northern and Islington Dispensary.

THE great diversity of opinion existing amongst authors respecting the *Lepros vulgaris* of Willan, or the *Dartre furfuracée arrondie* of Alibert, has induced me to offer a few observations on the subject, with cases by way of illustration. The causes which tend to the development of this disease—the immediate seat of the organic change—the nature of that change—and the best mode of treatment, are all more or less involved in doubt and perplexity. The following brief remarks are rather intended to shew in what respect my experience concurs with the theories of this disease already before the profession, than with any intention of proposing new remedies; yet as concurrent testimony has naturally much influence in recommending particular modes of treatment, these details may not be without their use in that respect also.

Lepros vulgaris is by no means an uncommon disease in this country, particularly in the low marshy districts of the West of England, where it appears to be endemic.

With regard to the causes of leprosy, our knowledge appears to be chiefly negative and conjectural. It is stated by Rayer† (and, I believe, by all authors), that this disease is not contagious; “that patients are not kept isolated in our hospitals, and that husband and wife continue to cohabit without one infecting the other.” Bateman‡ likewise observes, that “it is certainly not

communicable by contagion.” He also remarks, “I have met with one gentleman in whom spices or alcohol speedily produce it.” Larrey* attributes the attacks of leprosy which the French army suffered in Egypt, to the unwholesome quality of the pork in that country.

Bakers, and those who are much exposed to the irritating influence of dry powdered substances, are supposed to be more liable to this disease. Dr. Willan considers leprosy to be principally produced by exposure to cold and moisture, an opinion with which I am strongly inclined to agree, and which is supported by the facts contained in the first case subjoined. The physiology as well as pathology of the skin is not less interesting than important. Since the investigations of Malpighi, modern anatomists have bestowed much pains in endeavouring to unravel the minute and complex structure of the skin, which we may hope will ultimately lead to a better knowledge than we at present possess of the seat, as well as the cause, of its various lesions. If it is capable of being demonstrated that there is in the composition of the skin, as stated by Breschet and Roussel de Vauzeme†, “a mucific apparatus, composed of a secreting and an excreting gland, furnishing a soft material which becomes epidermis by desiccation,” we shall have less difficulty in accounting for some of the phenomena observed in leprosy, and in suggesting a probable cause for the profuse secretion of cuticle which attends this malady, as well as for its altered character.

According, then, to the views of Breschet and Roussel de Vauzeme, the excretory duct, which they describe as furnishing the epidermis, must be lined by a *mucous membrane*, which is the case with all open tubes in similar structures throughout the animal kingdom. Now the influence of cold and moisture in promoting copious secretions from mucous membranes cannot be denied. Supposing, therefore, these tubes and the connected apparatus to be in a state of chronic inflammation, the copious secretion and altered character of the cuticle in leprosy may be satisfactorily explained.

* Relation Chirurgicale de l'Armée d'Orient.

† Nouvelles Recherches sur la Structure de la Peau, par M. G. Breschet, M.D., et M. Roussel de Vauzeme, M.D. Paris, 1835.

The shades of character which serve to distinguish leproa vulgaris from psoriasis are almost imperceptible; but the experienced eye will immediately distinguish the squame of leproa from those of secondary syphilis. It is well known that the whole of the tissues which enter into the formation of the skin are not alike affected in leproa. Its first stage of development, according to Rayer, Bateman, and others, is the appearance of small solid elevations, about a line in diameter, of a circular form, and firm consistence; a character and result in accordance with the hypothesis here proposed, and which, presuming the accuracy of the anatomical details on which it is based, is supported both by analogy and observation.

The remedial measures recommended for the cure of leproa are as various as they are indefinite in their results. The most important of the external remedies are, 1st, baths, simple and medicated. A common vapour-bath, according to Rayer, sometimes proves sufficient of itself for the cure of leproa, whilst he observes that the sulphur vapour-bath generally fails in procuring relief, though we find that it is recommended by Galis, Clarks, and Willan. 2dly. Mineral waters, applied both externally and internally, are supposed by many to be highly beneficial. The most celebrated of these are the waters of Barèges, Caunterets, Bagnères, Bagnoles, and Enghien, in France; and those of Bath, Harrogate, Leamington, and Crofton, in England. 3dly. Ointments composed either of the phosphate, acetate, nitrate, or the proto-chloride of mercury; the latter may be used in the proportions of one drachm to an ounce of lard. I have, however, preferred the use of the ung. hydrarg. nitrat., with the most beneficial results. 4thly. Counter-irritants, and stimulating liniments, have been found useful.

Now although endermic remedies may be of essential service as auxiliaries, still they cannot be relied upon alone, when the disease is of long standing, or of an aggravated character, inasmuch as they exercise but a very indirect and uncertain control over the morbid action of the internal organs, or the vitiated states of the blood, which accompany this disease; nor do they secure the patient against a relapse. In illustration of which, a case is re-

corded by Alibert*, to this effect:—“Tout le système dermoïde étoit affecté, et se résolvait en squames furfuracées ou en molécules farineuses. Nous traitâmes cet infortuné par le régime le plus doux; des bains émollients qui lui furent assiduellement prodigués, assouplirent l'épiderme, lui donnèrent une apparence plus saine, finirent même par détruire jusqu'aux moindres traces de cette affection herpétique; mais, cet homme étant sorti de l'hôpital, négligea tous les soins qui rendent une guérison solide et permanente.” It seems that this man, after losing every external trace of the disease by the use of the baths, subsequently relapsed, and fell a victim to the disease.

The catalogue of internal remedies, is, perhaps, still more extensive, and sometimes not a little curious. Riemer and Carmenati have recommended viper and lizard broths. Carrère, Crichton, Razon, and Bertrand Lagrèsie, have extolled the efficacy of dulcamara. Bateman† recommends dulcamara to be used in combination with 1-12th of a grain of the oxymuriate of mercury. Pitch, “in doses of from six to twelve grains, and turpentine, in doses of from ten to thirty grains,” administered in the form of pills, are productive of a similar good effect, where the cutaneous circulation is very inert. Gurdlestone‡, Willan, Batty§, Bateman, Duffin, and many others, have more especially recommended the arsenical preparations. It is to the beneficial effects of the latter, which I have used very extensively, that I desire to draw attention in the following details.

CASE I.—Mrs. Galpin, a lady, aged 60, residing in the country, requested my attendance on her case in the month of March 1831. On visiting her, she stated that she had enjoyed excellent health for many years, until the commencement of the year 1827. Having at that period occasion to walk to a neighbouring village, the day being warm, and her pace rather brisk, she found herself in a copious perspiration; whilst in this condition, a heavy shower of rain suddenly fell, which penetrated her clothes and wet her to the skin. A severe cold was the consequence, which was succeeded by an itching sensation,

* Description des Maladies de la Peau, par J. L. Alibert, p. 55.

† Synopsis, p. 51.

‡ 15th vol. Med.-Physical Journal.]

§ Ibid. 17th vol.

extending over nearly the whole surface of the body, and she almost simultaneously observed on her extremities detached bright patches, which, after a short interval, terminated in desquamation of the cuticle, and thence extending over the whole body. The secretion of the epidermis now became profuse, one layer succeeding another, until, after the lapse of a few months, every part of the body was invested; the growth of the hair was destroyed, the eyelids were incrustated, and the nostrils blocked up; so that it was requisite to detach the scales from the eyelids before she could open them, and to clear the nostrils with a netting-needle, in order to permit the passage of air. The matrices of the nails, both of the fingers and toes, became affected, and the destruction of the nails followed; her strength began to decline; the extremities, burdened with multiplied layers of epidermis, no longer obeyed the impulse of the will; and the mind was ultimately enfeebled by the combination of protracted suffering with disordered functions. She thus became permanently confined to her bed, and incapable of moving without assistance, presenting an appearance not only disgusting, but it may be said, horrible.

She had now laboured under this disease about three years, during which she had been variously treated by several intelligent practitioners, without the slightest relief. The itching she experienced was almost intolerable. Plumbe* attributes this sensation "to the raising up of the edge of the scale detaching the centre forcibly from the cutis." In the state just related I first saw her, when the symptoms, in addition to those already mentioned, were these:—

The epidermis, which was of an opaque dirty-white colour, was so profuse, that the friction of a small soft brush was sufficient to detach a large basin full; the itching continued exceedingly painful; there was also great prostration of strength; the tongue was of a morbid redness, with prominent papillæ; the tunica conjunctiva of both eyes was slightly inflamed; the bowels were usually constipated; the urine was scanty and high coloured, and deposited a sediment on cooling; the appetite began to fail, and there was occasionally nausea; the pulse became

low and feeble, and her mind was impressed with the conviction that she could not recover. Having, in the first place, allayed this apprehension by expressing an assurance that she would recover, I prescribed as follows:—

R Liq. Potassæ Arsenitis; Liq. Potassæ, aa. ʒi.; Decoct. Sarsap. Comp. Oj. M. capiat cyathum ter quotidie.—Pil. Hydrarg. Submur. co. gr. v., omni nocte sumend.

R Magnes. Sulphat. ʒij. c. cyatho Aquæ Menthæ viridis quoties alvus minus laxa fuerit.

These remedies were continued without intermission for about six weeks. At the expiration of that period the first symptom of relief observed was a great diminution of the itching, amounting almost to a total absence; the desquamation appeared more transparent. The dose of the liquor potassæ arsenitis in the same form was now increased to eight drops, and repeated as before, three times a day. The parts of the skin which appeared more irritable were touched at night with a little of the ung. hyd. nitrat. apparently with good effect; a further period of six weeks was devoted to this treatment, at the expiration of which, the itching had entirely subsided, the production of scales had ceased in many parts, and the general health and strength were improved. The same remedies were, therefore, continued. After the lapse of six months, the head and face began to assume a natural appearance, and the body presented isolated patches rather than a continuous surface of scales, the interval being occupied with healthy skin. The patient being now desirous of discontinuing the sarsaparilla, the liq. potass. arsenitis was given in doses of ten drops, in a little tea, three times a day. At the expiration of a few weeks, however, the stomach became irritable from the action of arsenic in this form, and the scales had not entirely disappeared. She, therefore, resumed the remedy, in combination with sarsaparilla, which agreed perfectly well. At length, after having used the arsenic without intermission, for twelve months, the skin was restored to its healthy functions, the hair and nails began to grow, the strength returned, so that after recommending her to use the medicine occasionally, with a view to prevent a relapse, I left her in a state of convalescence.

The points of greatest importance in

* On Diseases of the Skin.

this case I consider to be, first, that the existing cause of the disease was easily traceable by the effects immediately produced in consequence of exposure to cold, moisture, and suddenly suppressed perspiration. Secondly, That the liq. potassæ arsenitis, exhibited in small, but long-continued doses, was found capable of curing this most aggravated case. Thirdly, That the copious formation of the epidermis under such circumstances favours the opinion, that it is produced by an apparatus, the vessels of which are lined by a mucous membrane.

The last proposition may be regarded as purely hypothetical; but, independently of the concordant theory of Willan, we find that Dr. Duffin* entertains the same general notion, though in a less specific form, owing, no doubt, to his want of that knowledge of the structure of the skin, which we now possess, as a basis for his observations. He, however, remarks, "I imagine that the primary evil lies in the secretions of the true skin, which becoming vitiated by their local irritation, induce chronic or subacute inflammation of the vessels, that either nourish or produce the cuticle, and that they produce a superabundant supply of morbid cuticle."

The next case was that of a female servant who had been in the employ of the lady whose case has just been detailed. Her history was briefly as follows:—

CASE II.—Ann —, aged thirty, of fair complexion, and robust constitution, stated that she had been in excellent health until the period of her engaging in the service of the above-mentioned lady, during her residence with whom she had at times made use of her comb, and on one occasion she accidentally pricked her head, upon which appeared almost immediately afterwards a complaint of similar character to that of her mistress, commencing at the point where the comb had penetrated, extending itself over the whole head, and accompanied with a sensation of itching over the whole body. This patient was subjected to the plan of treatment just described, with the exception that she used the liq. pot. ars. dropped into a little tea, instead of its being combined with sarsaparilla; the ung. hyd. nitratis was the only local application employed. Without reciting unnecessary details,

it will perhaps be sufficient to say, that after using these remedies for six weeks, the itching began to subside, and when another similar period had elapsed, the dose of arsenic having been increased from six to ten drops, three times a day, it had entirely subsided; the cuticle appeared more transparent; the disease no longer extended its boundaries; and, finally, after persisting in the use of arsenic for nearly nine months, she became convalescent.

Having now for several years pursued the same mode of treating this disease, during which a great many cases have been subjected to this plan of treatment in public and private practice, I can with confidence deduce the following remarks from these details:—The last case established the important fact, that although lepra vulgaris be not perhaps communicable by ordinary contact, it may nevertheless be transmitted from one person to another by inoculation. This notion is opposed to all theories respecting the propagation of the disease. It appears also that six weeks usually elapse before the first indications of relief are observed, and that it requires many months to effect a complete cure, by means of the arsenical preparations administered in small, but long-continued and gradually increased doses. Bateman recommends the liq. pot. arsenitis to be used "in doses of four or five drops, which may be slowly increased to eight, and persevered in for a month, or more," a period which appears insufficient to effect even the first stage of improvement; and it probably is through want of continuing the remedy for a sufficient time, that, in the hands of many practitioners, the arsenical preparations have proved ineffectual. The arsenical solutions, if largely diluted either with the decoct. of sarsaparilla or the decoct. of dulcamara, will rarely disorder the digestive organs: they appear also, independently of their specific effects on the disease under consideration, to give a stimulating impulse to the circulation, to effect a change on the morbid state of the capillaries, to infuse tone and vigour in the vital organs, and to raise patients labouring under extreme constitutional debility to health and strength. Such, at least, has been the effects of the arsenic under my observation.

Bernard-street, Russell-square,

OBSERVATIONS

ON THE

ANATOMY OF THE ORGANS OF
CIRCULATION IN THE SCOLO-
PENDRA.

To the Editor of the Medical Gazette.

SIR,

BEFORE proceeding to relate the observations that I have made on the circulating system in the Scolopendra, I will give a short statement of what is already known concerning the anatomy of that system in this animal.

In the excellent publication of Straus* on the anatomy of the articulated classes, the circulating system in the Myriapoda, as in the Insecta, is described as consisting of a heart without an auricle, and an artery which distributes the blood throughout the body; after which this fluid returns, and again enters the heart by several orifices. In the scolopendra he describes the heart, or dorsal vessels, as commencing in the last segment of the body, and continuing forwards, in the median line, until it arrives at the second segment; where it terminates by giving origin to a large artery, which, passing forwards into the head, becomes so small near the mouth that it cannot be followed further. At its commencement, this artery gives origin to a pair of branches smaller than the vessel itself, which are directed forwards into the basilar segment. Towards the middle of the head, the trunk gives origin to a second pair of branches, more slender than the former pair, but following the same direction. A third pair goes to the organs about the mouth. After having given this description, the above author states that he has been unable to follow any of these branches to their extremities, in order to ascertain in what manner they terminate.

The above description, as far as regards the dorsal vessel, or heart, and central artery continued from it into the head, is perfectly correct; but the two lateral vessels (fig. 1 and 2, *a*), situated at the commencement of this artery, form a more important part of the circulating system than this author is aware of. Instead of being smaller in size than the cephalic vessel (fig. 2, *b*), I have found them to be, in the specimens of scolopendra that I have examined, considerably larger; they take their

origin, in common with that vessel, immediately from the heart (fig. 2, *c*), and follow a course outwards and downwards on either side of the œsophagus (fig. 2, *d*), to reach its inferior surface, where they unite and form a single trunk (fig. 1 and 2, *e*). Thus the œsophagus in this situation is completely surrounded by a vascular collar, as it is more anteriorly by a nervous one. The lateral communicating vessels descend abruptly, forming short arches. The point of junction of the two vessels is situated almost exactly beneath the anterior termination of the heart, and a little in front of the second infra-œsophageal ganglion: it also nearly corresponds to the posterior border of the second segment of the skeleton. The two recurrent nerves, in their course backwards from the brain (fig. 1 and 2, *f*), pass with the œsophagus through its vascular collar.

The single trunk thus formed runs directly backwards to the posterior extremity of the animal. In this course it rests on the nervous columns and their ganglia (fig. 1 and 2, *g*), but is easily separated from them: it lies beneath the alimentary canal and its peritoneal investment. The vessel appears to terminate posteriorly, after having passed over the last ganglion, by dividing into minute branches; but it here becomes so small and transparent, that it is difficult to ascertain satisfactorily its mode of termination: I have been unable to trace any connexion between it and the posterior extremity of the dorsal vessel. During its course along the abdomen, this vessel gives off several small branches on each side.

The lateral communicating vessels while passing around the œsophagus give off each a small branch (fig. 1, 2, *h*) which proceeds forwards to the muscles, moving the powerful maxillæ of this animal. From the point of junction of the lateral vessels a single small branch (fig. 1, *i*) is continued forwards between the œsophagus and the sub-œsophageal ganglion towards the mouth.

Treviranus (Vermischte Schriften, bd. 2, p. 32) describes the nervous ganglia of the scolopendra as being connected to each other by three instead of by two cords, although in the representation he has given of the nervous system of this insect he has only figured them as being connected by two cords. From the fact of the connecting columns

* *Considérations Générales sur l'Anatomie Comp. des Anim. Articulés.*

in this class of animals being only two in number, it is probable that this author may have mistaken the longitudinal vessel above described for a part of the nervous system.

Mr. Newport has likewise fallen into the same error, inasmuch as he has described and represented this vessel as part of the nervous system (*Phil. Trans.*, part 2, 1834): he is correct, however, in figuring it as not connecting the ganglia to each other, but passing over both ganglia and columns, being but slightly connected to them.

Müller has described (*Meckel's Archiv. für Anat. und Phys.* 1828) in the scorpion a cord of a peculiar nature, lying on the abdominal ganglia and columns, giving off no branches, and thicker than both the abdominal cords put together. He states that it is con-

nected to the nervous cords and ganglia loosely, and can be easily separated from them, excepting at the last ganglion. It is distinguished from the nervous columns by its uniform non-ganglionic nature, and duller and more indistinct colour: he adds that it is not hollow, and is, in his opinion, certainly only a ligament (band): it diminishes in size posteriorly, and can be traced as far anteriorly as the vertebral piece of the thoracic segment, where it ends by an abrupt extremity, within the opening through which the nervous cord passes.

From many points in this description of Müller, and from the representation given of this cord by him, and from examination of the parts myself, I am inclined to consider this band as analogous to the vessel above described as occupying the same situation in the scolopendra.

FIG. 1.

Description of the Wood cuts.

Fig. 1 is a view from above of the anterior part of a scolopendra, the heart and alimentary canal having been removed, and the lateral vessels divided: *a*, lateral communicating vessels; *c*, heart or dorsal vessel; *e*, trunk formed by the union of the lateral vessels; *f*, brain; *g*, nervous co-

FIG. 2.

lumns; *h*, branches of lateral vessels going to maxillæ; *k*, sub-oesophageal ganglion.

Fig. 2 gives a lateral view of the parts. The same letters refer to similar organs as in fig. 1, excepting *b*, cephalic vessel; *d*, oesophagus; *i*, the single branch of the point of junction.

pendra. Its close resemblance to that vessel is very obvious on comparing the plate of Müller with the wood-cuts here given, and with the plates of Mr. Newport. No connexion has been traced between it and the brain.

From the small size of the scorpions that I have examined, I have not been enabled to ascertain in a perfectly satisfactory manner the exact relation which exists between this cord and the heart.

Your obedient servant,

W. LORD.

University College, Feb. 24, 1838.

RUPTURE OF THE HEART AND AORTA.

To the Editor of the Medical Gazette.

SIR,

IN the last number of your journal are contained some observations on Rupture of the Heart, by Mr. Thurnam. As instances of this lesion are by no means of common occurrence, I beg to forward you the particulars of a case which has recently come under my notice. I likewise send you the notes of two other cases of interest in connexion with the pathology of the heart. In one of them, hæmorrhage into the pericardium was occasioned by ulceration through one of the sinuses at the root of the aorta, excited by ossification of the semilunar valves,—a termination of the disease which must be exceedingly rare. The other is a case of Rupture of an Aneurism of the Aorta into the right Auricle of the Heart, of which I believe there are only two similar examples on record.

I am, sir,

Your obedient servant,

T. B. CURLING.

1, Mount Place, London Hospital,
February 23d, 1838.

CASE I.—*Spontaneous Rupture of the Left Ventricle of the Heart.*

I was sent for in a great hurry on the 29th of December last, about eight in the evening, to see a Mrs. M—, an inhabitant of the Trinity Alms-Houses, Mile End, who was reported to be dying. I hastened immediately to her residence, but she had expired before I arrived. It appeared that her servant, who was in the room above, hearing a slight noise below, instantly descended, and found her mistress insensible and

gasping for breath, and in another minute she expired.

There was much opposition to the post-mortem examination on the part of the friends; but a medico-legal investigation being considered necessary, the body was opened by a coroner's order. The chest only, however, was examined. There was a tolerably thick layer of adipose tissue over the thorax. The pericardium was distended with dark coagulated blood, which completely invested the heart. On the anterior surface, about an inch from the septum of the ventricles, and two inches from the apex, there was a ruptured opening communicating with the left ventricle, about eight lines in extent, in the direction of the muscular fibres. The muscular tissue of the organ was sound, and not particularly soft; there was no appearance of ulceration in the interior of the ventricle. The coronary arteries were ossified, but the valves were healthy. There was a good deal of fat about the heart.

Mrs. M— was 76 years of age, and had been for many years a complete martyr to the gout. Her toes and fingers were crippled with chalk stones, and she had been confined to her couch from the effects of this disease for several months. I had attended her at various times during the last twelve-months, but she had never complained of any thing which induced me to suspect the existence of any disease of the heart. A few hours previous to her sudden death she had been visited by some of her family, and had appeared in excellent spirits. This would appear to be an example of the *senile* form of rupture*.

CASE II.—*Sudden Death from Hæmorrhage into the Pericardium through a small ulcerated opening in one of the sinuses of Morgagni, caused by ossification of the aortic valves.*

Thomas Ferguson, a stout man, aged 35, was brought into the London hospital, July 2d, 1836, dead. It appeared that he had been taken ill somewhat suddenly, and had expired whilst being conveyed to the hospital; but no further account of him was obtained, except that he had been labouring for

* Some interesting cases of Rupture of the Heart are contained in Farre's *Journal of Morbid Anatomy*.

some time from an affection of the chest.

On examining the body on the following day, the pericardium appeared much distended; and, on laying it open, the heart was found to be surrounded with blood partially coagulated. On removing the blood and making a careful inspection, no rupture of vessel or source of the hæmorrhage could be discovered. The heart was therefore removed for a more minute examination. The cavities on the right side, and the left auricle, were healthy; the left ventricle, however, was greatly hypertrophied. The aortic valves were ossified, and of remarkable thickness, the aperture for the efflux of blood being reduced to fully one-half its natural size. One of the irregular ossified valves was four lines in thickness, and the corresponding sinus was dilated around it. One part of the sinus, surrounding a projecting part of the ossific deposit, was extremely thin, and had a small pin-hole aperture, caused apparently by ulceration. It was evidently through this opening that the blood had escaped into the pericardium. The lungs and abdominal viscera were sound.

CASE III.—Aneurism at the origin of the Aorta, terminating by Rupture into the right Auricle of the Heart.

Nov. 28, 1834, I examined the body of John Osborn, a man aged 35, who had died in the London Hospital the previous day.

The cutaneous vessels, and superficial and large deep-seated veins, especially of the head and neck, were extremely turgid. The vessels on the surface of the brain were likewise much injected; but the organ itself was healthy. There were tolerably firm old adhesions of the pleura, on the right side of the chest, and about sixteen ounces of serum on the left. The lungs were sound, but congested. On opening the pericardium four ounces of serum were observed, and the heart seemed greatly enlarged and displaced, the right auricle being partly concealed by a tumor, which was found to be formed by an aneurism at the root of the aorta, about the size of a hen's egg. The appendix of the right auricle was completely adherent to the exterior of the aneurismal sac, which encroached very much on the right auricle, and diminished considerably the cavity. At the

pars venosa, near the ostium venosum, there was an opening capable of admitting a crow-quill, and having an irregular margin, as if caused by rupture, which communicated with the lower part of the aneurismal sac. There was a good deal of hypertrophy, with dilatation of the left ventricle; also a small ossific deposit in one of the aortic valves, and deposition at various parts of the aneurismal sac and interior of the aorta. The auriculo-ventricular valves, and the valves of the pulmonary artery, were healthy. There were about twenty ounces of serum in the cavity of the abdomen, and there was extreme sanguineous congestion of the liver, and an injected state of the portal system*.

I did not see this patient during life, but I ascertained that he was admitted into the physicians' wards in the preceding August, with general anasarca, cough, and great dyspnoea. A distinct pulsation, and a *bruit de soufflet*, were perceived on the right side of the sternum, and the pulse was weak and resilient. By bleeding, and the exhibition of elaterium and digitalis, the anasarca was removed, but the difficulty of breathing continued to increase. The countenance became livid and anxious, and he was unable to remain in the horizontal position. In the morning of the day before he died, the dyspnoea suddenly became extremely urgent; he could not bear the clothes near his chest, but kept throwing his arms about, calling out for fresh air, and struggling in the greatest possible distress for nearly twenty-four hours before he expired.

The prolonged period of the dying agonies in this case affords a striking contrast to the suddenness of death in the two preceding. In the first case death was almost instantaneous; and in the second, where the opening into the pericardium, at the sinus Morgagni, was very small, a sufficient quantity of blood to arrest the action of the heart escaped in a few moments. In the last case, however, the blood which rushed out of the aneurismal sac passed still into the current of the circulation, but so freely as to oppress the right side of the heart, and interfere with the return of blood to that organ, ending very gradually in fatal congestion of the important viscera.

* The heart is preserved in the Hospital museum.

MEDICAL RELIEF TO THE POOR.

COLCHESTER UNION.

To the Editor of the Medical Gazette.

SIR,

As any thing connected with the medical department of the new Poor Law must be interesting to the profession, I think it right to communicate, through the valuable pages of the GAZETTE, an important alteration that has taken place lately in the medical department of the Colchester Union House. The Guardians have resolved, in future, that all medicines required for the use of the paupers, in the house, should be paid for by them; and the medical officer be remunerated by salary for his services. This I consider to be a very important alteration, and a favourable omen towards a better management in the medical affairs of union houses; and I think the Chairman and Board of Guardians of the Colchester Union deserve the best thanks of the profession, in being the first, so far as my knowledge extends, in doing away with that abominable system of *drugging paupers' stomachs* by contract.

It is to be hoped that, before long, we shall have still more important changes, and that those stately buildings that have been reared up throughout the length and breadth of the land, may yet be formed into valuable medical institutions: at present, so far as regards the profession, they are next to useless. So desirable an end might be effected by intrusting the medical affairs of the several unions in the hands of a medical board in London, who should have the entire management as to the duties required, and the payment of the medical officers. I fear that if any of those who are pursuing particular departments of the profession were at present to look for information from the medical returns of unions, they would be rather disappointed, as the form now used gives but scanty information to a medical inquirer. If a form was issued to the different unions similar to that used in the public services, and the books to be yearly sent for the examination and approval of the medical board, and to be used as they thought proper, what a valuable public medical record would this constitute. It is impossible, under the present pal-

try remuneration, that the medical officers can perform this duty as it ought to be done.

From a few of your editorial remarks, in a late number of the GAZETTE, one unacquainted with the subject might be led to suppose that the present diet is not sufficient for the health of the inmates in union houses; but that such an impression is erroneous, I have only to refer to the Colchester, Lexden, and Wenstree Union Houses (to both of which I have the honour to be attached), where, by reference to the medical returns, it will be seen that the inmates enjoy the best possible health. In the Lexden House, which is altogether an agricultural union, there have been for the last quarter 292 inmates, and our daily sick list has not averaged more than seven. In the Colchester House, in about the same number of paupers, our sick list has been double; this arises in part from being a town union, and also, I may state, it has been doing the duty of a general hospital to the town, from some unhappily misunderstanding betwixt the two establishments. Indeed, in both houses the sick list is nearly made up of people entering already in a state of illness. In either a death has not occurred of any one who has been taken ill while living in the house, with the exception of two children in the Lexden House, who died of measles, out of a number of 35 cases; and these two entered while measles were prevalent amongst the children, and both were of one family, who came into the house in a sickly ill-conditioned state; in fact, with only two other exceptions, all deaths have been in persons upwards of 65 years, and in one case lately at the advanced age of 99.

These facts will, I think, prove, that if the diet table is not over-plentiful, it is sufficient for the good health of the inmates.—I am, sir,

Your obedient servant,

GEO. B. CLARK, M.D.

Surgeon to the Colchester, Lexden, and Wenstree Union Houses.

Trinity-street, Colchester,
Jan. 21, 1838.

[We readily give insertion to the above, although in opposition to the opinions we have ourselves expressed. Much more extended evidence, however, would be requisite to convince us that the diet is sufficient.—Ed. Gaz.]

ON DELIRIUM TREMENS.

To the Editor of the Medical Gazette.

SIR,

I HAVE read with considerable interest Dr. Munk's observations on delirium tremens. My attention was first called to this subject during my attendance on Dr. Hannay's lectures at the Andersonian University of Glasgow. This gentleman has for upwards of twelve years taught his pupils that the disease in question depends on inflammation of the mucous membrane of the alimentary canal, and that it is best treated by local depletion and anodynes. So far as my own observations extend, I have not the slightest hesitation in affirming that these views are correct; consequently to Dr. Munk's remarks, so far as they coincide with them, I cordially assent. There are some of his conclusions in which, however, I cannot acquiesce.

He endeavours to establish four distinct varieties of the disease, each of which he seems to imagine differs from the other in its proximate cause. 1st. He has a form resulting from debility. 2ndly. One in which much cerebral affection exists. 3rdly. Another which is of an asthenic nature, and accompanied with gastritis, *not as a cause, but as a complication*. 4thly. That form of which gastritis is the proximate cause. These distinctions I humbly submit are not well-founded, and therefore have a tendency to confuse our ideas respecting the nature of the disease. Though I freely admit that much evil is to be dreaded by too hasty generalizations, yet I firmly believe that as great danger is to be apprehended from groundless and shadowy distinctions. Dr. M. has entirely overlooked the only data on which he ought to have founded his distinctions. In the first three varieties which he makes, he does not condescend to give the least information regarding the cause of the disease. Now he must surely be aware of the truth of the maxim, "*scire vere est scire causas.*" He neither endeavours to elucidate the difference of their pathological states, nor to point out what is their dissimilarity in this respect from that of the fourth variety. Such a task would, indeed, be futile, as delirium tremens universally depends on gastritis, which, to a greater or less extent, is the real pathology of the affection; the first three

of Dr. Munk's forms being neither more nor less than modifications of the fourth, which he himself states depends on gastritis. This is the true "*origo mali*," however unwilling many practitioners are to admit the fact. But it may be asked, what proof can be adduced in confirmation of this assertion. To this I would answer, 1st. The symptoms. 2ndly. Appearances after death. 3rdly. The effects of remedies. And 4thly. The nature of the exciting cause. 1st. In delirium tremens we have a set of symptoms present in every case, however complicated it may be, or whatever modification it may assume—such as nausea, vomiting, that peculiar state of the tongue (well described by Dr. M.), tenderness and oppression at epigaster, &c. Let me ask, what do these indicate? Do they not clearly point out a disordered state of the stomach? In some cases we have symptoms conjoined to those enumerated, denoting nervous irritability; in others, signs expressive of cerebral affection; and again, we may have a class of symptoms indicating debility. These signs do not, however, occur in every case; but we have always those present indicative of gastric derangement. The others are merely expressive of complications, either lighted up by it, or induced by some peculiarity in the constitution of the individual.

2ndly. Dissections reveal gastritis in all its phases, from its slightest forms to its highest state of disorganization. It may be said that in some cases no traces of inflammation of the mucous membrane can be detected. Such instances, I presume, are indeed rare. It should be borne in mind that the inflammation of the mucous texture may have subsided, and the affections which it lighted up through sympathy in other organs have caused the patient's death.

3rdly. The effects of the treatment afford a proof of no ordinary moment. The benefit resulting from the application of leeches to the epigaster is so marked, and so instantaneous, as to leave no doubt of the presence of gastric inflammation.

4thly. The nature of the exciting cause, the constant and direct application of it to the mucous membrane, are circumstances highly confirmative of the existence of gastritis. Much more might be argued in support of this view. I will not, however, transgress any farther on your space at present.

With respect to the employment of morphia in the disease under consideration, I regard it as a remedy of the highest utility. I would perhaps hesitate to administer it in many acute cases, previous to local depletions; but when this has been premised, morphia is of the utmost value: it allays the irritability of the nervous system, and procures sleep—a circumstance of paramount importance in the treatment of delirium tremens: sleeplessness is one of its most distressing symptoms. In the cases adduced by Dr. Munk, this very symptom holds a prominent place, although he seems to have overlooked it, as he has not had recourse to any means by which it might have been obviated. In the last case which he quotes, morphia was given, and he states with the best effects. Morphia, in subacute inflammatory affections of the mucous textures, seems to possess considerable antiphlogistic powers. But be this as it may, I am confident that it is of infinite service in delirium cum tremore.

“Its balmy influence bestows
On anxious thought a sweet repose.”

The practice which I follow in the affection in question is that recommended by Dr. Hannay in his lectures, namely, the application of leeches to the epigaster, varying the number according to circumstances. After the leeches fall off, fomentations are used to encourage the bleeding; the bowels are kept open by enemata; and morphia given in doses according to the age, the constitution of the patient, and the degree of excitement under which he labours. This treatment, in all the cases which have come under my observation, was followed by immediate relief. In some instances in which leeches could not be obtained I have substituted sinapisms with very good effect. The following case may serve as an example of this:—

Jan. 3d.—A. W., a stout man, aged 26, by trade a bricklayer, complains of severe oppression at epigaster, which is painful on pressure; vomits all matters taken into stomach; eyes suffused; tongue tremulous, red at tip and margins, covered with a dirty white fur in centre. Pulse about 118, but cannot be exactly counted, from tremors, which are almost incessant in extremities. Bowels costive; thirst exceedingly urgent. At some times he imagines himself surrounded by his comrades, who are “mocking” him; at others he sees

a number of “little black fellows,” who are going to fix chains on him. When labouring under this delusion he starts from bed. He sleeps none; became affected three days ago, before which time he had been constantly intoxicated for about six days; and he is generally intemperate in his habits. Leeches could not be obtained.

Admov. Sinapism. epigast. et hab. Sol.
Mur. Morph. ʒss. 4tā qq. h. Injiciatur Enema domest. quamprimum.

4th.—Is more collected; slept a little; bowels moved by enema; tremors much mitigated; pulse 108; vomiting ceased; thirst somewhat abated; oppression at epigaster relieved, but not gone.

Rep. Sinapism, et cont. alia.

This treatment was persevered in (with the exception of sinapism), and on the fifth day from my first visit he was enabled to commence his work.

In conclusion I would remark, that it must certainly be gratifying to Dr. Hannay to think that the experience of others is daily corroborating those views which he has been carefully inculcating to his students for many years, regarding the nature and treatment of this very distressing disease.

If the foregoing observations be deemed worthy of a place in your valuable journal, by inserting them in an early number, you will much oblige

Your obedient servant,
JOSEPH BELL.

Baerhead, Feb. 15, 1883.

FEMALE WITH THREE MAMMÆ.

To the Editor of the Medical Gazette.

SIR,

In the number for Jan. 20 of your valuable journal is “The History of a Female with four Mammæ and Nipples,” communicated by Dr. Robert Lee to the Royal Med. and Chir. Society. Allow me to transmit you the particulars of a case occurring in my practice.

I was called at one A.M. during last spring to a poor woman residing in this town, who was said to be in a fit, and on entering the room found her lying on her back quite dead, with an infant about three months old still sucking at the right mamma; whilst from a small

wart-like nipple, about three inches below the breast, and rather nearer the median line, a few drops of milk were oozing.

On a post-mortem examination, I found this smaller nipple had a mammary gland about the size of a walnut, which was supplied by an artery of the breast above, returning the blood by two veins running parallel to it.

It appeared, upon questioning the bystanders, that she had never given the smaller nipple to any of her children, but had always suffered inconvenience from the escape of milk during the time the child was applied to the breast.

I am, sir,

Your obedient servant,

THOS. THURFIELD, M.R.C.S.

Kidderminster, Feb. 17, 1888.

LACED STOCKINGS.

To the Editor of the Medical Gazette.

SIR,

A PATIENT came to consult me with that peculiar kind of sore leg produced by the rupture of a varicose vein, and from irritation, bad treatment, and inattention, a wound is the consequence, with surrounding tenderness and swelling. He had had this for several years, and as his occupation caused him much walking he was anxious to get it cured, which I effected, by first strapping the leg from the knee downwards with soap plaster, thereby lessening the calibre of the veins, and getting the circulation more equal. The wound in the ankle was dressed with the lotio nig., and soon healed, and a circle of nitrate of silver drawn round to prevent a disposition to erysipelas extending. When he could bear it, and the tenderness of the skin a little subsided, the parts were first protected by the ung. zinci spread on lint, and then strapped over with the soap plaster, and removed weekly; and in order to get the skin firm and healthy, the liq. plumbi subacetatis was put on with a soft brush, and lint over that, and plastered up again: a firm healthy leg was the consequence of this treatment. I then advised an elastic stocking, which, if of a proper description, was to be used for the future.

A week afterwards he brought me a jean stocking, prepared with the caoutchouc, like Mackintosh's patent

cloaks. I did not like to put this on, and told him what I thought would be the result, which has proved to be the case. The stocking thus prepared effectually resists radiation; consequently, with a walk every day, varying from six to sixteen miles, the perspiration is formed, and remains upon the limb.

I had prepared the limb before putting on the stocking, by placing pieces of lint round it to absorb this; but the consequence is, that when I undo the stocking, twice a week, the stench of the perspiration is exceedingly offensive, independently of the skin getting into a very thin, tender, and irritable state.

This prepared stuff, now in general use for stockings of this description, is radically bad, as it takes upon itself the office of the epidermis, without its porosity, the epidermis of the patient becoming the cutis vera in consequence.

It is with the desire to prevent loss of time to patients for the recovery of their ailments, for which a laced stocking is necessary, loss of credit to the surgeon by adopting proper instead of improper means, and finding it out afterwards, for the cure of their patients, and loss to the maker of these bandages or stockings, for they never can keep a good character, that I have now addressed you; and if you find these remarks fit for your journal, you will oblige me by inserting them for a constant reader and subscriber, and

Your obedient servant,

B. RIDGE, M.R.C.S.L.

Terrace, Patney,
6th Feb. 1888

ON THE FORMATION OF PUS.

To the Editor of the Medical Gazette.

SIR,

VARIOUS opinions have been lately put forth concerning the origin and mode of formation of pus. Every one seems to agree that it is a product of inflammation, but how or in what manner the fluid itself is formed, is a matter by no means agreed upon. Equal uncertainty also prevails as to the nature and essence of inflammation,—whether this is in all cases the same affection, or whether there be several varieties of it, and what it is which constitutes its constant and invariable proximate cause, or pathological condition.

An investigation of this kind is beset with many difficulties, although there are those who would cut the matter very short, by affirming that inflammation existed when the vessels of a part took on an inflammatory action; but how this action was produced, or in what it differed from any other action, they are by no means prepared to say; indeed, the word action, as it is frequently employed, seems destitute of any precise meaning. I can easily comprehend that action may vary in its degree of force, or of regularity, but any alteration in the quality of action I do not understand. The terms inflammatory action, gouty action, rheumatic action, scrofulous or venereal action, convey no distinct notion to my mind. When a modern pathologist ascribes the origin of a scrofulous or venereal sore to the vessels of the part taking on respectively a scrofulous or venereal action, I am no better satisfied than if, when I saw a sudden gush of tears consequent to some emotion of the mind, he were to inform me that they were occasioned by the vessels of the eyes taking on a lachrymal action.

If we attend to the symptoms ordinarily present in inflammation, and the manifestation of which all persons agree to be evidence of this state, we shall not find any one to be truly pathognomonic. When inflammation arises in a part to which we have access, we discover increased circulation through that part, redness, swelling, and pain; yet is neither of these symptoms pathognomonic, as each one may take place when no inflammation is present.

By contrasting in a part the state very nearly resembling inflammation with the state of actual inflammation, we may perhaps arrive at some notion of what actually constitutes inflammation—what is its proximate cause and essential nature.

If I immerse my hand some time in hot water, there will be produced increased circulation, redness, swelling, but no pain; if to these symptoms pain was added, we should pronounce the part to be in a state of inflammation. In what consists the difference? Clearly in this; that in the one case the increased flow of blood is freely transmitted through the vessels of the part; in the other case, the increased flow is resisted by the contraction of the vessels through which it has to pass; they

resist the efforts made to distend them, and thus pain is produced, a state of inflammation is brought on. If the vessels readily receive the increased quantity of blood, no actual inflammation arises; it is the resistance offered which gives rise to disease.

It would occupy too much time to go into further consideration of the essential nature of inflammation, concerning which so much discrepancy of opinion exists. I shall content myself with assuming that inflammation is to be explained by considering the relative force of action between the propelling and the recipient vessels: whilst the natural balance is preserved, no inflammation takes place; when the force of the propelling vessels is increased the resistance of the recipient vessels remaining the same, inflammation will occur: the same thing will happen, of course, if the resisting power is increased whilst the propelling power remains the same. If the propelling power is increased, and also the resisting power at the same time, then the inflammation must be of a more intense degree, so that it may be properly said inflammation exists in a compound ratio of force and resistance.

Inflammation thus defined varies considerably in different cases in its progress and terminations—modified, perhaps, by the tissue of the part in which it is situated, or by some other circumstances not very obvious; thus gout and rheumatism, although displaying some of the characters of ordinary inflammation, differ from it in many essential particulars, and in none more than in its indisposition to the formation of pus; a fact which militates against the hypothesis of Dr. Marshall Hall, who says, "I believe that the secreting vessels are variously affected by the various degrees of inflammatory action, an effusion of serum marking the lower, a secretion of albumino-fibrin the higher degrees, and pus the highest of all;" yet in what disease does "inflammatory action run higher than in an acute paroxysm of articular gout wherein no pus is produced? By the by, the Doctor speaks merely of various degrees of action, not difference of quality. I am to confine myself to common phlegmonous inflammation terminating in suppuration, and to say a word or two on the mode in which the pus is produced.

Two different opinions have been entertained, although one is much more modern than the other, concerning the source and manner of production of pus, in inflammation; some attributing its production to a *peculiar* fermentation taking place in the fluid effused during inflammation; others to the peculiar action of the inflamed vessels *secreting* pus, and pouring it out instead of the usual fluids furnished by them in a state of health. An objection to the first opinion, the conversion of the effused fluid into pus, has been raised, on the ground that no fermentation takes place in the fluid effused; but this objection is rather verbal than solid, being founded upon a mistaken apprehension of the term fermentation. Nothing more is meant by the term here applied, than a spontaneous separation and recombination of the primary elements of a compound body.

All the solid parts of the animal body, and all the various fluids, however different in the structure and properties, consist but of a very few primary elements—as nitrogen, carbon, hydrogen, and oxygen, to the peculiar arrangement and proportion of which elements all the difference is owing. The separation of the compound body into its primary elements, and the recombination of them in different proportions, was demonstrated fermentation; the process is universally acknowledged to take place; the propriety of the term when applied to the living animal system is denied; although we have no hesitation in admitting that the process takes place, or in applying the term when the influence of life is withdrawn, viz. the putrefactive fermentation.

A stronger objection to the notion of the production of pus by fermentation, as the word has now been defined, is the fact of this fluid being found on the surfaces of inflamed membranes, where no cavity exists for the collection or accumulation of any fluid to undergo this process or spontaneous decomposition; and it is therefore contended that in this instance at least pus must be secreted. Allowing this fact its due weight, it does not explain the formation of pus out of those extravasated fluids in inflammation, which are certainly not pus when first poured out, but which become so in a short time afterwards if the inflammation con-

tinues. It is said that in phlegmons, the removal of the parts injured, or whose vitality is destroyed, is effected by the action of the absorbents, and a cavity is thus formed capable of receiving the secreted pus. But it is also said, and I believe has been proved, that pus has a solvent power, and it may, therefore, dissolve the solid part in contact with it, and bring them into a state fit for the absorbents to act upon and take up. If such be the case, the old doctrine of pus converting solids into a fluid similar to or identical with itself, may still be true; the absorption of the solid matter without its being converted into pus may be a gratuitous assumption, and would seem to be a superfluous process.

As to the secretion of pus in contradistinction to its formation, we may observe, that on the surface of membranes whereon this is said to be secreted, the fluid, at its first appearance, is not globular, the characteristic of genuine pus, but a transparent fluid, of a consistence in some sort resembling jelly: the globules are produced whilst the fluid lies on the surface of the sore. And in the pustular eruption in small-pox, the fluid in the vesicles is at first thin and transparent, afterwards becoming thick and purulent.

Purulent secretion, as it is termed, is surrounded by no less difficulties than are the various natural secretions themselves; a process not at all understood, but one which has been the subject of much discussion. An attempt has lately been made, I believe, to explain secretion by attributing this function to the electric power with which the nerves are supposed to be endued. But as all the various secreted fluids are obtained from the same identical mass (the blood), and as the action of electricity must always be precisely the same, under given circumstances of temperature and conducting power of the substance acted upon, which in the blood are always equal, how is the variety of results to be accounted for? Were this hypothesis truth, the secreted fluids might be obtained from the blood when drawn out of the body by the application of electric power, which has never yet been done. Life, therefore, is essential to animal secretion; and as electric power alone cannot effect this process, the superadding this power to the influence of life is a mere gratuitous

assumption, and contributes nothing to the explanation.

If it be said that the different secretions are produced from different constituent principles of the blood, each being acted upon by the electric power of its appropriate secreting organ, how is it that the secretion in the same secreting organ ever varies? For instance, if the effect of the electric power in the kidneys is (according to Dr. Wollaston) "to secrete acid urine from blood that is known to be alkaline," whence arises it that other conditions of the urine are produced, as sugar in diabetes? Is there a change in the degree, or in the quality, of the electric power? The degree of power is considerably within our own management; and were this alone requisite to produce secretion, we might succeed in effecting similar results out of the body, as we can obtain different degrees of intensity at our pleasure. If there be a change in the quality of the power, it is no longer electricity; to call it, therefore, electric power, is merely to substitute another name for living principle.

The same arguments will apply to the hypothesis of secretion being effected by galvanic power.

M. Gendrin has published some observations on this subject. He denies pus to be a secretion, and says that inflammation, from its very commencement, produces a state of infiltration of the tissues: at first the infiltration differs little from that in health, except in quantity. As soon as the infiltration has reached a certain stage of its development, it is very easy to recognize a copious deposition of a substance, of the consistence of jelly, interspersed between the fibres of the tissue of the part. This infiltration, interspersed between the fibres and in the interstices of the inflamed tissue, is easily recognized; not only by the presence of a fluid more or less black and gelatinous, but also of a liquid of a yellowish-white colour, which appears slightly incorporated with, or adherent to, the diseased tissue. If we examine with a microscope the fluids thus infiltrated, we recognize the pus by its characteristic globules. At the boundaries of the purulent infiltration, and in those points where the infiltrated fluid *begins* to be purulent, we detect the true globules of pus mixed with smaller globules, which still preserve, in a slight degree, the pale rosy

colour of the globules of the blood, partially deprived of their colouring-matter by rest, *after* their escape from the vessels. It is, then, evident (adds M. Gendrin) that infiltrated pus is only a modification of the spontaneously coagulable fluid, the infiltration of which has *preceded* the appearance of the pus, and which we can recognize in its *transition* into a state of pus.

Can we, then, to a certainty, say whether pus is really and strictly a secretion, or whether only the materials necessary to its formation are at first poured out, and that these are afterwards converted into pus by spontaneous separation and recombination of the primary elements, in the same manner as takes place in the conversion of farina into sugar, or sugar into wine; a process in the animal system depending upon, and effected by, the principle of life, or living principle?

It may be said that the agitation of this question can contribute but little to the improvement of practical medicine; but if (as is confidently asserted) our skill in medical science is in exact proportion to the correctness of our notions of physiology and pathology, it is worth while occasionally to inquire into the solidity of the foundation upon which our science is said to be based, although the result of the inquiry may prove that we know just as much, and no more, on the subject than was known half a century ago. We are too apt erroneously to suppose, that by changing one ill-defined term for another term equally ill-defined, and adopting some novel phraseology, we are making advance in our knowledge of medical science, whilst we are but wandering from the right path; for after all, practical medicine can only be really improved by patient study of the natural history of diseases, and the cautious investigation of the properties of remedial agents.

A plausible hypothesis, maintained with ingenuity, will sometimes wear the semblance of science, and may procure for its inventor a temporary reputation for brilliant discovery; but the best knowledge a physician can possess is that which, being derived from observation and experience, enables him most successfully to grapple with diseases at the bed-side of his patient.

MEDICUS.

MEDICAL GAZETTE.

Saturday, March 3, 1838.

"*Licet omnibus, licet etiam nihil, dignitatem Artis Medicæ tueri; potestas modo venendi in publicum sit, dicendi periculum non recuso.*"
CICERO.

THE RIVAL DISCOVERERS.

A MEDICAL man can scarcely have a greater misfortune in this country, than to love the scientific pursuit of his profession, or to become a discoverer. Sir Charles Bell (than whom no one could more fairly judge) was in the habit of telling his pupils to beware how they let the public suppose that they were any thing but practitioners. "I believe," he says, "the philosophy and the practice of the profession to be necessary to each other, and both to the true respectability of the individual. Is it not strange that the prejudice of society should run against this association of objects so natural and so just? But I have felt that it does; for on each occasion that has joined my name with science, it has been necessary to double my attention to practice*." If we look at the most successful practitioners around us, we find no one who devotes more than a very small portion of his time to anatomy or physiology, or any abstract scientific investigation; and this, not merely because their time is much occupied in actual practice, but because they have learned the danger of a high reputation for any thing but a knowledge of the *art* of medicine or surgery. Many of them, in the earlier part of their life, continued the studies of their pupillage, and first gained the public attention by their works on the sciences ministering to practice; but woe has been to those who, when they had once succeeded thus far, did not timely check

their taste for these investigations. The imputation already cast upon them needed to be wiped off by long abstinence from similar pursuits, if not by the penance of publishing some work of pure practice, in which their *science* should appear only at very distant intervals.

Many of those who read this will see their own course described; we have several in our mind who now congratulate themselves on their opportune change of pursuit, and many who are in vain trying to make scientific studies compatible with the successful pursuit of practice; but we scarcely know one who has succeeded in maintaining the compound reputation of the able practitioner and the accomplished *savant*. The *critical period*, if we may so speak, in the life of a medical man in London, is that at which he leaves off science and commences art.

But the injury which he is likely to sustain in his practice by the reputation of being a good anatomist, or physiologist, or chemist (which, with the public, are expressive of negative qualifications as a physician or surgeon), is not the only danger which the medical student of science has to encounter. If he should make what, as it were in derision, he would call a fortunate discovery, he has to run the gauntlet of numerous competitors for the honour of originality, and, pirate or not, he must fight or give up his claim. And these, too, he finds no childish combats; he has too often to bear up against hard words and ridicule, not to say positive abuse.

We have often made remarks somewhat similar to these, but we never had the ideas so strongly impressed on us as by reading certain letters which Dr. Grant and Dr. Marshall Hall have recently published, as replies to one by Mr. Newport, claiming the discovery of the arrangement of the

* Clinical Lecture, in MED. GAZ. vol. xiii. p. 697.

motor nerves in the articulata. They both, indeed, seem to have been determined to add documents well worthy of the *Bibliotheca Bellica*, and to maintain the bad spirit with which the interminable subject of the spinal cord has been too generally discussed.

Of Mr. Newport personally we know nothing, but we think that his having received very honourable notice from many besides his present persecutors, is a sufficient evidence that his character cannot be quite what they represent it, while his well-known industry, and the untrodden field in which he labours, would, *a priori*, render it very probable that discoveries might be made there. We have carefully examined the case, and to us it appears perfectly clear that his pretensions have been altogether misrepresented in the letters to which we have alluded. In his papers in the *Philosophical Transactions* for 1832 and 1834, he never claims in the most remote manner the discovery of the superior transverse nerves in the articulata; for descriptions of these he expressly refers to Lyonet and Müller, and says that their longitudinal connexions were made out by him after Dr. Grant had suggested the probability of their existence. His discovery is quite separate from this; and though it is the most prominent part of the paper, Dr. Grant *never once alludes* to it, but would imply that all the present question relates to the point above mentioned. Mr. Newport found, and has clearly proved, that the motor tract of the nervous cord in the articulata is not this which is situated above, free, and *widely separated from* the main cord, but that it forms part of the latter, being separated only by a linear depression from the anterior part, from which the sensitive nervous roots on which the ganglia are formed, arise. This principal nervous cord of the articulata, therefore, was first proved by Mr. Newport to be exactly analogous to the

spinal cord of vertebrata, consisting of two columns, from one of which arise sensitive roots bearing ganglia, and from the other motor roots, which have no ganglia, but which join the others just beyond theirs. Whether the superadded transverse nerves, which Dr. Grant had described as the motor nerves, form, as Mr. Newport imagines, from their supplying the parts connected with the tracheæ and respiratory muscles (a separate respiratory system,) is a point of far less importance. It is certain that they *do not form*, as Dr. Grant thought, the true general motor column. Surely, then, Mr. Newport was justified in his complaint, and will be so still more, since his opponents have published their accusations without even alluding, in an intelligible manner, to his real discovery, but heaping upon him the most virulent abuse, for having claimed another to which he never made the smallest pretension.

The original papers will make the truth of our opinions quite evident to any one who will consult them. But we will quote the words of Professor Müller, on whom Dr. Grant would have it believed that Mr. Newport has been guilty of piracy. He says, in his *Retrospect of the Progress of Medical Science* in 1834, "Among the most distinguished investigations in comparative anatomy, is that of Mr. Newport." Then having given him great credit for his accurate descriptions of the development of the nervous cords, of the vagi, and of the transverse superadded nerves, he adds, "An important discovery of the author is, that he has found the abdominal cord of insects and crustacea composed of an anterior and posterior pair of cords. The upper pair have no part in the ganglia, which belong to the lower pair only. In this manner the analogy of the abdominal cord of insects with the spinal system of vertebrata is now much more evident than it has hitherto

been, and the discoveries of Bell on the motor and sensitive systems of spinal nerves find their application in the invertebrata."

We have no doubt that Mr. Newport will be fully justified by all of the profession who read the above statement, or his own, if he should publish one.

But granting, for an instant, that his conduct had been utterly shameless, and that his plagiarism was quite evident, there could be no necessity for such virulence as he has been treated with. A simple statement of the facts of the case ought to have been sufficient, if his opponents do not unjustly hold their present place in public reputation. How can it affect his claims that he should be called by Dr. Grant an "ungrateful parasite," "this cunning and arrogant egotist"—or be accused of "sucking Sir Charles Bell's brain or his purse," of having "arrogant pretensions," and of "directing insolent insinuations against his eminent and honourable patron"—*videlicet* Dr. Marshall Hall? Or what evidence is afforded by the gentleman last mentioned telling us, "I fed, and clothed, and housed, this same individual! yes, I lent him money, I procured him a home in his distress for many months*," or, by way of parenthesis, referring us to the fact of his keeping an account with "Sir Claude Scott, Bart. and Co.?" We are surprised that one who is himself constantly writhing under the vexation of having his pretensions questioned, should thus attack a fellow-sufferer. From no one could accusations of this kind come with so bad a grace as from Dr. M. Hall. He vituperates Mr. Owen, and informs us that he does *not* withdraw the epithet of "*brutal*" from the Council of the Royal

Society, because they disallowed his claim to originality; and heaps the most unmeasured abuse on one who had with comparative mildness asserted his own pretensions in a case in which Dr. M. Hall was not personally interested.

This is not the only occasion on which both these gentlemen have sullied the character of their profession by the coarseness of their language, when they have been excited to attack either public bodies or private individuals; and the silent punishment which they must feel that they have received, might, we should have imagined, have made them rather more gentle. We would point them out to all students who are flattering themselves with a hope of reputation by novelty of investigations, as specimens of a class too common in the scientific world, and distinguished by a grasping, miserly anxiety after renown, for which their love, like the love of money, increases with the having.

*Crevant et opes, et opum furiosa cupido,
Et cum possideant plurima plura petunt.*

Both these gentlemen have done many things well, and have obtained a fair share of credit for them; they ought not thus to try to crush a young aspirant for fame, nor ought they to grudge him the reputation he has earned, and which they do not want; above all, if they would enjoy the good opinion of those whose applause they so much covet, let them desist from private and unproved aspersions, and from that violence and vulgarity of language which is sufficient of itself to obtain for them a denial of the attention they so vociferously demand.

It is much to be regretted that there is no means of remedying the evil that results from the coincident claiming of one discovery by several persons. The establishment of the truth is important, for the honour that redounds from success is the only reward for the labour required to ensure it; and this honour

* As this was passing the press we received Mr. Newport's answer to Drs. Grant and Hall. It places these gentlemen, particularly the latter, in a very awkward position. Mr. Newport positively states, that the *feeding* consisted in occasional invitations to dinner or tea; and that the money affair amounted to the loan of *15*l.**, since repaid!—ED. GAZ.

should be sufficient, not only to pay for the labour, but at the same time to afford compensation for the injury sustained by loss of practice, and the expenses of warfare. When a man's discovery in science is disputed, or pirated, it is, as it were, an invasion of an intellectual patent, and as such deserves punishment as the analogous case, which falls under the penalties of the law. The chastisement inflicted should correspond with the subject and nature of the offence. We should be glad to see such conduct visited, in every instance, by a published exposure by an authorized scientific society; for we are sure that a plan of this kind would insure a fair reward for unpaid labour, and secure those interested in science from the loss of much time, and the annoyance of angry feelings, which they are now so constantly obliged to incur.

The present is not the only case of dispute that we have lately noticed. Dr. M. Hall is, as usual, tilting at every one that does not acknowledge the supremacy of the reflex function, and the correctness of every view of every thing that ever he looked at. Professor Müller's short residence in England was sufficient, we understand, to break the fragile bands of scientific attachment which had existed between him and several of our *martial* literati. Mr. Mayo has published a brochure containing, amongst other matters, a copy of his account-current against the medical public; in which we see he credits himself with some very heavy sums: we are glad to hear, however, that he has consented to accept the amount which Mr. Whewell adjudicated to him, for the spinal nerves. Mr. Owen has been writing, through M. Arago, to the Institute of France, to prove that the claim which M. Coste advanced (in a memoir read before its members,) to the discovery of the allantois in the embryo of the kangaroo, was utterly unfounded, for

that that structure had (as is well known) been described by him in his paper in the *Philosophical Transactions*, long previously. M. Coste seems to have been misled by having examined Mr. Owen's plates without referring to the text; an oversight so glaring, that it is scarcely possible not to believe that it was intentional, especially as there is evidence of his having *guessed* at the structure of the chorion, which was not shown to him.

Many minor wars are also going on. The phrenologists are, of course, embroiled in hot disputes. They now fight both abroad and at home by their own little fire-side at the Phrenological Society, where the disciples of Gall and those of Spurzheim expend a great deal of their remarkable volubility in defence, each of their own master. The magnetic dispute is going on warmly, the magnetizers beating up every where for recruits, though, we believe, with more perseverance than success. In short, war is in all our quarters; there are so many about

"Jealous of honour, sudden and quick in
quarrel,
Seeking the bubble reputation"—

that one can scarcely walk abroad in safety. It is a most inconvenient state of things, and we should like to see it remedied. Many of the present champions will retire from the field as soon as they begin to acquire more lucrative occupation; but more will rise up in their places. Till men of science, generally, will agree that intentional plagiarism, and unfounded claims of discoveries, should be treated much more severely than they now are, the annoyance will of course remain. They should determine on doing this; and a general chronicle of observations, with an accurate record of their dates and publication, should be kept at some scientific society. We might then hope to have peace.

CONTROVERSY REGARDING THE IRISH COLLEGE OF SURGEONS.

A LETTER has been addressed to our publishers, by authority of the College of Surgeons in Dublin, to "require" that we should give up the name of the writer of an article regarding some of their recent proceedings, which appeared in our number of February 10th. We determined not to comply with this demand, and for the following reason:—At the time the paper in question was published, an official member of the Irish College happened to be in London, and immediately wrote an answer to our first correspondent, requesting its immediate insertion. This answer accordingly appeared in the following number of the GAZETTE; while the second part of the paper complained of, although in type and on the eve of publication, was withheld. Now we do not think that a party attacked in a journal has a right first to answer the attack, and then to require the name of the original writer, with a view to ulterior proceedings. This was the view we took of the matter, and we refer to it now as it may be of use to have the question set at rest by the establishment of a precedent. On the present occasion the principle only can be established, because it so happens that the gentleman whose name was sought, and which was always privately attached to his papers, has come forward spontaneously, and declared his readiness to enter the lists against the Irish College. This letter will accordingly be found at page 909*, *extra limites*, of the present number; and if the College or any other party choose to join in the controversy, they will of course see the propriety of complying with the conditions already imposed on Dr. Alcock.

TARTAR EMETIC IN HYDROPS ARTICULI.

THE treatment of effusion into the joints by tartar emetic, in large doses, is an improvement which we owe to the experiments of M. Gimelle.

We shall here content ourselves with giving a few general points in the treatment, in anticipation of the work which M. Gimelle is about to publish on this subject. Since the period when he first became aware of the great advantage to be derived from tartar emetic in this disease, he has treated twenty-two patients in this manner, and all have been cured. The efficacy of the remedy was the same in every case; the differences in the seat of the disease, in the age, sex, constitution, or temperament of the patient, in the cause of the effusion, or in its tendency to be acute or chronic, seemed to have no influence on the cure, which, in every case, was speedy. The tartar emetic was never administered during more than eighteen days in succession, and the dose never exceeded sixteen grains in twenty-four hours. Its first effect was soothing, and it made the pain cease almost immediately. The improvement was obviously more speedy whenever it was borne by the digestive organs, and caused neither vomiting nor purging.

In almost every case these symptoms came on during the first days of the employment of the medicine, which, nevertheless, was ultimately tolerated. When these evacuations had ceased, in some instances there was an increased activity in one or more of the secretions, such as profuse sweats, or pyalism.

The exhibition of the medicine was often followed by a slight feverishness, which sometimes lasted until night. The application of leeches at the commencement was useful, in cases where the inflammatory symptoms were very intense. At the same time poultices were employed, with or without laudanum.

The food was proportioned to the appetite of the patients; on an average, they ate a quarter of the hospital full diet, or its equivalent. Wine was given whenever it was not contra-indicated by the general state of the patient. All kinds of food were given, without selection; raw food, however, must be avoided—such as fruit, or salad, and acids; for instance, vinegar and lemon-juice.

Opium was given for sleeplessness; and dandelion *tisane* sweetened was used in every case.

Such are the general points. We will now give the details of three cases treated

after this method, by M. Gimelle, in the syphilitic wards of the *Hôtel des Invalides*. Two of them (Picard and Demolombe) are still detained in St. Côme's ward, by venereal affections.

CASE I.—Successive Effusion in both Knees.

Claude Picard, a soldier, aged 36, of a lymphatic constitution, injured by syphilis, came into St. Côme's ward on the 12th of July, 1837. His disease was caries of the nasal bones, produced by the venereal virus. His right leg had been crushed by a fall from his horse, so that he could not walk without a wooden leg. After he had been in the ward a fortnight, he was seized with pain in the right knee. In the morning, after putting on his wooden leg, he tried to get out of bed; but he had hardly put it on the ground, when the pain came on so violently that he was obliged to get into bed again. In a short time there was a considerable swelling of the knee, without change of colour in the skin; the part, too, was hotter. The pain was lancinating, and was present only when the patient moved. The swelling increased, and there was evident fluctuation.

For twenty days the patient was treated with antiphlogistics and emollients; thirty leeches were applied, and two blisters, as well as poultices with and without laudanum; but no improvement took place.

The tartar emetic was now administered, and it was given for eleven days running, in the following doses:—

First day.....	4 grains.
Second day.....	6 do.
Third, fourth, fifth, and sixth days	8 do.
Seventh day	10 do.
Eighth, ninth, tenth, and eleventh days	12 do.

For the first three days the medicine caused slight feverishness, very frequent vomiting, and abundant purging. The improvement in the knee was remarkable, for the pain had entirely ceased.

On the following days the medicine was borne by the stomach, and no longer caused purging. The improvement was now more rapid; the serous effusion was re-absorbed, and motion was soon restored.

On the twelfth day the tartar emetic was omitted; on the fifteenth the knee was of its natural size, and the cure was complete.

Ten days after the cure of the right knee the left one was attacked. This time the pain began about two inches below the patella; it was lancinating, and of the

same kind as the former one. It was hardly perceptible when the patient was in bed, but increased in proportion as he moved.

At the end of three days it passed into the knee, still preserving these characteristics. The application of fifteen leeches had but a slight effect on the inflammatory symptoms; the pain remained equally intense, the knee speedily became larger, and there was evident fluctuation. M. Gimelle now began to exhibit the tartar emetic, and continued it for eight days, in the following doses:—

First day.....	4 grains.
Second day.....	6 do.
Third day	8 do.
Fourth day.....	10 do.
Fifth, sixth, seventh, and eighth days	12 do.

As before, there was vomiting and purging for three days, during which period the pain ceased and improvement began.

On the following days the tartar emetic was borne, and the patient merely experienced slight nausea; there were no stools. The effusion was now rapidly absorbed, and the cure was perfect two or three days after the medicine had been left off.

To complete the history of this case we must add—

1st. That during both periods of the treatment with tartar emetic the patient's appetite was middling; he ate quarter-diet, and drank no wine.

2dly.—That sleep was procured by opium.

3dly.—That the patient had profuse perspiration, and an increased flow of saliva: the quantity of urine remained the same.

CASE II.—Effusion into the Elbow Joint.

A man named Clavel, aged 47, of lymphatic temperament, and a medium constitution, who had had several venereal affections, was admitted into St. Côme's ward.

The patient complained of having had a pain in his right elbow for eight or ten days, without any cause that he knew of. The pain had increased gradually, particularly when the joint was moved, and this at last became impossible; there was swelling without redness; increased heat; want of appetite; sleeplessness.

The symptoms were the same when the patient was admitted into the ward; to which we may add, that at the posterior part of the elbow, and upon the sides of the olecranon, there were two round and

fluctuating tumors, which were painful when touched.

M. Gimelle's diagnosis was, that it was a case of effusion into the humero cubital joint.

For ten days successive trial was made of antiphlogistics (such as leeches, and poultices both with and without laudanum) blisters on various spots, and mercurial and hydriodated frictions. These remedies were useless, excepting that the antiphlogistics somewhat soothed the pain. The tartar emetic was then exhibited for eight days in the following doses:—

First day	4 grains.
Second day	6 do.
Third day	8 do.
Fourth day	10 do.
Fifth, sixth, seventh, and } eighth days	12 do.

The medicine was borne perfectly well, and was omitted on the ninth day. There were neither vomitings nor copious stools, in spite of the food which was allowed the patient. The improvement was very rapid, and the cure was complete on the tenth day.

CASE III.—*Effusion into the Knee.*

Joseph Demolombe, a soldier, of strong constitution, and sanguine temperament, who had suffered from the venereal disease, was admitted into St. Côme's ward on the 8th of January, 1838. He was labouring under effusion into the knee, which had appeared for the first time, and without any apparent cause. The swelling began without pain, which did not come on till the fourth day. It was intermittent, and was felt when the patient moved the limbs.

When Demolombe was admitted, the knee had become of enormous size, and there was manifest fluctuation. The general reaction was intense. For the first three days nothing was done but applying poultices to the knee. On the fourth day twenty leeches were put on. On the fifth day the pain was relieved, but the knee was as large as before. On the sixth day two blisters were applied. The size of the knee did not lessen on the two subsequent days.

The employment of the tartar emetic was now begun, and was continued for five days, in the following doses:—

First and second days . .	4 grains.
Third and fourth days . .	6 do.
Fifth day	8 do.

The patient vomited several times on the first day, but not at all on the following ones. On the third day there were frequent and copious stools, which ceased entirely on the fourth.

On the sixth day (which was the 20th of January) the swelling had diminished by four fifths, and the disease was clearly getting well.

The bystanders now requested M. Gimelle to omit the tartar emetic, in order that they might be better able to form an opinion of the efficacy of the remedy. M. Gimelle readily granted their request, as he did not see any danger to the patient in so doing.

The medicine was omitted on the 20th, 21st, and 22nd of January. On the 20th and 21st, the improvement continued; on the 22nd, the condition of the patient was stationary. On the 23rd, M. Gimelle and the bystanders agreed that the malady was aggravated. On the 24th, the medicine was again administered in the dose of four grains, which produced vomiting and abundant stools.

On the 25th and 26th, the medicine was administered in the same dose, but was not followed by any evacuation. At this period there was no longer any fluid in the synovial membrane. The patient walked for a considerable time without feeling pain, or augmenting the symptoms; only, on pressing the joint strongly from above downwards, a slight relaxation could be felt in the parts of the synovial membrane which are extended over the sides of the patella.

From the 27th to the 30th of January, the patient walked about every day; he ate and drank as usual, and felt neither pain nor uneasiness in the knee. Nevertheless, the symptom above mentioned still remained.

On the 31st of January and 1st of February, the tartar emetic was again administered in four grain doses. There were slight vomitings on the first day only. On the 2nd of February the remedy was discontinued. On the 5th, Demolombe was entirely cured, after having taken 42 grains of tartar emetic at three different periods, the dose having never been more than eight grains in any one day.

In this patient the tartar emetic never produced any feverishness; nor were there sweats, nor more abundant spitting than usual. His sleep was always good, so that it was not necessary to give opium. Demolombe's appetite did not fail, and he continued to eat quarter-diet, and to drink wine.—*From the Gazette des Hôpitaux of Feb. 8th, 1838.*

[It strikes us, that had purging been added to the other antiphlogistic remedies employed before the administration of the tartar emetic, the use of so distressing a medicine might perhaps have been dispensed with.—TRANSLATOR.]

ROYAL INSTITUTION.

Friday, Feb. 16, 1833.

DR. AINSWORTH, of the Euphrates expedition, delivered a lecture on the Alluvial Deposits on the banks of the river Euphrates, and entered at some length on the ancient and modern geography of the country about Babylon.

Friday, February 23.

Dr. Faraday delivered a very interesting lecture,

On the Atmosphere of this and of other Planets.

Of our atmosphere the principal ingredients are oxygen and nitrogen, in the proportion of one of the former to four of the latter; but a small quantity of carbonic acid is also found in it. And to this the other arrangements in nature are nicely adapted, so that any material change in the composition of the air would be followed by the most pernicious effects; for if it consisted merely of nitrogen, combustion would be at an end: as substances which burn in common air will not burn in nitrogen, but are immediately extinguished by it. Again, substances which hardly burn in common air, burn fiercely in oxygen. Thus a small quantity of oil, being made so hot as almost to burn in air, if dipped into a vessel containing oxygen, will instantly run into combustion. The consequence of the atmosphere consisting wholly of this gas, would therefore be, that when one thing took fire, the fire would spread with the utmost rapidity to things which at present are not combustible, and every thing would soon be destroyed. And as oxygen is necessary for respiration, it is evident that we could not exist in an atmosphere of nitrogen alone. Hence we can perceive that an atmosphere either of oxygen alone or of nitrogen alone, would not be at all adapted to the present condition of this planet. As to these gases existing together in a somewhat different proportion from that in which we find them at present, although this might not materially affect combustion, it would, however, affect animal life, and superinduce disease. The weight of the atmosphere, too, is wonderfully adapted to the operations which have to be carried on in it. Indeed, of so much importance is its pressure, that if it were taken away, all the changes of season and temperature would disappear.

As regards the other planets, it is only by minute and accurate observation of these bodies, when passed by any other, that we can ascertain any thing respecting their atmosphere. Now in the case of Mars, another body, in passing it, was

observed to be considerably disturbed; whence it is concluded that it is possessed of a somewhat dense atmosphere. The Moon bears no signs of atmosphere, but continually presents one appearance, which has been observed with the utmost accuracy; and mountains, of a mile in extent, may be clearly seen with a good telescope. In observing the Moon pass a star, some have thought they discerned a slight degree of atmosphere: Sir J. South, however, has never perceived any thing of this kind, and we may conclude, that if it has any atmosphere, it is too minute for us to discern.

Sir W. Herschel at certain times described Saturn as having a bright appearance at the poles, while the rest of the planet is colourless; and this he supposed to be snow collected together in immense masses. If this is the case, then there must be water; and if there is water, there must be clouds, or something of that kind, otherwise the temperature would become equalized, and the snow would be at an end. The water, however, need not necessarily be the same as ours, nor do philosophers pretend to say that the snow is the same as ours; for if it were of the same materials as ours, the specific gravity of the planet could not be, as it is, only 1-8th part of the earth.

In Jupiter, the belts which are visible show that there is something moveable (though what we know not) on its surface. Sir W. Herschel one evening observed this planet covered with belts, and on returning, after an absence of scarcely half an hour, these had all disappeared. How this happened we cannot explain. It is, indeed, difficult to account for so sudden a disappearance in a body of so large a diameter as 87,000 miles; yet we must, of course, place the most perfect confidence in Sir W. Herschel, and content ourselves with hoping, that when still further advances shall have been made in this most interesting and important science of astronomy, we shall be able to give full and satisfactory reasons for what in this, as in other cases, appears at present strange and unaccountable. Dr. Faraday then concluded by stating, that though it has not yet been proved that the other planets have any atmosphere, yet they resemble our planet so much in other external circumstances, that we can hardly suppose ours to be the only one in which living creatures have been placed: and that He who made the globe with its atmosphere and its inhabitants, might with as great ease have placed an atmosphere and inhabitants in the others, adapted to the order and arrangement which in them he may have seen fit to establish.

(a.) In this case the wound was inflicted with a bullet from a pocket pistol, which was discharged about a yard from the patient's face, by a young man who did not know that it was loaded. The ball entered on the right side of the nose, traversed obliquely downwards to the left side, avoiding the palate, and appears to be lodged somewhere behind the angle of the lower jaw. Blood continued to ooze from the nose and mouth for some hours. There was much pain, swelling, and constitutional irritation, for several days; but by the repeated application of leeches and other means, this has subsided, and the woman is now in a fair way for recovery; but the bullet has not yet been extracted.

NOTICE.

We have received several letters on the subject of the discussion which is now taking place in Dublin, with reference to some recent regulations of the Irish College of Surgeons. We are unavoidably compelled to postpone their publication. Among them we ought to mention a letter dated Feb. 10, from "A Professor in the School of the Apothecaries' Hall," in answer to one which had appeared in a preceding number.

CHANGES IN THE
ROYAL COLLEGE OF SURGEONS IN IRELAND.

To the Editor of the Medical Gazette.

SIR,

I SUBSCRIBE my name to this letter. My former signature of "Member of the College of Surgeons," was a real and not a feigned one, and I adopted it not for the purpose of concealment, for voluntarily and of my own accord I transmitted to you my name, but under the impression that the letter of a member of the Corporation would excite more attention than my own name would command.

I was not unprepared for an intemperate reply to my letter of the 10th ult., which I here avow, but I confess that the reply which has been attempted has taken me altogether by surprise. If my letter were, as asserted by your correspondent, "neither more nor less than a collection of direct falsehoods," what more was necessary than to have refuted them? *Magna est veritas et prevalebit!* I am therefore much at a loss to explain the total abandonment of temper and courtesy displayed in that reply. Did the writer imagine that he would thereby deter me from my purpose? If so, he has greatly mistaken me. Vituperative violence never shall deter me, while I feel myself in the right. Did he imagine that he could thereby lure me to descend from my position, and to imitate his example? No, no, sir! He that has truth on his side can afford to keep his temper; and no man loses it until he has lost his cause. Can it be, as his forward authority to you to publish his name would seem to imply, that he intended to impress you, the profession, and me, with the idea that he contemplated maintaining his charges even by the *duello*? If so, I beg to assure you that he must do so by other means, at least so far as I am concerned: or can it be

that this violence was a last resource—a gamester's hazard—to retrieve the falling fortunes of his party? I cannot answer. The result must decide.

He has pronounced my letter to be "a collection of direct falsehoods," and he has "*pledged* himself to support his statements by reference to the minutes of the College and its committees." I accept his challenge, and I call upon him to redeem his pledge. I call also upon you to bear witness to the pledge, and to be umpire in the quarrel. And now for the falsehoods:—

No. 1 states that my assertion "that the publication of an article headed Irish College of Surgeons—Pharmacy Laws, was not sanctioned by the College," is absolutely untrue. My statement, sir, is, that the article has not been published "by the order and with the sanction" of the College. And I repeat it. If it had been, the minutes of the College would contain the order, and a record that its sanction for the publication had been asked and given. I demand the production of them. They exist not. He has told you, and perhaps will tell you again, that it was done by the committee. Sir, I never said that it was not. In truth, until I had read his letter, I did not know by whom it was done, for the statement is anonymous, and could not be recognised as the act of any party. But, sir, the committee is not the College, and I recognise no right in any committee to make use of the name of the College, and above all an anonymous use of it, without its express authority and sanction. And I call again upon the College to see to it.

No. 2.—I refer to No. 6.

No. 3.—"The proposed change has not received due consideration, or sufficient sanction from the College, or the profession." In proof of the falsehood

of this, he informs you that "the proposed change has been under consideration since the month of November last;" *i. e.* from November 9th, when the committee was appointed, to January 8th, when it agreed to its report. An amazing length of time, doubtless, for so unimportant a measure! But, sir, the truth, according to his own statement, (for out of his own mouth I'll judge him,) is that the proposed change had not received any consideration at all. For what does he say? "The appointment of a committee" to consider the change! No; but "to take measures for its accomplishment was at that time made," &c. So that, according to his own admission, the first step taken in the business was to appoint a committee for its accomplishment. In ordinary cases, sir, the first step is to appoint a committee to decide upon the principle, and the propriety of its adoption, but that seems to have been deemed unnecessary in this case, and to have been disregarded. In the second place, he tells you "that the report was unanimously agreed to at one of the *largest* meetings of the College known for years!" Sir, this is a rash—a mad assertion. In reply, I demand to know, 1st, how many members composed the College at which the report was agreed to? 2d, What is the greatest number of members who have attended a meeting of the College within, we shall say, the last five years? On the true answers to these questions I might rest my cause; they alone would suffice. He terms my proportion between the number who voted upon the question and that of the entire body, an equivocation; why I cannot say, since he does not deny the accuracy of my premises. But he says that "there are not more than 90 members resident in Dublin." Well, where were they? Half that number did not vote upon the adoption of the report. Where were the rest? The entire number, more or less by three or four, have been present at the College within the time which I have specified, and why were they not on this occasion? But he says "more than one-third, in consequence of old age, indolence, &c., never attend." There is not, I believe, sir, at this moment, a single member, resident in Dublin, incapacitated from attendance by old age, and I hardly think that you will admit indolence to be a sufficient apology for absence on such an occasion.

No. 4. "The proportion of the communications from the country, favourable to the change, does not exceed a third of the entire." I demand that the falsehood of this statement shall be proved by the production of the letters. And here I have to lay before the profession a flagrant breach of privilege committed against me. I have sought to see these letters. It is my right, as a member of the College, to see them if I please, and when I please, and they are withheld from me. They have been removed from the College, and (as I have been informed by the secretary of the committee) intrusted to a clerk! to make an abstract of them! An abstract of ninety-eight letters from different persons!!! And the secretary declines to inform me who has them, or where the person is to be found, without leave of the committee, who have no authority in the matter.

But leaving your correspondent to redeem his pledge, I shall here submit the published opinions of those practitioners in the country, who have as yet, to my knowledge, expressed them. The profession in Cork have declared themselves averse to interfering with the province of the apothecary. In Limerick they object to the "union of the practice of medicine and pharmacy in the person of the apothecary;" and, on the other hand, they state "that they would by no means sanction the sale of medicines, compounded or otherwise, on the part of the physician or surgeon, whether prescribed by himself or others." (See Limerick Standard, January 26.) And in Sligo, the *licentiates of the College* resident there, and six in number, have declared "that they never have to the College authoritatively offered any opinion whatever on the subject of the bill." And, "though they may possibly anticipate, they would lament, the necessity which should require them to make up medicines for their patients." (See Sligo Journal.) Sir, I ask, are these "unreservedly favourable?"

No. 5. "The licentiates of Dublin have actually protested against the measure." "This is totally false." The following is an extract from the report presented by their committee to the general meeting of the licentiates, adopted thereby, and presented to the pharmacy committee. It has been taken from a copy of the report furnished to me by a member of the licentiates' committee:—

"They must, at the same time, express their deep regret, that, to the discredit of the medical profession, instances are not wanting where a licensed practitioner has combined the profession of the physician with the business of the apothecary, an union which your committee strongly deprecate, as one disreputable to our profession, as at present constituted, unjust to the apothecary, and highly dangerous to the interests of society." What think you now, sir? Do the licentiates, "with very few exceptions, heartily concur in the proposed change?" Have they or have they not protested against it? Your correspondent states that those of them, who are advocates for another plan, are yet willing and *anxious*, in the event of its failure, to recur to the general-practitioner-system as an alternative. Hear what they do say:—"Should they fail to procure from parliament the redress they *with confidence* demand, they feel there will be left for them but one alternative, namely, to look for an enactment by which the physician and surgeon will be entitled to dispense medicines to their own patients; a course, however, to which they acknowledge *it will be repugnant* to their feelings to be obliged to bend." Where is the falsehood now, sir?

Nos. 2—6. No. 2. All "the provisions which it is intended that the Act of Parliament shall contain have not been made public." No. 6. "They appear to me to be only a mask for another as yet not avowed design." To the latter he replies—"I can only on the part of the College, the committee, and myself, flatly deny this statement." You smile, sir, I doubt not, at such a method of proving my assertion false, that "they *appear to me* to be so." I have resolved to refrain from comment; else surely I might make one on the propriety

of gentlemen learning the meaning of language before they venture to use it. But we will suppose his meaning expressed. Now, sir, the published statement contains but six propositions. The petition contains seven; I *demand* the seventh. Is it, or is it not, part of the instruction to the committee that the College shall be empowered to educate and qualify a general practitioner? I *demand* the answer. The published statement contains it not.

Before I conclude, I beg to remind you that you have given insertion to the charges against me on a *pledge* that they should be substantiated. You will therefore not think it too much that I should now expect that you require the fulfilment of that pledge. If it be not redeemed you have been duped as much as I malign'd, and I regard it as an act only of impartial justice that my accuser be required to fulfil his pledge, and that he shall not be permitted to take shelter under any pretext. Let him not imagine that he shall escape under cover of College rules; he was not ignorant of them when he gave the pledge, which was to stamp accuracy upon his statements, and College rules shall not now save him from its redemption. He is a committee-man, and it would seem can do as he pleases. At all events, he can easily obtain from the College, and I will advocate and vote for it, dispensation from any rule which may stand in his way.

I beg to remind the profession that under the bill which is to be sought they are to sell medicine.

I have the honour now, sir, to subscribe myself,

Your very obedient servant,
BENJAMIN ALCOCK,
M.B. M.R.C.S.I.

Dublin, Feb. 24, 1838.

THE
LONDON MEDICAL GAZETTE,

BEING A
WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

SATURDAY, MARCH 10, 1838.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE XV.

Diseases of the Air-tubes (concluded).—Changes of Structure: Thickening of the Membranes; Hypertrophy of the Longitudinal Fibres; Rigidity; Pathology and Signs; Treatment.—Dilatations of the Bronchi; Varieties; Pathology and Mode of Production; Symptoms and Effects; Physical Signs, and their distinction from those of Phthisis; Amphoric Sound on Percussion; Treatment and Prevention.—Ulcers of the Bronchi.

WE have now to notice certain changes of structure which the air-tubes occasionally present. These are, I believe, generally the consequences either of inflammation, or of some kindred modification of the vascular function affecting the nutritive process. Inflammation, when often recurring or long continued in the bronchial membranes, as elsewhere, induces a change of structure; and the mechanical forces to which they are subjected in the function of respiration, may modify this change in various manners.

The most simple change of structure is a mere thickening of the mucous and sub-mucous membranes, which you see exhibited in these drawings. This generally, in some degree, accompanies acute inflammation; but it is then only temporary, and subsides as the secretion becomes free

and albuminous, being caused, probably, by only an infiltration of the pores of the tissues with soft lymph, which, as the inflammation subsides, is eliminated and expectorated with the mucus of the membrane. The deposits that are the most readily produced by inflammation in highly vital tissues, are also the most readily removed; and thus it is, that the soft albuminous matter that is effused by acute inflammation in cellular textures, and in parenchymata in general, if it be not so abundant as to interfere with the absorbent functions of the vessels, becomes absorbed as the inflammation subsides.

But it is otherwise when the inflammation recurs frequently, or is of long duration; for it then causes an effusion of a less absorbable nature, involves the less vital structures, and, as the changes induced are slow, so they are more permanent, because they become identified with the nutritive or reparative functions of these tissues. There will then be produced a degree of hypertrophy of some or all of the various tissues composing the tubes. Sometimes there will be an extraordinary growth of the mucous membrane, such as appears to be represented in this plate of Dr. Carswell's, where there is also a great dilatation of the tubes. More commonly, however, it is the harder and less vital textures, that undergo the change, and its effect is to increase the rigidity of the tubes, so that there is a diminution of their expansibility and contractility. Nothing is more common than to see the air-tubes of persons who have long suffered from bronchitis, presenting an undue development of the longitudinal elastic fibres; whilst in other cases the outer cellular coat of the larger bronchi is thick and indurated, and their cartilages are sometimes partially ossified. Any of these changes has the effect of rendering the lungs less easily expandible in respiration; the first in particular is a common cause of the short breath, which persons

frequently affected with bronchitis generally manifest; and although not often serious in itself, yet it may so abridge the sphere of the function of respiration as to make its increased exertion, on bodily exercise, a matter of difficulty and disorder, and to render it ill able to bear any other attacks of disease, to which the lungs can in general adapt themselves by supplementary efforts. Thus, when one portion of a healthy lung is attacked with pneumonia, or compressed by a pleuritic effusion, its function is supplied by the increased and quickened movements of the other portions, which, in their natural state, are equal to this augmented task; but if their pliant elasticity be impaired, and their size more fixed by an increased stiffness, they will be, in proportion, less available for additional exertion, and the body will suffer the more from the crippled state of the function.

The chief sign of hypertrophy of the longitudinal fibres, and of increased rigidity of the tubes generally, is, *difficulty of inspiration*, which is short, quick, and performed with an effort, especially on making any exertion; whilst the expiration is comparatively easy; but both acts are often accompanied by wheezing sounds, from irregularities in the caliber of some of the tubes, and frequently from partial congestions or inflammation, from which tubes thus diseased are rarely free. The vesicular murmur is impaired, and the expansion of the whole chest is perceptibly limited. These signs resemble those of spasmodic asthma, except that they are permanent, and are not removed as the latter may be for an instant, on breathing after holding the breath, as I described to you in the last lecture.

Inasmuch as these lesions seem to arise from continued inflammation, it becomes of the more importance to direct remedies against those forms of bronchitis that are habitual, or frequently recurring. An imperfectly cured cough will often hang on a patient for months, and even for years. Not being much incommoded by it, and the general health not suffering materially, he will not think it worth while to persevere in the use of remedies, or of a proper regimen. In the process of time, however, especially under the influence of fresh colds, to which he is always more liable, the breathing becomes permanently shortened, and an irritation is often fixed in some of the affected tubes, and manifests its effect on their secreting function by an habitual expectoration, generally of a thin mucous, or pituitous character. This affection varies greatly in degree. I have seen several cases of severe habitual dyspnoea, which ultimately proved fatal, present all the characters which I have described; and there was found, after

death, no other lesion than a general redness of the membrane lining the larger tubes, and an extraordinary development of the longitudinal fibres. This appearance is very common in the bodies of old people who have long been subject to cough and shortness of breath; but I have seen it also in the middle aged, and in a few instances in younger subjects. It is not, however, met with in all cases of protracted bronchitis; these sometimes lead to other and opposite results; and it is probably connected especially with some kinds of inflammation, which, as in other situations, show a particular disposition to affect the fibrous tissues; but further observations are wanted on the subject. There is one point with regard to treatment, which is suggested by a knowledge of this change of structure—that not only should we persevere in the use of the means which tend to eradicate the low degrees of inflammation that produce it, especially alkaline expectorants and counter-irritants, but we should also endeavour to countervail, by mechanical means, that mechanical limitation which this change induces in the size of the tubes. If the patient use no exertion, and give his lungs little play, any increase in the rigidity of the tubes will more readily fix them in their present contracted state: but if he take moderate exercise, increased as habit improves his power, the lungs will be kept in that free mobile condition that is least favourable to rigidity or deposition of any kind. Probably even special efforts of inhalation would be useful with the same view; and as this might be combined with some mildly stimulating vapour, such as that of water impregnated with tar, camphor, or the like, it might be made also serviceable in improving the condition of the secreting membrane. You can readily perceive, however, that great discretion is necessary in the employment of these mechanical means; for if they strain the tubes beyond the due limits, they may cause a morbid yielding of their walls, and increased inflammation; and if exertion be used beyond what the function of respiration can support, it will occasion congestions in the lungs, which may aggravate the original disease, and may induce lesions of other kinds. They are more eligible in young than in old subjects, for in the latter the change is more likely to be permanent, under the influence of that general law by which, as age advances, fibrous tissues tend to assume a cartilaginous hardness, and cartilage becomes rigid with osseous matter.

There is another kind of alteration of the air-tubes that has attracted more attention than those which I have hitherto described; I mean *dilatation of the bronchi*.

This affection deserves attention, not only on its own account, but also because it sometimes produces physical signs which closely resemble those of phthisis. The drawings before you exhibit different forms which the dilatations assume. To show them well, the bronchi should be laid open, from their large to their small branches, with a pair of scissors; and in examining lungs in this way, it is not at all uncommon to find the calibers of the branches larger than those of the trunks from which they proceed, the enlargement being generally most manifest in those parts of the tubes where the cartilaginous plates are small and few; but occasionally the larger tubes are dilated also, their rings only here and there limiting the dilatation. Sometimes the dilatations are pretty uniform through some length of a tube (as in fig. 1.) In other cases they form irregular roundish cells, or pouches, freely communicating with each other, and from which tubes of unchanged size here and there arise (fig. 2.) The tissues composing the tubes are generally, at the same time, more or less altered. They are least

so in the tubular form of dilatation (fig. 1), in which the coats are often quite thin, and the longitudinal fibres are distinct, although occasionally enlarged. But in the more globular dilatations, the walls of the tubes are generally much altered. They are irregularly thickened; the thickening being formed in part by hypertrophy of the mucous or submucous tissues lining the cells, which sometimes form folds or wrinkles around the tubes, and partly by a dense tissue on their outside, probably consisting of the parenchyma of the lung compressed by the encroaching tube. There is little or no trace of the longitudinal or circular fibres in this form of dilatation, and the lining membrane is generally in a softened state, and of a red colour, whilst there may be considerable rigidity in some parts of the tubes. This is the worst kind of dilatation, as you may suppose, from its more complicated character; but you will be better able to understand this if we examine a little further into the causes and pathology of dilatation of the air-tubes.

Laennec, who first described these le-

FIG. 1.

FIG. 2.

sions, attributed them to the frequent accumulation of mucus in the tubes, causing their mechanical distension. He con-

sidered that they were formed especially by long-continued chronic bronchitis, and that the continual recurrence of the same

distension of the tubes led to their permanent dilatation. But this view has always appeared to me to be quite insufficient to account for the remarkable changes which we frequently see in the structures of the dilated tubes; and, according to my observation, these lesions do not by any means constantly occur where the bronchial secretion is copious, and most calculated to cause distension. Neither do we in chronic bronchitis often meet with such a complete suspension of the respiratory murmur as these supposed distensions with mucus ought to produce. The expectoration is generally more diffuent, and less likely to accumulate in the tubes, than that of dry catarrh, and the latter stages of acute bronchitis. M. Andral takes a more rational view of these lesions, in ascribing them to a modification of the nutrition of the textures composing the tubes; but he does not attempt to give any specific explanation of the mode in which their form becomes so remarkably altered.

If you bear in mind all the circumstances of the mechanism of respiration, as we have been considering them in this course, and the various modes in which they may be deranged by the effect of disease on the textures which form parts of it, you will soon find no difficulty in accounting, in several ways, for the dilatations of the air-tubes, as well as for the modifications of nutrition which accompany them, and their effects on the adjoining tissues. I have had occasion to point out to you more than once that a mutual pressure is continually exerted between the interior of the bronchial tree and the air admitted into it by respiration; in inspiration, by the air which enters to distend the tubes; in expiration, by the tubes contracting to expel the air. In forcible acts of respiration, such as coughing, or energetic breathing, this pressure is increased; but in the normal condition of the tubes, when they all convey the air equally and freely to and fro, and meet the pressure with a well-proportioned degree of elasticity and contractility, this pressure is balanced and borne well; and instead of causing disturbance, it serves to keep the air in a constant relation to the blood, and to regulate the circulation through the lungs. But disturb in any way the equality of this pressure, or derange those elastic and contractile properties which are opposed to it, and you may then convert it into a cause of unnatural distension in some parts, whilst it does not reach others with sufficient force. Now there are several circumstances that may cause these disturbances, and they are especially to be met with in those diseases which are known to lead to dilatation of the air-tubes. Bronchitis may act in both of these ways. By

thickening of the membranes or viscid secretions it may cause partial or complete obstructions, which by preventing the free entry of air into some tubes, give increased force to its pressure in others, which become distended in consequence; and it may so alter the condition of the tissues composing the tubes, that, losing their elastic and contractile properties, they yield to the pressure, and become fixed in this dilated condition. Perhaps, as Dr. W. Stokes has suggested, the mere loss of contractility may be sufficient in itself to cause dilatation of the bronchi; but I think that our view will be more complete if we take into account other circumstances which we know to be often present, and the operation of which is perfectly intelligible. Just glance at this sketch (fig. 3), and you will see at once how

FIG. 3.

an obstruction (*a*) preventing the air in inspiration from entering one set of tubes (*b*), will cause the excessive distension of the adjoining tubes (*c*); and recollect that this is taking place in tubes softened or otherwise modified by inflammation, and you will perceive how the dilatations may become perpetuated, and liable to increase through the altered condition of the constituent textures. Hence the lesions are often not simply dilatations of the tubes, but comprehend also irregular softening

and indurations, absence and thickenings of their several textures; so that when the lung is cut open after death, it may be at first difficult to distinguish that the irregular cavities which it presents are formed by dilated tubes. Then in the production of these dilatations we are not to forget the influence of violence in the acts of respiration. They have been observed especially to succeed to hooping-cough and other bronchial affections in which the cough is particularly violent and long-continued. The effects of these violent acts of breathing may be two-fold; they may cause the dilatations by the prolonged and forcible inspiration in the manner already described; and they may increase them irregularly when so distended, by the sudden pressure of the expiratory forces upon them. But I have met with cases of dilated bronchi in which there had been very little cough, and none of any violence; and here we must suppose that the other conditions, the irregular introduction of air and the yielding of the membranes, were more exclusively concerned in the production of the lesion. I will tell you of another manner in which the bronchi become dilated. In the disease called pleuro-pneumonia the lung is inflamed, and at the same time compressed by an effusion in the sac of the pleura. Now if it remain long in this state, the smaller air-tubes and cells become obliterated by the adhesion of their sides, so that when the liquid is removed from the pleura they will not expand again with the enlargement of the chest; but the large and middle-sized bronchi are not obliterated; they bear the whole force of the inspired air, and become consequently dilated by it. This kind of dilatation is usually conjoined with contraction of the affected side: we shall notice these cases hereafter; they are not very uncommon, although they are not to my knowledge noticed by any writer. Any other circumstance which causes the obliteration or obstruction of a considerable number of the bronchial tubes and cells, must tend to produce a dilatation of the adjoining tubes on which the motions of the chest would act with augmented force.

The symptoms produced by dilatations of the bronchi will be according to the extent of the lesion. Slight degrees of it are met with in the bodies of persons who had not during life manifested any prominent disorder of the respiration; and its simpler forms may exist to a greater extent without producing other effect than a liability to attacks of bronchitis. But where it affects many tubes, has modified their structure, and has enlarged them to such an amount that they press on and obliterate a considerable extent of the

pulmonary parenchyma, it then causes habitual dyspnoea, with more or less cough and mucopurulent expectoration, which is often remarkable for its force. There are, generally, present also the ordinary symptoms of severe chronic bronchitis, from which some parts of the affected tubes are scarcely ever free; and the permanency of these symptoms, together with a degree of lividity, dropsical effusion, and cachectic condition, often induced by the crippled condition of the lungs, forms the usual general character of the aggravated forms of dilated bronchi.

Now you may say that these symptoms look very like those of consumptive disease; and so they well may, for there is injury to the function of respiration, profuse expectoration, hectic fever, and the patient is often slowly wasted away. In their aggravated forms, dilated bronchi are not more tractable than tubercular consumption itself; but their tendencies and constitutional effects are different, and merit as much of a distinction as our means of diagnosis can find for them. Unfortunately, this is not one of a very marked kind; in fact, in many instances it is to be made only by those much experienced in diagnosis; and even they will give it in terms rather of probability than of certainty.

You can readily understand that the air passing in bronchi dilated to a large size, or into cavities, will give a hollower, a more blowing sound, than in those of the natural dimensions; hence, over them the sound of respiration may be bronchial, tracheal, or cavernous, in regions where it is naturally purely vesicular; and if, as it frequently happens, there be liquid in the tubes, the bubbling into which it is thrown will be heard to be coarse and gurgling, instead of the finer mucous rhonchus of common bronchitis. So, also, the voice may be powerfully transmitted through these enlarged tubes; not in a diffused *trémulo*, as usual, but loud and startling, as if issuing from the spot; in some cases cracked and jarring, as in bronchophony; in others more articulate, and with a snuffling and hollow sound, as in pectoriloquy. But these are also the signs of tubercles and excavations in consumption; and we must seek for further distinctions. Besides, in the history of the case, and the character of the constitution, these distinctions are sometimes to be found;—in the situation of these sounds, which, in phthisis, is usually in the superior parts, but in dilated bronchi in the middle regions of the chest; in their character in relation to time, those in phthisis tending to increase and spread as the excavations proceed, whilst those of dilated bronchi remain nearly stationary for weeks

and months; in there being less change in the shape of the chest with dilated bronchi than with phthisis, unless they have arisen from pleuro-pneumonia, in which case the change is different; and, finally, in the nature of the sound on percussion, which, in phthisis, is more extensively dull, especially under the clavicles, whereas, in dilated bronchi, if any dullness exist, it is generally in the mammary, lateral, or scapular regions of the chest, and is often accompanied by a sound of a peculiar kind. This is a hollow tube-like sound, and from its resemblance to that produced by mediate percussion on the trachea, or by tapping with the finger on the mouth of a small phial, I have given it the name of *tracheal* or *amphoric*. I can give you a notion of the kind of sound, by filipping on a finger pressed on the larynx or trachea, or on the cheek when the mouth is opened in the manner of sounding the letter O, thus —. This sound depends, not essentially on the vibration of the walls, as in the case of the ordinary sounds of striking the chest, but on that of the air in the tubes or cavities, which give a note according to their length and size, precisely in the manner of a pan-pipe, or of this India-rubber bottle. In the natural condition of the chest you do not obtain this sound, because the stroke of percussion, and the resonance of the large tubes, are intercepted by the ill-conducting tissue of the lung; but when the bronchi are dilated so as to reach nearly to the surface, or, as we shall hereafter see, more perfectly when the large tubes are brought in contact with the walls of the chest by the pressure of a liquid effusion; or when, by perfect hepatization, the stroke and the resonance can be transmitted to and from these tubes near the root of the lung, you will then get various degrees of this amphoric sound, which it is not difficult to distinguish from the duller and deeper resonance of the healthy chest. The circumstances which favour the production of this sound are the same as those which cause morbid bronchophony and bronchial respiration, and pectoriloquy and cavernous respiration; but it requires a more perfect degree of them. Hence, although somewhat of the amphoric sound is occasionally yielded by empty cavities in phthisis, this does not often occur, it being damped by the irregularity of their form and materials, and the remains of spongy tissue on their surface. The cracked-jar sound (*bruit de pot fêlé* of Laennec) is of the same class, being a slight noise of a sudden motion of air and liquid within resonant tubes or cavities, produced by the impulse of external percussion. It is more common in large phthisical cavities, because their form and size more readily

expose them to the influence of an impulse on the walls of the chest.

Finally, you will be better able to distinguish dilated bronchi from phthisical cavities, when you become fully acquainted with the signs and general symptoms of the latter; and I shall now only add, by way of recapitulation, when you meet with a case in which long continued cough, with purulent expectoration, dyspnoea, loss of flesh and strength, hectic fever, even with some of the physical signs of cavities in the lungs, beware of pronouncing it to be tubercular, if qualified by all or most of the following conditions:—If no proofs of a scrofulous habit can be traced; if the complaint have originated in a long-continued and violent cough, or in an attack of pleuro-pneumonia, and, considering its duration, emaciation have not proceeded very far; if the purulent expectoration have been fetid and sanious rather than flocculent or cascosus; if the bronchial or cavernous respiration, voice, or gurgling, be heard rather in the middle than in the upper portions of the chest, and be there spread over a considerable extent of surface; if these middle portions chiefly sound differently on percussion, being dull when the rest of that side sounds pretty well, or amphoric when the side is generally dull and contracted; and if, although the cough and expectoration continue undiminished, these signs remain stationary for many weeks together.

I have little to say on the treatment of dilatations of the bronchi. You can perceive that when once formed, they can be little under the influence of medicine. The profuseness of the secretion may sometimes be restrained by acid mixtures; and I have known the nitro-muriatic acid in two or three instances succeed in removing its factor. Probably inhalations of chlorine would be useful in such cases. Where the cough is violent or troublesome, it should be allayed as much as possible by sedatives, such as hyoscyamus, belladonna, conium, and particularly opium, or some of the preparations of morphia, due attention being at the same time paid to the state of the excreting functions, and the general condition of the system, which may need various kinds of treatment in different cases. The co-existence of chronic bronchitis often renders external counter-irritation of some service in dilatations of the bronchi; and other antiphlogistic measures are occasionally required on the supervention of intercurrent acute inflammation, which sometimes takes place. It is, however, from preventive measures that we may expect more success; and our knowledge of the causes and tendencies of this lesion suggests the expediency of not abandoning the treatment

of cases of bronchitis, pertussis, and pleuro-pneumonia, until all cough, and the physical signs, have been satisfactorily removed. Most of the severe cases of dilated bronchi that have fallen under my observation, I have traced to imperfect treatment in former inflammatory attacks, and I am fully convinced that many examples of the different structural changes of which I have been speaking in this lecture, may be prevented by an efficient plan of medication, when the complaint is considered merely as a severe cold, a cough, or "the influenza."

I need not detain you on other structural lesions of the air tubes, for they are of too rare occurrence to be of much practical importance. Cases of the bronchi seldom occur but in connexion with some cause which concentrates inflammation in the bronchial membrane in a peculiar manner, such as the habitual inhalation of irritating particles of dust, in the occupations of needle-pointers, stone-masons, and leather-dressers; the continued passage of tubercular matter in phthisis, and occasionally the specific influence of measles, small pox, and syphilis. I do not know of any signs by which the presence of ulcers in the bronchi can be distinguished; they rarely, if ever, exist without a similar affection of the larynx, in which case the voice is impaired or lost; but this happens commonly when the bronchi are not ulcerated, or only so far as to give vent to the matter of vomica in phthisis.

LECTURES ON TUMORS.

Delivered at St. George's Hospital.

By CÆSAR HAWKINS, ESQ.

II. OSSEOUS TUMORS.

1. Tumors of or upon the Bones.
2. Conversion of natural Textures into Bone.
3. New formations of Bone.
 - a. Osteo-cartilaginous Tumors.
 - b. Osteo-stomatous Tumors.
 - c. Osteo-sarcomatous Tumors.

III. SARCOMATOUS TUMORS.

1. Adipose Tumors.
 - a. Common Adipose Tumor.
 - b. Adipose Tumor with retained Cyst.
 - c. Cutaneous Adipose Tumor.
 - d. Hypertrophy of the Adipose texture.
2. Fibrous Tumors.
 - a. In fibrous texture.
 - b. In cellular texture.
 - c. Painful sub-cutaneous Fibrous Tumor.
3. Neuromatous Tumor.

II. Osseous Tumors.

As a second order of tumors, we will take those in whose structure more or less

bone forms an element, and we will call them *osseous tumors*, and the circumstances in which bone is found in unusual situations are chiefly these:—

II. 1. The most frequent situation, as you would naturally anticipate, for a bony tumor to be found, is upon the natural osseous structure; the nature of all tumors, as we have seen, being in some measure determined by the texture in which they arise. But I shall not say any thing at present upon this subject, which we will leave to be considered with the other diseases of the bones.

II. 2. Another mode in which bone is deposited, so as to constitute a tumor or otherwise to be perceived in examination, is by *ossification of the natural textures*, and chiefly of the *fibrous texture*. Here is a mass of bone in the falx cerebri, where it is not unfrequently met with as a cause of epilepsy, or of an insupportable dullness, such was the case, for instance, in the late Dr. Pemberton. Here again you see the conversion of the *fibrous covering of the spleen* below the peritoneum into a thick layer of bone, such as seen occasionally in the pericardium, beneath its serous layer, or on the surface of the liver or lung. This is a specimen of the conversion of ligament into bone in the anterior longitudinal ligament of the spine, constituting a singular kind of anchylosis between the vertebrae. It is not infrequent in our worked horses; and Sir Charles Bell relates a remarkable case, in which a man, subjected to an injury of the spine, broke across this bony splint which he happened to have, and which was, of course, less able to resist injury than the elastic structure whose place it supplied. In many persons tendons and muscular fibres are sometimes converted into bone, as, in this instance, of a portion of what should have been the tendon of the *psoas magnus*. In the late Mr. Heavyside's museum was a preparation where the femur was arched over by a great number of bony spicules, occupying the situation of the vasti muscles. These cases constitute a kind of exostosis not usually productive of much inconvenience, because the morbid growths occupy the places nearly of the muscle or tendon, so as only to shorten their point of attachment, without preventing the action of the muscles, and without interfering with other textures, and because the change is seldom produced to a great extent.

Unless we could discover the elixir vitae, and realise the dream of our ancestors, and make our patients young again, I know not how we are to check this instance, among many others, of the gradual failure of their corporeal frames. There is occasionally, however, a similar disposition to ossific deposit exhibited in early

life, which constitutes a very serious disease, in which ligaments, tendons, and muscles, are all implicated. Mr. Abernethy met with a boy in whom the tendency to ossification was so strong, that besides exostosis, the least blow produced the ossification of numerous soft parts;—in the ligamentum nuchæ, so that his head was fixed; and in the margins of the axillæ, so that his arms were pinioned to his side. In the College of Surgeons is a skeleton in which this disease is seen in a remarkable degree, the most extensive ossification of muscles having taken place, among others of the long muscles of the back down the whole spine, so that the unfortunate subject of this affection must have been a wretched cripple. It would seem that the use of acids, to prevent the deposit—of the nitro-muriatic bath, as it used to be called, and other remedies, have been tried in vain to check this peculiar condition of the system, whatever it may be.

In one of the numbers of the *MEDICAL GAZETTE* is the description of a curious example of the ossification of muscle, or formation of bone in them, said to be common among Prussian recruits, and known familiarly among them by the name of the exercise bone; though I am not aware that it is observed among our own troops. It is the formation of a bony tumor, or ossification of the fibres of the deltoid and pectoralis major muscles of the left side, where the musket rests. There takes place a small red painful spot, which, if neglected, terminates in the formation of a mass of bone, from four to seven inches long, and weighing from two drachms to an ounce; the excision of which becomes necessary, to get rid of this curious result of inflammation.

II. 3. The third genus of ossific deposit consists of those cases in which ossification takes place in *new situations*, not upon the bones, nor occupying the place of the original textures, but as an entirely *new formation* among soft parts; and you may divide them into three species, according to the kind of soft substance usually mixed with the bone.

a. *Osteo-cartilaginous Tumors*.—These are usually met with in the serous membranes, where, after a time, they lie free, like the loose cartilages of the joints, and they are formed in the same manner, no doubt. Here is a small one, which I took from the tunica vaginalis testis, and you can distinguish a solid hard nucleus of bone inclosed in a firm close cartilaginous texture, and covered by a smooth surface of serous membrane, derived from the membrane to which it was originally attached. I had a patient, not long since, with excessively irritable testis, which resisted all the usual remedies, and which I believe arose from a body of this kind, which I wished to re-

move, but could not persuade the patient to submit to it. You may see in this preparation a large irregular mass of bone, which was mixed with very little semicartilaginous matter, and which was formed in an ovarian cyst, from which several other pieces of the same material came away.

b. A second species of osseous tumor consists of a bony cyst, with matter of different kinds in its interior, frequently fatty substance, or a glairy mucilaginous fluid. It is called by some *osteosteoma*, from the former secretion. You may see this large bony cyst, which I took from the dissecting-room, so that I do not know its history, the contents of which were of this kind; it is attached to the testis, which is perfectly sound and natural at its upper end. You will understand by this situation that it is perfectly distinct from the sebaceous encysted tumor, with steatomatous contents; but I believe it is frequently only the sequel of the serous and hydatid encysted tumors, the cysts being, in these cases, changed into fibrous texture, and ultimately into bone, partly or entirely: look, for instance, at this large osseous cyst in the liver. I have not one to show you in the common cellular texture, nor are they often met with. You may see this plate of a large one on the cheek in Alibert's splendid work, which he says was unconnected at first, but became subsequently attached to the upper jaw, and required removal.

c. The third species of osseous tumors may be called *osteosarcomatous* tumors, as the name has been used by surgical writers, though it is not a very good one, and they consist of a mixture of bone with solid substance, not attached to any of the bones of the body. Here is a large mass of fibrous tumors, or fleshy tubercle, looking like a child's head, and completely filling the uterus, all the outer part of which is bone, so thick as to require a saw to divide it. They are occasionally met with in the external parts of the body, though not commonly. I recollect assisting Sir Benjamin Brodie in removing a bony tumor, mixed with soft substance, from the situation of the parotid gland, where such a structure is occasionally met with. I believe the disease returned. Mr. Abernethy saw one of considerable size in the ham. There is somewhere in the museum, but I could not find it just now, a very large tumor with bone in its interior, which was removed from the inside of the thigh, by a surgeon (not in this hospital), in which case, I believe, the patient died of hæmorrhage on the table, or immediately after the operation, from its involving the great vessels of the thigh.

I am inclined to believe that the loose unattached osteo-sarcomatous tumors, like

the tumors of the same name attached to the bones, are of two different kinds; in one of which there is bone formed on the outside of some innocent solid tumor, generally of the fibrous kind, which may be removed with safety when accessible, or a limb removed, if the dissection of the tumor is impracticable, without any fear of the disease returning; while, in the other form of tumor there is a small proportion only of osseous deposition, and this is found chiefly in loose spicular distributed through the substance of the tumor, which is of the nature of fungus hamatodes; consequently, although an operation is equally proper to be performed, it is done with much less confidence, on the part of the surgeon, that the operation will be followed by a successful result. I amputated the thigh for this large malignant disease of the knee joint, originating, as it seemed, in the ligamentum patellæ, which was of the cerebriiform kind, mixed with bone, and which had ulcerated so as to bleed profusely. The patient died a few days afterwards of copious vomiting of blood, which came not from an internal tumor, as I was inclined to suspect, but from some disease of the vessels of the stomach and bowels, distending them with blood, and causing their coats to give way.

In all cases of osseous tumors, except the malignant form, in which the soft substance predominating may obscure the diagnosis, there is no difficulty in recognizing the structure by the feeling conveyed by its solid, firm, unyielding material, which is perceptible even at a considerable depth; and there is, of course, no chance of any cure of an osseous tumor, except by its entire removal by excision or amputation.

III. SARCOMATOUS TUMORS.

The third order of tumors are the *Sarcomatous Tumors*, meaning, as was formerly explained, such new formations as are firm and solid to the touch, not consisting of a single cyst, like the encysted, nor of bone, like the osseous tumors; or, at least, if either cysts or bone are found in them, these appearances bear a very small proportion to the bulk of the solid materials of the tumor. We may adopt a division of them, from the variety they present, into eleven genera, some of which are innocent, others of a malignant character; and the principal circumstance to determine, in their investigation, is whether they are or are not malignant, in order that, in the former case, their removal may be earlier effected by the knife; for unfortunately we shall find, as we proceed, that there is scarcely any one of them which admits of being removed by

remedial means independent of an operation,

III. 1. The first genus is the adipose, or *fatty tumor—adipose sarcoma*. It is a very common kind of formation, and requires, therefore, to be fully understood by you; and let me observe, that it is sometimes called *lipoma*—a bad name, since it is employed also for other formations; and *statoma*, as in the late work of Dr. Warren—a bad name also, since it is more frequently used to designate one of the sebaceous encysted tumors. It is called, too, *cellular tumor*, as by Mr. Burns; and this is as injudicious a term as the others, since it is not formed of the cellular texture at all, but of fat in its appropriate cells. There are three species of adipose tumor; the first of which is,

a. The *common adipose tumor*; which consists of a mass of fat, rather whiter and firmer than ordinary, and of a closer texture, which is inclosed in a thin cellular membrane, separating it from the surrounding fat, and dipping into its interior, so as to divide the tumor into a great number of lobes. The membranous cyst is very loosely connected to the bed in which it lies, except at one point where a vessel or two enter it, or if long, the vessels supply it at two or three places. Its vascularity is very slight, however, so as hardly to bleed if it is cut. You saw yesterday a tumor of several ounces weight removed from the shoulder, irregularly shaped, and lobulated; and I have seen it sometimes almost like a bunch of grapes in shape. Fatty tumors are found chiefly, as you would expect, below the skin in the common adipose texture, and they are common on the back, or thighs, or chest. It is said they do not occur in the eyelids or scrotum, where there is no fat; they have, however, been met with in the scrotum, though of necessity very rarely. They sometimes attain a great size. I have seen one, removed by Sir Everard Home, weighing 26lbs., and one of 10lbs. has been removed. They arise from a blow, or other injury, sometimes; but more frequently without any evident cause. Sometimes, after growing to a certain size, they remain stationary, and undergo no further increase; and whatever size they attain, they generally produce little pain or inconvenience, except from their bulk, dragging thus upon other textures, and being, of course, very unsightly. Here is a small fatty tumor, however, which occasioned very great pain, from its having accidentally a small nerve stretched over it. Occasionally, however, when large, the skin becomes distended over them, and ulcerates, and the tumor projects, with an unhealthy

fungus growing from it, of apparently a bad character, though not really malignant. Here is a small one, ulcerated, and it shows you the yellowish-brown colour which the fat then acquires. Rarely is any inflammation established in a fatty tumor, but Sir Benjamin Brodie met with one case in which the centre suppurated, and matter formed, mixed with oily substance from the tumor.

The diagnosis of a fatty tumor is generally very easy; it is unaccompanied with pain; it is soft and elastic, with a peculiar feeling to the touch that you can seldom mistake after having once felt it, and is different from that of every other swelling, except sometimes the subcutaneous navus, the vascularity and colour of which are usually apparent, and except sometimes a small deep chronic abscess, where the matter is too thick, or too small in quantity, to be rendered sensible by fluctuation, which is very seldom the case; and such an abscess is less elastic and less moveable than the fatty tumor. Medicine has no influence on this tumor, nor have any local remedies power over it, except to do harm. You may often see the tumor after stimulant plasters or blisters have been applied; and the consequence is adhesion to the skin, making dissection necessary in the operation. Pressure also by the clothes, or by other means, induces sometimes the same adhesion, and makes the operation more difficult.

The operation is generally very easy and very safe, and union readily takes place afterwards, in most cases, where no inflammation has preceded it, and the skin has not been rendered thin by pressure and tension.

If the tumor is small and stationary, and not in an inconvenient situation, no operation is absolutely necessary; but it is generally better to do it as soon as the patient consents, as it is so much slighter an operation when small, and, if left, it may grow to a considerable size, or it may inflame, or become of a different character at some future time. The operation is best done by a simple incision through the skin, cutting through the cellular covering of the tumor into its substance; you are then certain of the boundaries of the tumor, and you can readily separate the attachments of the cyst by the fingers, so that you have nothing to cut through except the vessels at its base, and, as we have seen, even a large one will hardly have more than one or two requiring to be tied; you will then bring the skin together, and make pressure over the sides of the cavity from which the tumor has been removed, by plasters and bandages. If you try to dissect round the tumor without cutting into the cyst, you are very liable

to leave a portion behind for the tumor to be re-formed, and you will have much more hemorrhage, especially if the tumor is attached to muscles. If it is torn away, on the contrary, you are sure to remove every portion, even of the most lobulated form of tumor, from the cavities in which the several portions lie. If there is adhesion of the skin to the cyst, you are sometimes obliged to dissect off the skin, and then you can tear away the rest of the tumor; and if the tumor is very large, and the skin is thin, or ulcerated on the surface, a portion of it may be removed, by a double incision, with the tumor.

If an adipose tumor is situated under a fascia, its diagnosis is more difficult, as it loses much of its elasticity, and feels more solid, or sometimes more like an abscess; but directly an incision is made through the fascia, the tumor starts out, and can be easily torn away. If the tumor has been subject to much pressure, however, the operation becomes more difficult, from the necessity you are then under of using the knife, which is to be done with caution, in order to distinguish the fat of the tumor from that around. A gentleman with whom I am acquainted had a fatty tumor on one side of the nates, which an eminent surgeon advised his doing nothing to. He followed this advice rather longer than was intended, I presume—namely, for twenty years; at the end of which time it was very large, and could not be concealed in his clothes, and was a somewhat inconvenient cushion to sit upon; in fact, he hardly liked to stir out. He came to town while I was absent, so that I did not see him, but the tumor was removed by Sir Benjamin Brodie, who informed me that the pressure to which the tumor had been subjected had pushed it deep even into the sciatic notch, and had produced a good deal of adhesion to the important parts there situated, making the dissection both difficult and dangerous.

There is a singular situation in which the fatty tumor is sometimes found—namely, in the fat below the transversalis abdominis: one such case I saw in this hospital, removed safely by Sir B. Brodie. The tumor here makes its way through the abdominal muscles, so as to be perceptible externally, and has been called, erroneously, a fatty hernia (*Hernie graisseuse*). It requires caution, however, in the operation, as it is sometimes attached to the peritoneum, and this membrane may be dragged out and endangered, if untended to.

b. A second species of adipose tumor possesses a reflected cyst. The common fatty tumor has an entire membranous covering, but the one I am now alluding to has a loose reflected bag around the

other, and connected with it at the base, like the two layers of the pericardium. The tumor, in short, has no attachment except where the vessels enter, and the surface is smooth, instead of the rough cellular connexion which it usually possesses to the surrounding fat. Here is a small tumor, said to have been of this kind, but it is rare, and I have not seen it in the living body. I suppose, however, there is no apparent distinction between the two forms before operation, since no fluid is secreted between the attached and the reflected layers of the cyst. In fact, I should regard it as a mere accidental circumstance, such as I have sometimes seen with *navi* and other tumors which usually are attached all round. The operation must be equally necessary as in the other case; and I presume the loose cyst need not be removed, since it has nothing to do with the formation of the fat of the tumor, and is probably no more capable of reproducing the tumor than the less organized cellular membrane attached to the cyst of the common adipose tumor.

c. The third genus I call the *cutaneous adipose tumor*. In this preparation you may see a great mass, of half a pound weight, attached to the body by a very narrow pedicle, from which it hung loose on the skin, and which was cut through, leaving a surface of not more than a third of an inch for a tumor nearly four inches in diameter. It is composed of a thicker kind of fat than usual, whiter and firmer, more lardaceous in appearance, and it is covered only by a thin white skin, without any natural fat below it, and scarcely capable of being dissected off, from fibrous bands running from the cutis into it. There are sometimes a great number of these tumors attached to the skin, and connected with it; and from their whiter and more solid appearance they may be mistaken for medullary tumors of this structure, especially when, after having removed one or more of the little tumors, you perceive others rising near the cicatrix perhaps. This form of disease is not well described any where, and from the resemblance to malignant disease in the circumstances I have mentioned, you must bear it in mind. In this plate of Albert's, under the name of *kupes graisseux*, is what appears to have been a case of this form of disease, since you seldom see such an immense number of the common adipose tumors. It is not a common form of tumor, but I have known it subside under the use of liquor potassæ continued for a great length of time, which I have combined with sarsaparilla in one person of a weak constitution. Of this medicine you may give from half a drachm to a drachm three times a day. I think a little benefit

might be derived from the local application of a solution of iodine and hydrodate of potash, such as you see used in the hospital occasionally; but I have not tried it. If this medicine does not disperse the tumors, any one of them that is growing faster than the rest may easily be removed by the knife; or, if there is only one, the patient may have the choice of its removal at once by this means, and a shorter course of medicine afterwards, to lessen the chance of a return.

d. Another form of adipose growth may be called *hypertrophy* of the adipose texture, in which there is a vast increase of fat below the skin; but the fat has no boundary, no cyst, as in the former genera. Sometimes there is only a general growth of fat in all parts of the body, as in this plate of a child, making the unfortunate object of it quite unwieldy, and seriously incommode him; but this is only common obesity in a remarkable degree. At another time, however, the fat of a particular part of the body only increases in this manner, and this is generally of the chin, where you may sometimes see an enormous bag of fat, as large as the head, which might well be called a tumor, though not quite in accordance with the definition before given. Sometimes, instead of being on the chin, you see a great mass hanging on the front of the abdomen, or some other part of the body. In a man now in the hospital under my care, many of you have seen a remarkable specimen of this tendency to adipose hypertrophy; at least, I believe it to be this form of complaint rather than the first genus. This man has two masses of fat on the back of the neck, each as large almost as your double fist, the division having been, in fact, made by the pressure of his neckcloth. Another great mass hangs below his chin; he has another over each deltoid muscle; and on the abdomen is a large quantity, divided into the appearance of two tumors by his waistband; besides which he is tolerably fat every where, so as to form altogether a remarkable figure.

Such tumors as these do not admit of removal by the knife, since there is no distinction between the increased mass and the rest of the fat; but, as it is a constitutional disease, it is capable of being remedied by medical treatment, and the masses of fat disappear under the use of liquor potassæ, which you should gradually increase till the patient takes a drachm and a half, or two drachms, three times daily in milk or beer. My patient has taken it now nearly three months, and the tumors, though not obviously lessened, are considerably less full, and the lobules are more distinct where the cellular tex-

ture divides the separate portions; but it requires to be continued for nearly a year, I believe; and from his having epilepsy and rheumatism, the medicine has hardly yet had fair play. I recollect, when a pupil, a servant who was in attendance at the hospital for a great mass of this description under the chin, which was so unsightly as to prevent the man from gaining his livelihood; this man took the potash for a twelvemonth, I believe, and the fat at last disappeared, leaving an empty loose bag of skin; and I mention the case, because Sir Benjamin Brodie, whose patient he was, informs me that he was accosted ten or eleven years afterwards by a servant, in a house which he was visiting, who proved to have been this individual, and who had remained quite well since, the redundant skin having, of course, contracted. Wherever, then, you have several masses of fat of this kind, try this medicine in the large doses I have mentioned, for a considerable time. How it acts I don't know, unless it forms a kind of soap in the body. It generally produces some degree of universal emaciation after a time, by its effects probably on the stomach; but the effect is evident in a much greater proportion upon the tumors than upon the rest of the body; and this general thinness is recovered from, as it would seem, without reproduction of the fat. Sir Benjamin Brodie once tried iodine in this kind of disease; but although it caused the usual emaciation which that medicine creates, it did not influence the local deposit of fat, which increased notwithstanding the general falling away.

III. 2. The second genus of solid tumors is the *fibrous tumors*, which may be subdivided into three species.

a. One form of fibrous tumor is connected with *fibrous textures*, such as fascia, ligament, dura mater, and the contractile fibrous tissue of the uterus. A common situation is on the fascia, under the skin, in the arms or legs. Here is one which I removed from over the annular ligament of the instep. I have seen three or four, in the same person, on both fore-arms; I have seen it also in the thigh, arising from the fascia lata, and on the back of the hand.

Examine the tumor, and you find it from any of these situations hard, whitish, semi-cartilaginous; the knife cuts it with difficulty, like a cancerous tumor; and it cures, as the French call it, when cut; it is, in fact, just like a mass of firm condensed ligament, in a circumscribed and generally a circular form. To distinguish it below the skin, you will feel it hard and firm, nearly unattended with pain;

moveable, except at the point of attachment, which is easily perceived; possessing little elasticity, smooth on the surface, and the skin generally moving freely upon it.

When increasing, the tumor may easily be removed by the knife; but you must be very careful to remove not only the tumor itself, but the whole of the fascial or ligamentous structure to which it is attached, otherwise the disease will return. A patient came under Mr. Babington's care for a tumor of considerable size, apparently of this kind, connected with the upper and outer part of the thigh, which had already been twice removed by operation, and which, I believe, was perfectly innocent in its character, and thus returned from want of attention to this circumstance in the former operations. There is often no necessity, however, for operation, if the patient is unwilling to have it performed, as the tumor is very slow in its progress; for instance, a man came under my care for some other cause, in whom, over the edge of each radius, a tumor of this kind existed; but although seven or eight years had elapsed since their first formation, they were not so large as a walnut, and he had no inconvenience from them, and would not, therefore, have them excised.

Fibrous tumors of the *dura mater* of the spine, or brain, are somewhat softer, and more yellow in texture, and produce of course the symptoms of pressure, but very slowly. I have seen the spinal marrow compressed to half its natural diameter. It is unnecessary to dwell upon them, however, from their incurable nature.

The *fibrous tumor of the uterus*, or *fleshy tubercle* of this organ, as it is also denominated, is very common, and is generally, like the structure of the uterus itself, a little condensed; it is consequently considerably less ligamentous than the former varieties. They grow in this situation in any direction; here is a section of one which I found filling the uterus, which was thinly expanded over it; it was nearly as large as a child's head, and the surface is a mass of firm bone, which required the saw to divide it. You may see them projecting into the pelvis and abdomen, covered by peritoneum. I once saw one larger than any one's head, which had been removed by operation. The operator who shewed it me very naturally expected to find a diseased ovary in a moveable tumor of this magnitude, and the patient as naturally died of peritonitis. There is a long paper by Dupuytren, on the Fibrous Tumor of the Uterus, and a complete account of them by Dr. Lee, in the 19th volume of the *Medico-Chirurgical Transactions*.

When situated towards the interior of

the uterus, they project into the cavity of that organ, and into the vagina; and when accessible, they may be removed by the double canula, or by excision, but not so easily as the ordinary polypus. The operation is not, however, devoid of risk; for instance, in the present year I had a woman under my care, with a tumor of the size of the fist in the vagina, with a neck an inch and a half wide. I tried to bring it down so as to excise it, but could not do so without more force than I liked to employ, and therefore tied it with a ligature. The mass separated by ulceration; but when the patient was apparently getting well, a low inflammation spread to the uterus, and to the peritoneum, and destroyed her. I found on examination, that besides the mass which I had removed, and which was attached by its neck to one side of the cervix uteri, another, which had met with less pressure and resistance in that direction, had enlarged to the size of the fist within the cavity of the uterus. They are fatal by irritation and hæmorrhage, in some cases, without operation. I attended a woman with Mr. Malton lately, and removed a polypus from the cervix uteri by excision, but was obliged to leave a fibrous tumor distending the cavity of the uterus, which proved fatal a few months afterwards. When of very large size, a change takes place occasionally in the interior, and the tumor becomes very vascular, and ulcerates, so as to look like a malignant tumor, as in this drawing from a patient of Dr. Seymour's, who died in the hospital, with this immense tumor hanging down in the vagina, and connected with the fundus of the uterus.

b. A second form of fibrous tumor seems to originate in the cellular texture: it is somewhat similar to the last, but much softer, and more elastic, the fibres softer and less distinct, and not so white and shining; and it contains some fluid, which exudes on a section being made, and thus leaves the tough fibrous cellular membrane, which composes the solid part, to a certain degree flaccid. It is smooth and elastic in the living body, little painful, and grows to a considerable size sometimes. The most frequent situation in which it is met with seems to be in the cellular texture, by the side of the vagina, perhaps from the stronger and more fibrous nature of the cellular membrane in this situation. Here is one of several inches length, which I saw removed by Sir Benjamin Brodie from this situation, which it was difficult to extract entire, from the great depth to which the end dipped into the pelvic cavity. This circumstance makes the operation difficult, and requires care in the dissection; but its nature seems

to be innocent, so that it does not return if the whole tumor be extracted from its cellular bed. A very remarkable case has been published by Mr. Lawrence, of this disease, which he calls a cellular tumor; but as it contains no cells, and is tolerably firm in structure, I think the name fibrous tumor of the cellular membrane less likely to be misunderstood. In this case the tumor had grown for four years, was thirty-two inches in circumference, and was as large as a double head; it returned after the first operation, from the end being cut across; and a second operation being performed two years after the first, this end was dragged out of its deep situation, and the disease did not return again.

This tumor must not be confounded with a peculiar growth of the labia and nymphæ, which will be described to you by and by, a kind of hypertrophy only of the cellular membrane, which becomes distended to a great size; this is a disease of the same kind as that which is called the Barbadoes leg. The fibrous tumor has, on the contrary, no connexion with the skin, and is hard and firm.

c. The third species of tumor in this genus may be called the *painful subcutaneous fibrous tumor*, or, as it was called originally by some English authors, *painful subcutaneous tubercle*. The best description, however, of the disease, is by Dupuytren, who remarks that it has been erroneously called a nervous tumor, and who calls it himself a fibro-cellular tumor. It contains no cells, however, as this name would seem to imply, and is really a fibrous tumor, with a singular painful sensation.

It is observed as a little hard lump below the skin, the size of a grain of wheat, perhaps, and never more than as large as a pea or small bean; you have seen me lately remove one of seven years' growth, which was even then not half as large as a small pea; I could not find it this evening to show it you, though it is somewhere in the museum. Its texture is firm and fibrous, sometimes almost like cartilage in hardness, whitish, or brownish white, and with a rather firm covering. It is exquisitely tender, the least touch exciting violent pain; even the passage of cold air over it, or the friction of the clothes, may produce complete torture. The pain is sudden, darting, like an electric shock; sometimes so severe and frequent, as to induce convulsions, and become quite wearing and injurious to the general health. I amputated the leg of a man this year, who had one near the tubercle of the tibia, and the pressure of the wooden leg after the operation obliged me to remove the little tumor, from the pain which was produced by it, and which seemed to extend over the whole side. Sir Benjamin

Brodie not long since removed one from the cheek, in which situation they are not uncommon, though they may be met with any where. You can scarcely account for the production of such violent pain in these little tumors; occasionally, indeed, you can trace some nervous twig into them, or over them, but very often you will look in vain for any distinct fibre of nerve. Dupuytren attributes the pain to the density of the kind of capsule which surrounds the tumor; but this is by no means always met with; in the one I have just alluded to, the capsule was rather delicate, and there was a reflected cyst besides, which, like a bursa, must have still further defended the tumor from friction; in this case, by the by, the pain was only occasioned by pressure in one direction, which dragged probably on a nerve.

The skin is generally loose and moveable, but is sometimes attached to the tumor. It may occur from falls, or blows, or other injuries, but often takes place without any evident cause. Dupuytren says that women are more subject to it than men: it so happens, as to myself, that I have only seen it in the male sex; but yet he may be right. There is scarcely ever more than one in the same person. The only disease for which it can well be mistaken is the donlounrenx, the pain being similar in the two cases; but the existence of the little tumor, and the production of pain by pressure, easily serve as diagnostic marks between them.

Narcotics and various other remedies have often been tried for a great length of time, without any avail, and the removal of the little tumor by the knife is the best remedy, which is also generally easily and safely done, though some of you have seen extensive abscess follow the operation in the recent case of my own, which I have alluded to before. You may make an incision through the skin over it, and catch hold of it with a hook to cut it out. Dupuytren gives an additional reason for the operation; viz., the tendency of the tumor to become cancerous, and end in carcinomatous ulceration. I think he is probably not correct, however, as to their having any natural tendency of this kind; all tumors no doubt may become changed into cancer, but certainly very many years will elapse without any alteration. The operation is, however, right, for the pain produced by the tumor, whether Dupuytren be correct or not as to its probable termination.

III. 3. The third genus of sarcomatous tumor is really a tumor of a nerve, or rather in the coverings of a nerve, and you may call it the *neuromatous tumor*. It is not common, however,

a. Sir Everard Home has given a very good description of one that he removed in this hospital from the axillary plexus. The tumor was situated in the texture of the nerve, between its fibres, and was of a tolerably firm consistence, with a mixture of fluid of a white or light brown colour, and the nerve was flattened into two portions by the separation of its fibres. It was firm in its feeling; and after growing slowly for several years, it had increased more rapidly. It could be moved laterally without pain; but if dragged upon, violent pain was produced in the course of the nerve. A small cord could be felt at each end of the tumor, which was the continuation of the nerve, and the neurilema of the nerve formed the covering of the tumor. Dr. Gills, who was house-surgeon here, I believe, and who paid us a visit not long since from St. Petersburg, where he resides, removed another from the muscular spinal nerve, the fibres of which were more reticulated and expanded, and the fluid in the centre was dark coloured, like blood. In the removal, a large artery in the centre bled freely. The return of sensation and motion took place here slowly; but you must be prepared, if such a case presented itself to you, for the patient suffering great inconvenience for a long time, from want of nervous power, and should not be in haste to operate.

The situation of the tumor, its connexion with a nerve above and below, the peculiar pain and nervous symptoms in the parts supplied by the nerve, will form grounds for an accurate diagnosis; unless, as I have seen, a tumor involves a nerve in its structure, in which case it may erroneously appear to have originated in the nerve.

I apprehend such tumors are of the same kind as what you may see in this preparation, and which frequently thus form in stumps, and occasionally require a second amputation, from the severity of the pain; or such as you may examine in this preparation formed in the median nerve after an apparent injury which divided the nerve into two portions. The tumor is on the upper end of the nerve, and when recent was two inches long and one broad. In this case, too, the power of the part below seems to have been restored by anastomosing branches between the muscular spinal nerve and the lower end of the median.

Such tumors do not appear to result from common inflammation, which only thickens and condenses the cellular texture and neurilema of the nerve, but they seem rather to arise from some peculiar action, by which a fluid is effused between the fibres of the nerve, with a cellular covering. And judging from what

is seen after amputation, there is probably a peculiar condition of the nervous system, that would make one indisposed to meddle with the tumor, if it can be avoided. The loss of motion, sensation, and vital properties, is of serious consequence; and in one case of tumor of a nerve, in which Sir Everard Home operated, the patient died on the fifth day afterwards, with violent nervous excitement, after the small nerve had thus been cut through in which it was situated.

b. The case, however, which I have just alluded to, was a tumor of a different kind from what I have been describing. It was one in which he found that the tumor was an encysted tumor, which could be turned out of its bed in the nerve, leaving the fibres uninvolved. And it would appear from preparations which I have seen in the College of Surgeons, and elsewhere, that a variety of tumors may possibly be met with of a fibrous or other character, merely situated in a nerve, and not deriving any peculiarity from that locality, and which probably cannot be distinguished from the neuromatous tumor till a dissection of the parts is made. But I can say nothing on this subject from my own experience.

MEDICAL GAZETTE.

Saturday, March 10, 1838.

“*Flect omnibus, flect etiam nihil, dignitatem Artis Medicæ tueri; potestas modo venendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

ILLUSTRATIONS OF MEDICAL COMPETITION.

WE were somewhat struck, not long ago, by a paragraph which appeared in a daily newspaper*, with the quaint heading *Her Merchants are Princes*. The body of the article was in a strange and facetious contradiction with the title; for while the latter alluded to the princely liberality for which the merchants of London have long been famous, the former betrayed the astounding fact that it is a usual thing for a surgeon on board a merchant vessel to receive the same pay as a common sailor, or even less. Accustomed, as we have

long been, to contemplate the various phases of medical life, we yet could not help being staggered by this announcement. The shrewd practitioner, skilled in the twofold art of curing diseases by drugs and by manual operation, or, to adopt the language of the ship-advertisements, “an experienced surgeon,” his head full of knowledge, his chest of books and instruments—placed side by side with Jack Tar, and rewarded on the same scale by the merchant-princes, seemed at first a contrast too strange to be true. Yet, after all, except in the circumstances of the juxtaposition of persons, the table of precedence being inverted, and the surgeon (in the pence-table at any rate) coming after the mate and the cook, there is, unfortunately, nothing very new in the case. The extreme tonuity of the pay may easily be matched or exceeded in our profession. The Lancashire surgeon, for instance, who attends 1,173 factory operatives for six guineas a year*, is even worse paid than the surgeon-sailor on board the *Nancy*, or the *Susan*. There is, indeed, some slight nominal difference between the cases. The surgeon confined on board the whaler, or emigration ship, has his modicum of indurated pork, or granitic beef, besides his lodgings gratis, in what Dr. Johnson defined as “a prison with the chance of being drowned.” The factory doctor, on the other hand, has neither board nor hammock, but, in compensation, may take private practice—if he can get it. Yet, in the main, both situations are very similar; for, in both, large services are expected for an infinitesimal remuneration, and in each case this is submitted to, under the vain delusion that the painful drudgery which is but nominally rewarded, is a prologue to better things.

The more we see of the disappointed expectations of medical men, on the one

* The Globe of February 10th, 1838.

* MED. GAZ. vol. xx p. 243.

hand, and the popular notions concerning medical profits on the other, the more we are convinced that an honest and candid writer might do the community some service, who should set forth the real state of the matter, and thus diminish the number of the deluded. Such a philanthropist, however, must be satisfied with effecting good, and should not be disheartened if he finds that he meets with much obloquy, and little gratitude. It is a thankless office to endeavour to persuade children that tinsel is not gold.

If we aspired to so unpopular an office as that of censor and adviser, we should address ourselves to parents; to those especially who had but little capital to bestow on the education of their children, and none to set them afloat with when their education was ended. We should ask them to look at that division of the newspapers which, above any other, shows "the very age and body of the time, its form and pressure," (we mean the advertisements); and to ascertain what kind of offers are made to and by medical assistants. Let them inquire among their professional friends for additional information as to the salaries doled out to medical assistants. Will they find it a common thing for these useful ministers of a liberal art to receive 200*l.*, or 150*l.*, or 100*l.* per annum? On the contrary, they will learn, that in the medical market such rewards would be laughed at, as ridiculous and exorbitant; the real wages being 40*l.*, or 30*l.*, or 20*l.*, or even nothing at all per annum! Yes, nothing at all; as, take for example, the following advertisement: "Medical. — Wanted immediately, an humble young lad, to take charge of a small retail at the West End. He must be competent to read and make up prescriptions. A comfortable home, and advantages for study, and, should his conduct entitle him, liberty to attend a lecture or two

daily, at the adjacent school, would be considered equivalent to salary. Good references will be necessary *."

Surely the advertiser need not so specially have demanded "an humble" assistant: even if the very taking such a situation as the one described were not in itself an act of the most saint-like humility, assuredly the place would soon humble the lad to any desirable point below the zero of pride.

How strange that any one should wilfully expend capital in bringing up his son to such a lot as this! Is it not as clear as day, that many situations which are nominally lower on the social scale, are infinitely above it in salary and comfort? Does any one offer a butler a salary of £0 0*s.* 0*d.* a year, and desire, besides, that he should be "humble?" Is he ever made to sleep under a counter?

Or, to drop the topic of assistants, and resume the question as it regards those who are practising independently, let us turn to a controversy which has been raging in the columns of a contemporary. Mr. Bree, a surgeon, of Stowmarket, in Suffolk, writes to complain of the Rev. Mr. Steggall, of that neighbourhood, who has two strings to his bow, and practises physie as well as divinity. He asserts that the charges of his clerical rival, particularly in midwifery, are rather less than half of those of the regular practitioners in the neighbourhood; and that, in consequence of this, a representation was made to the solicitor of the Apothecaries' Company. He replied, however, that Mr. Steggall claimed exemption from the act, having been in practice before 1815: if the medical remonstrants could bring evidence to disprove this, the Company would prosecute; if not, Mr. Steggall might continue to be an apothecary. As it did

* *Times*, Feb. 14, 1838.

not seem easy, or even possible, to obtain the negative evidence required, the undersold doctors next betook themselves to Mr. Steggall's spiritual superior, the Bishop of Ely; but here, again, they were destined to disappointment, as the right reverend Prelate replied that he could not interfere, as no complaint was made of the reverend *Doctor* having neglected his clerical duties.

But it is plain that he must sometimes neglect his medical, chirurgical, or obstetrical duties. With us ordinary medical men, a professional engagement is paramount to every other consideration; the messenger finds the *Doctor* at church, and off they go together. But with Mr. Steggall the case must be quite different,—as, for example, it is Sunday morning; the bell has just done ringing for service, and Mr. Steggall is walking up to the reading-desk, in his canonicals, when a horseman is seen coming up to the church-door at a fearful pace. He has galloped all the way from Rattlesden, where Mr. Steggall practises medically, to Ashfield, where he practises spiritually—a distance of no less than seven miles, according to Mr. Bree, though only five according to his reverend rival. Be this as it may, he has come at a spanking pace, as his reeking horse full well displays, and has hardly breath enough to say that Mr. Steggall is wanted on the instant. A lady in an interesting situation, at Rattlesden, was seized with premonitory pains early in the morning, and at half-past ten precisely was crying out, *Juno Lucina, fer opem*, with great vivacity. Never was clerk or doctor in a more perplexing quandary: if he leaves the church, he will be hauled up before the Bishop; if he clings to the desk, the ladies of Rattlesden will begin to suspect that half-price midwifery is not an unmingled good. He cannot expect any aid from the remonstrants, and is lost unless he has some "humble" lad

in his service ready to take his place on such occasions.

In the same letter Mr. Bree complains of prescribing chemists, and of an "impudent quack" who visits his patients, taking medicines to them, and fees from them. The writer also wishes that some member of the House of Commons would move for a return of the number of the prosecutions instituted by the Company since 1815. The fact is, that this return is to be found annexed to the evidence given by the Worshipful Society before Mr. Warburton's Committee*.

So far Mr. Bree is at least always intelligible. But he goes far out of our reach, when, in speaking of the act of 1815, he says, "Let the world see, that instead of providing for the *safety* of the public, the only effect of that act has been to establish a monopoly alike degrading to the character of the profession, and ineffective in protecting its interests." A monopoly! Why, all the facts he brings forward (to which every one could add something similar from his own experience), go to prove the existence of the most ruinous competition—that is, of a state of things the very antipodes of monopoly. The grinding monopolist sells at his own price, and has no competitor to dread; while the apothecaries of Rattlesden sell physic and advice at a painfully low rate, and then find themselves undersold by their clerical antagonist. Monopoly, indeed! Why, Mrs. Malaprop never used a word more unseasonably.

Mr. Steggall, in his answer, gives Mr. Bree at least as good as he brought. He observes "that the accusation of low charges comes with peculiar ill grace from one who bled and drew teeth at Bidleston, at sixpence a head—who wanted to establish the same charges in

* The reader who does not know it already, may learn from this paper that law is one of the most expensive of luxuries; many of the defendants, too, were not worth powder and shot, being unable to pay costs and damages.

his penny club—and who first introduced half-guinea midwifery into Stow-market." He gives another instance of overwrought competition (or, as Mr. Bree would call it, monopoly), in the person of a clerical magistrate, who is a physician to boot.

On the whole, we think that our clerical competitor comes out of the contest with flying colours: he seems to be perfectly entitled to go on as he began; and the efforts which have been made to dislodge him from his Janus-like position have but served to fix him there more firmly:—

"As the loud blast that rends the skies,
Serves but to root thy native oak!"

So far the present controversy has gone; but as to the rest, the ladies of Rattlesdun must take care how their hour of tribulation comes to clash with the hour of the church-service at Ashfield.

DR. MARSHALL HALL AND MR. NEWPORT.

WE have received the following letter from Dr. Marshall Hall:—

To the Editor of the Medical Gazette.

SIR,

As there is a "decided misrepresentation" in your remarks respecting my conduct towards Mr. Newport, I beg you to do me the justice to correct it, by the insertion of the few following lines, in your next number:—

It seems that I *thrice* responded to a request on the part of Mr. Newport to lend him 5*l*. I had forgotten the precise sum. I only remembered my willingness, nay my *desire*, to serve him. Was not this pretty well towards an *utter stranger*? towards a stranger who had no claim whatever upon me, except that created by his wants?

But this was not all. For I next *devised* a plan for his assistance, of a more extensive kind. I procured him a pupil (although he was but a pupil himself,) and on that gentleman's account I paid him *ten times* the sum of 5*l*. 8*s*. Was all this, viz. 15*l*. + 56*l*. 4*s*. such trifling assistance to a stranger, that I need be ashamed of it?

Nor would this have been all; for Mr. Newport himself abruptly terminated this arrangement by his own disgraceful conduct,—prying into his pupil's private letters, and addressing him with vulgar oaths. Can you be surprised that a parent removed a son under such circumstances, or that he even refused to pay the last monthly sum, partly due?

I will only add, that what I did I would do again, under similar circumstances. More I could not do.

I am, sir,
Your obedient servant,
MARSHALL HALL.

14, Manchester Square,
March 7, 1838.

On the preceding epistle we have to remark, in the first place, that when a correspondent accuses us of "decided misrepresentation," it is to be expected that he should take the trouble to state in what such misrepresentation consisted. But so far is this from being the case, that he does not even give us a clue to it; and on re-perusing our observations of last week we can discover nothing which is not fully borne out by Dr. M. Hall's present communication.

In our last number we called attention to two letters recently published, one having the signature of Dr. Grant, of University College, and the other of Dr. Marshall Hall, in which these gentlemen heaped upon Mr. Newport such a collection of epithets as shewed that they were tolerably versed in other terms besides those of science. The impression made upon our minds by the perusal of these documents was greatly in favour of the party whom they attacked—an impression which, it will be in the recollection of our readers, we did not hesitate to express. Since that time, however, we have seen a reply from the pen of Mr. Newport; and we must say, that unless Dr. Grant and Dr. M. Hall disprove his allegations, they have placed themselves in a predicament by no means to be envied.

Mr. Newport, the temperate and dignified tone of whose letter presents a

strong contrast to the vituperation and abuse of his opponents, charges both of them with untruth. Dr. Grant and Dr. M. Hall have mixed up private affairs with a question of science, and endeavoured to throw discredit on Mr. Newport as a physiologist, by referring to certain favours conferred on that gentleman at a time when he was not in circumstances to carry on his studies without some assistance. We never said that Dr. Marshall Hall "need be ashamed" of having rendered such aid; what we complained of was his playing the braggart, and bringing forward his own liberal loan of 5*l.* at three several times, as bearing upon a question in physiology.

But as Dr. Marshall Hall has thought fit to prolong the discussion, instead of adopting the more prudent course of letting it drop, it is due to Mr. Newport to let his side of the question be heard. Speaking of this gentleman, the Dr. says, "I fed, and clothed, and housed, this same individual! yes, I lent him money, I procured him a home in his distress for many months."

To this, Mr. Newport makes the following reply:—

"I shall reply to the charges of Dr. Hall *seriatim*. As to his having either housed or clothed me, the assertion is false, and Dr. Hall knows it to be so; I never slept in his house, or in any house of which the rent was paid by his money. He never procured clothes of any description for me. As to his having fed me, here I plead guilty, in so far as that I occasionally dined at Dr. Hall's house, by special invitations, and also took tea there, when engaged with him in prosecuting anatomical and physiological inquiries. Could I for a moment have believed that when I was accepting Dr. Hall's pressing invitations I was regarded by him as being fed like a wild beast, and destined afterwards to have this published to the world as an obligation? To the other charges, that I borrowed money of Dr. Hall, I grieve to say I must plead guilty. On three several occasions I solicited Dr. Hall to advance me 5*l.*, and he did so; for the two last sums I gave him a written receipt, and so soon

as it was convenient for me to discharge this debt of 15*l.* I did so. This is every farthing of money I ever received from him. If the payment has been sought late, like Shylock's, it has been, like Shylock's, claimed from near the heart. It ought to be known that, long before the period of this loan, it was offered to me, without solicitation, by Dr. Hall, and that before I asked for it I had spent much time in assisting him in his experiments. The statement of Dr. Hall, that he had procured me a house for many months "*in my distress*," is equally incorrect with the rest; and the designing statement, that the engagement with my pupil was abruptly terminated by my prying into his letters, &c., is equally untrue, since it was broken off in consequence of certain circumstances which I need not be the party to state. "On referring," says Dr. Hall, "to my account with Sir Claude Scott, Bart., and Co.," &c.;—had not this statement appeared in print, and with Dr. Hall's signature attached to it, it is impossible to conceive that it could have been made by him. Of course this statement must convey, and must be intended to convey to the reader, the impression that during the long period mentioned I was supplied by Dr. Hall's bounty; and yet what was the real fact? I received not one farthing of his own money during the period mentioned. The monthly payments to which Dr. Hall alludes were due to me on account of the gentleman who was living with me. It is true that it was through his recommendation that I received this pupil, but it is equally untrue, I believe, that any portion of the money came from the pocket of Dr. Hall. The terms on which I received this pupil were arranged with Dr. Hall, and the father of the gentleman in question, when it was then determined that I should receive the payments monthly, through the medium of Dr. Hall, on account of his friend, and he gave me cheques accordingly on Sir Claude Scott's bank. The obligation, then, which I lie under to Dr. Hall on this score, which appears, as he has stated it, so vast, amounts to this, that I owe to him the benefit of having had a pupil. Surely there never was such a monstrous practical sophistry attempted to be maintained, and hardly ever, I think, was

* This is the only part of Mr. Newport's answer which appears to us incomplete.—*Ed. Gaz.*

there put on record charges more unjust, or more insidious, than those which I have now exposed."

The next time that Dr. Marshall Hall trumpets forth his patronage, we recommend to Mr. Newport to content himself with the duty—

"To John I owed some obligation,
But John thought fit
To publish it to all the nation;
Sure John and I are more than quit."

IRISH COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

PERMIT me to correct two errors into which you have been led in your editorial remarks upon the "controversy," not "regarding the Irish College of Surgeons," as you have expressed it, but regarding the change proposed to be made in its character and functions. You state that a letter has been addressed to your publishers "by authority of the College of Surgeons in Dublin," to "require" that the name of the writer of the article in your number of February 10th, should be given up. Sir, I know not by what authority that letter was written; but I do assure you, on the authority of the Registrar of the College, that the College did not give authority for it; at least, that there is no record of such in the College minutes. And, sir, it is a most inexcusable proceeding, that any member or number of members shall venture thus to involve the name and authority of the College, and, at the same time, to cast an unfounded and indirect imputation of College displeasure upon any individual. You have also stated that I have entered the lists "against the Irish College." Allow me to assure you, that you have altogether mistaken, as well my intentions, as my conduct. I have not entered the lists against the College, but against that party in the College which seeks to subvert the original intention and constitution of the College. I am a member of it, as warmly attached to its true honour and dignity as any other. I contend for the preservation of the College, such as it was originally founded—such as it has ever since continued—and such as it still is. I am, therefore, the advocate of the College—its defender—and I have en-

tered the lists against those who would revolutionize it; but not against it.

Allow me now to protect myself against another misconception on the part of the profession. I am an advocate for the possession by every physician and surgeon of a right to give medicine if they please; but not to deal in, or to sell it.

I remain,

Your obedient servant,

BENJAMIN ALCOCK,

M.B. M.R.C.S.I.

Dublin, March 6.

[With all due deference to Dr. Alcock, we really do not see that we have fallen into any error. 1. A controversy regarding "the change proposed to be made in its character and functions," is surely still a controversy "regarding the Irish College of Surgeons," the character and functions of which it is proposed to change. 2. The letter which we alluded to is dated "Royal College of Surgeons, Dublin," and signed "C. O'KEEFE, Registrar," and this, we submit, was sufficient ground for our asserting that it was written by authority of the College. 3. In stating that Dr. Alcock had entered the lists "against the Irish College," we meant no reproach, as indeed the context shews, but simply that he was contending against certain measures which the ruling body in the College contemplated adopting.—ED. GAZ.]

WESTMINSTER HOSPITAL.

CLINICAL REMARKS BY MESSRS. WHITE
AND GUTHRIE,

*On Compound Fractures, Gun-shot Wounds,
and Necrosis.*

JOHN DACE, æt. 62, a hardy old man, with a frame (to use a Cockney simile) as tough as pin-wire, was admitted, under the care of Mr. White, December 27, 1837, having a compound fracture of the leg. Being employed at a floor-cloth manufactory, he fell from the top of a frame to the ground, a distance of six feet, and his leg came in contact with a piece of timber, which occasioned the fracture. When brought to the hospital, the patient had a wound two inches above the internal malleolus, extending from the spine of the tibia backwards to the fibula. The broken ends of the tibia, which were very uneven, had become entangled with the linen with which the leg had been rolled. Upon putting his finger into the wound, Mr. Dasent dis-

covered several loose pieces of bone. The fibula also was broken, as was evidenced by the distortion exhibited.

Such a severe injury, in so old a subject, indicated an unfavourable prognosis, and Mr. White was therefore sent for. On his arrival, he removed the entangled linen from the bony spicula, by extending the foot. A long spike of bone, projecting from the upper portion of the tibia, was sawn off. It was now ascertained that the fracture was not only compound and comminuted, but also that it extended into the joint.

Notwithstanding this complication of mischief, Mr. White determined to give the man a chance of saving his limb. Several of the fragments of bone were removed, after which the pulsations of the posterior tibial artery could be distinctly felt. The edges of the wound were brought together, and retained by means of ligatures. The leg was placed on Amesbury's apparatus, and very slightly bent. A piece of lint pledget was placed over the wound, and cold lotion was applied over the entire limb: a cup of tea, with brandy in it, was given to him, and when he was left he said he felt comfortable.

R Hydrarg. Chlorid gr. iv.; Extr. Col. Comp. gr. vi. ft. pul. ij. hora somni sumenda. Habcat haustum Senne sumenda.

4 p.m.—His pulse beating full and quick, he is ordered the following medicine:—

R Liq. Ammon. Aect. ℥ij.; Vin. Antim. Pot. Tart. ℥ij.; Mist. Camphora. ℥viij. M. Cap. ℥j. itis horis.

28th.—He has passed a comfortable night, and his pulse is quiet; his bowels have been opened.

2 p.m.—His pulse quick, 120, and not compressible; he is extremely restless. The skin is hot and dry. V. S. ad ⅔.

10 p.m.—The patient's pulse frequent, but a little softer; his skin is pungently hot, and he is restless.

29th, 2 a.m.—The nurse called Mr. Dasent up, stating that the man was dying. This gentleman (the house surgeon) found him "throwing himself about the bed," breathing hard, with his teeth clenched, and passing his faeces and urine in bed. He was insensible of what occurred. Mr. Dasent, with some difficulty, got some brandy down his throat. After some time he became tranquil.

9 a.m.—The patient is sleepy; his pulse is weak; the skin moist. He is ordered to continue the brandy.

12 m.—The wound presents a sloughy aspect. The integuments of the leg are pitted on pressure. The Amesbury apparatus is removed, and the leg is placed on

a pillow, a poultice being applied over the wound.

R Ammon. Sesquicarbon. ℥j.; Aquæ distillatæ, ℥viij. Solve, bat Mistura ejus cap. ℥j. in impetu effervescentiæ succi limonis recentis, ⅔ss. quartæ quæq. hora. Rice pudding for his diet.

30th.—The patient passed a tolerable night, the pulse is small and quick, the skin natural, tongue moist. Castor oil immediately, and the following mixture every two hours:—

R Ammon Carbon. ℥j.; Pulv. Aromat. ℥j.; Aquæ puræ, ℥viij. M. It. Mist. de q. a. sumat. 30. or ⅔ss. 2ds horis. A beef ground poultice to be applied to the wound.

31st.—The wound is beginning to suppurate, the pulse is stronger, but slightly intermittent.

1st Feb., New Year's day.—A superficial slough is forming in the middle third of the leg, near its inner side. The suppuration continues. The patient feels hungry, bowels stopped.

R Ol. Ricini. Tinct. Senne, aa. ⅔ss. M. It. potio statim sumenda.

2d.—Has occasional rigors. The pulse is small and weak.

3d.—Much constitutional disturbance, tongue dry, face flushed; pulse frequent and feeble. Extensive sloughing of the skin and fascia of the leg.

5th.—A collection of pus having formed on the fibular side of the leg, under the integuments, is let out by several long incisions.

6th.—The sloughs, both near the fracture and at a distance, are beginning to separate from the sound parts. His pulse is better. Half a pint of ale daily, in addition to his brandy.

8th.—The greater part of the slough is detached.

17th.—All the sloughs are removed; the granulations appear healthy. The limb has been again placed on Amesbury's apparatus.

Feb. 13th.—The wound continued to secrete healthy pus, and its surfaces to exhibit florid granulations, but no union could be produced between the disjoined portions of the bones. The continual discharge likewise began to produce an unfavourable impression on the patient's health. Under these circumstances Mr. White formed the resolution of amputating the affected limb, and carried his intention into effect to day. The limb was removed below the knee by the ordinary circular incision. After the patient had been removed to his bed Mr. White examined the amputated limb, and pointed

out the pathological appearances. No particle of granulation was visible on the fractured surfaces either of the tibia or fibula. Considerable laceration of the ligaments of the ankle-joint had taken place; the cartilaginous surfaces were seen to be completely absorbed, and the adjacent osseous surfaces were carious.

It was obvious, Mr. White observed, that the patient's powers were inadequate to repair the injury that had been inflicted on him. It would always, in his opinion, be a nice question to decide, which cases were fittest for immediate, and which for secondary, amputation. In civil practice he thought it the duty of the surgeon to lean to the side which suggested the saving of the limb, when the patient's constitution and temperament were favourable. The army surgeon had his judgment influenced by many casualties from which the civil surgeon is exempt; such as bad roads, rude means of transport, and a distant hospital. On shipboard, also, the rolling of the vessel is a circumstance that would prompt the surgeon to amputate, rather than leave a compound fracture to be exposed to multiplied risks. In the case before us, he said, he was justified in endeavouring to preserve a useful member for his patient, whose constitution had gone through the ordeal without receiving any detriment.

21st.—The patient has gone on well since the operation, not a single untoward symptom having shown itself. The wound is suppurating, and he feels quite comfortable.

In reference to this case Mr. Guthrie made the following clinical observations: If the rent of the integuments in a compound fracture unite when the cut edges are put in apposition, the compound fracture becomes a simple one, and the cure is effected by a very easy natural process. If it should not unite, the wound remains open, and the process of cure is much more complicated. A gun-shot fracture must always be a compound fracture, because the shot-hole cannot unite by the adhesive inflammatory process; but a compound fracture caused by a heavy cart-wheel going over the part must be a more dangerous injury than any musket-ball fracture. The treatment, therefore, in all serious cases, is pretty much the same.

In a gun-shot fracture the bone or bones may be more or less broken, and the splinters larger or smaller. In the first place, examine the wound at the moment, if you can. The object is to ascertain the state of the fracture and to remove the splinters, and the extent of the incision must depend on them. If the ball has merely struck the bone and passed out, causing a transverse fracture only, there is

no necessity for dilating such a wound at the moment, because the cut would have closed up before any bone would be ready to come away. This is one of the differences between a compound fracture from a slight accident and a gun-shot fracture. In the accidental fracture, the force being often applied to the ends of the bone, no injury is done to the broken part by direct collision. In the simplest gun-shot fracture the ball grazes and injures the bone, depriving it of a part of its periosteum, and a scale or portion will exfoliate at that place; but this is a process that takes time, and it is to give a free passage to this exfoliated bone that an incision is made. If the ball lodges in the soft parts after breaking the bones, an incision for its removal is proper, as it also is to give free vent to copious purulent discharge.

The peculiar danger from a gun-shot fracture, and which is not so great in a common compound fracture, arises from inflammation taking place in the membrane lining the shaft, and the cancellated structure of the bone. When this inflammation exceeds a certain point, it causes the death of the bone, and gives rise to a corresponding but peculiar action in the periosteum covering the bone externally. This membrane swells, thickens, and begins to deposit new bony matter, not only in its own structure but external to it, and induces the neighbouring vessels to take on a similar action, often to the extent of an inch or more. This ossific deposition begins early. I have seen it by the twentieth day, and even sooner, and by the end of the fourth week it is often very remarkable.

In a gun-shot fracture you have to dread the danger of shutting up splinters of bone by the newly-formed ossific matter; and the object you have in view is to prevent the extension, if not the establishment of this process. This is to be done by suppressing the inflammation in the internal part of the shaft, and in the limb generally. The splinters should be removed, if possible; the limb should be placed and maintained at perfect rest. Vascular action must be subdued by cold lotions and by leeches; and when cold is disagreeable, warm fomentations may be resorted to. When suppuration is fully established, the remaining splinters may be sought for and removed: but if this cannot be done, the gradual thickening of the limb begins to indicate the deposition of bony matter; and after a certain lapse of time, a spot of inflammation, at a particular part, implies an abscess in the new deposit. This is caused by the irritation of the dead splinter, and when it breaks, the probe will find its way through a hole to the rough *sequestrum*. The dead bone must be immediately removed. The earlier

it is done the softer is the deposit, which in such cases, will act like Parmesan cheese mixed with lime.

Mr. Guthrie gave the following rules for the guidance of the young military surgeon:—

1. An upper extremity should be amputated for scarcely any accident that may occur to it from a musket-ball.

2. If the head of the humerus is broken to pieces, that portion of the bone should be sawn off, but the arm must be saved.

3. If the elbow-joint is shot through, it is to be cut out, and the forearm brought into the bent position.

4. A forearm will bear so much fracturing and cutting, that it should not be amputated without especial reasons.

5. A finger and thumb, or two fingers, are worth saving; but a serious injury to the wrist generally requires amputation.

L.

ST. GEORGE'S HOSPITAL.

CASES OF CHOREA.

To the Editor of the Medical Gazette.

SIR,

HAVING noted the following cases, which were admitted into the physicians' wards of St. George's Hospital, I forward them to your journal for insertion.

I remain, sir,

Your obedient servant,

C. J. B. ALDIS, M.D.

13, Burlington-street,
Feb. 13, 1838.

CASE I.—Sarah Haines, æt. 12, admitted October 27, 1832. Pulse 96, soft; skin natural; tongue yellow, furred; bowels not open to-day.

Chorea Sancti Viti; no pain in the head. Had a slight attack of the same complaint twelve months ago; the present attack came on three weeks back.

℞ Hydrarg. Submur. gr. iv.; Jalapæ Radic. ʒss.; Muc. Acac. q. s. Fiat pil. iij. statim, et tertio quoque mane repetendæ.

Baln. Imbriferum diebus intermediis; with a draught composed of Senna et Mist. Camph. ter die.

27th.—Some giddiness.

Hirudines xij. temporibus.

29th.—Motions dark-coloured.—Perstet.
31st.—Bowels acted three times yesterday after the pills.

Rep. Pil. Hydrarg. et Jalapæ statim.

℞ Ferri Subcarb. ʒss.; Valer. in pulvere, ʒj ter die.

℞ Extract. Coloc. e. ʒss.; Extract. Hyosc. gr. iij. omni nocte. Omit. Haust. Sennæ.

She continued to improve under the same medicines, the doses of which were occasionally varied, according to circumstances, and on Dec. 12 was cured.

CASE II.—Ann Collier, æt. 12, admitted Feb. 22, 1833. Pulse 84, rather small; skin warm; tongue slightly coated; bowels open from medicine; emaciated.

Is affected with irregular motions of the muscles, chiefly of her hands, over which she has a partial control; no headache. Has been affected in this way two months.

℞ Haust. Sennæ; Decoct. Aloes e. aa. ʒvj. mane et meridie quotidie.
Diata ordinaria.

March 1st.—Perstet cum Haustu alterno mane. Balneum Imbrif. tepidum diebus intermediis.

4th.—Much steady; tongue clean; pulse weak and small; skin cool; bowels open four times; motions natural.

℞ Mist. Ferri e. ʒj. ter die. ℞ Pil. Aloes e. ʒss. o. n. Rep. Balneum ut antea.

18th.—℞ Infus. Rosæ e. ʒxj.; Quinæ Sulph., Ferri Sulph. aa. gr. j.; Tinct. Cardam. e. ʒj. ter die. Pil. Aloes ut antea.

22d.—Not quite so steady.

℞ Hydrarg. Submur. gr. v. horâ somni. Haust. Sennæ crâs, postea perstet.

25th.—Not quite so steady; complains of headache.

℞ Calomel, Extract. Coloc. e. aa. gr. iv. hæc nocte. Haust. Sennæ crâs, postea perstet.

April 1st.—Tongue clean; bowels well opened.—Perstet.

10th.—Cured.

CASE III.—Jane Elderfield, æt. 10, admitted July 31, 1833. Five weeks ago she was seized with convulsive actions in her left hand, which were involuntary, every day at five or six o'clock. She cries occasionally, and throws herself about; no headache; bowels open; tongue white, which protrudes to the left side of her mouth when she attempts to speak; much difficulty and hesitation of speech. The convulsive motions affect both hands, legs, face, and neck.

℞ Tinct. Ferri Muriat. ℥x.; Infus. Quassiae, ʒj.; Aq. Piment. ʒij. bis die.

℞ Calomel. gr. ij.; Pulv. Jalapæ, gr. v.; Zingib. gr. j. omni nocte.

R Haust. Sennæ, ʒj. omni mane. Balneum Imbriferum alt. mane.

Aug. 1st.—Bowels well opened by the medicine; spirits low.

Omit. Baln. Imbrif. Broth diet. Perstet.

3d.—Projects the tongue readily.—Perstet.

5th.—Much better.

6th.—Walks better.—Perstet.

7th.—Perstet cum Haustu bis in die.

R Pulv. Jalap. e. gr. x. omni nocte.
Enema Terebinth. omni alt. mane.

9th.—Slept very well; much quieter; puts out her tongue with less effort; very much improved.—Perstet.

R Ferri Carbon. ʒj. ter die. Perstet cum aliis. Pulv. Jalap. c. omni alt. nocte.

10th.—Can move her left arm; very much improved.—Perstet.

16th.—No spasm in sleep at night — Perstet.

19th.—Better; the motion of left arm is very much improved.

Diæta ordinaria.

She recovered by degrees.

CASE IV.—Charlotte Clements, æt. 15, single, Fulham, admitted May 22, 1833. Pulse 115, soft; skin moist and cool; tongue slightly furred; bowels open; urine free; catamenia have not appeared.

Chorea; twitching of all parts, one side not more than the other; no pain in the head or any where else; flatulence. Attacked a week ago, and her complaint is attributed to fright.

R Pil. Aloes e. ʒss. sextis horis.

R Tinct. Valer. Ammon. ʒj.; C. Decoct. Hordei sextis horis intermediis.
Diæta ordinaria.

May 24th.—Has brought up her draught each time she has taken it, and the pills have produced little effect; chorea the same; a large boil on the chin.

R Hydrarg. Submur. gr. v. statim.
Extract. Coloc. c. ʒss. tertiis horis donec exoneretur alvus.

25th.—Enema Oleosum. Perstet.

29th.—Skin cool; tongue nearly clean.

R Mist. Ferri e. ʒj. ter die. Rep. Pil. Coloc. c. ter die.

31st.—Rep. Pil. bis die. Perstet.

June 3d.—Somewhat steadier than she was; glands confined; pulse 52, soft; skin natural; tongue furred.

R Haust. Sennæ statim, et post horas quatuor. Repetatur postea pilula ter die. Adde Haustui Ferri Spir. Æth. Sulph. c. ʒss.

7th.—Much quieter; pulse 60.

Balneum Imbrif. tepidum alt. mane.
Rep. alia.

17th.—The bowels now act freely with only two pills; pulse 70; skin cool; tongue somewhat furred.—P.

She continued the use of purgatives and steel until July 8, when she was reported to be quite steady.

10th.—Cured.

CASE V.—Ann Blade, æt. 16, admitted August 14, 1833. Pulse 80; skin cool and moist; tongue slightly furred, rather dry; bowels open; urine free; catamenia regular.

Chorea; headache; throbbing in the head, relieved by being recumbent. Ailing two months, and has been getting worse up to the present time.

Applic. Hirud. xij. fronti.

R Hydrarg. Submur. gr. v. omni nocte.
H. Sennæ omni mane. Diæta ordinaria.

16th.—Balneum Imbrif. tepidum alt. mane. Haust. Sennæ alt. mane intermedio.

19th.—Bowels well opened; motions feculent, mud like, and very offensive; skin cool; tongue white.

R Hydrarg. Submur. gr. v. alt. noct.
Haust. Sennæ alt. diebus. Balneum ut antehac.

20th.—Not any steadier.

27th.—Motions of the limbs still the same; bowels well opened; pulse 100, small; skin cool.

R Mist. Ferri e. ʒj. ter die. Perstet.

30th.—Not any steadier; bowels opened.

Habeat Baln. Imbrif. frigidum vice tepidi. Perstet.

Sept. 2d.—Convulsive movements considerably less troublesome.

R Extract. Coloc. c., Pil. Galb. c. aa. gr. v. fiant pil. duæ omni nocte sumend. Augentur Mist. Ferri e. ad ʒjss. ter die.

7th.—Much improved; convulsive movements almost ceased; bowels open. Perstet.

16th.—Very little remains of the convulsive muscular movements can be perceived; in other respects quite well.

Discharged in a few days after, cured.

REMARKS.—If we refer to the ages of the persons whose cases have already been detailed, we shall find that the eldest was 16, and the youngest 12 years old. In two other cases, which I have not forwarded to

your journal, I find that the disease commenced in one about 17^s, in the other at 24^h. Dr. Reeve has stated, in the eighth volume of the *Edinburgh Medical and Surgical Journal*, that of 84 patients, only one man was 40, and four females above the age of 21. This is one of the nervous diseases in which modern practice has improved upon the older system of blood-letting, the most powerful remedy we possess against some of them. Sydenham's method of cure consisted in venesection and purgatives. Dr. Hamilton has more recently cured it with purgatives alone; besides which, the authority of many other medical men might be brought forward to prove the frequency of the cure of chorea without the assistance of venesection, clearly showing that it must have been formerly employed in several cases unnecessarily. Occasionally symptoms appear which indicate the necessity of the patients losing blood. I have seen the method adopted in the above cases practised a good many years at St. George's Hospital; and only one case has come under my observation in which it failed, and that was a patient in whom the disease had existed five years. I allude to Mary Preston, mentioned in the first note. The case of Lucy Blaydon, referred to in the second note, was also very obstinate, but it yielded to detraction of blood, blisters, and diuretics of digitalis and cantharides. The other cases treated with purgatives and steel produced a most satisfactory result. Some of my notes mention the utility of the liquor potassæ arsenitis combined with purgatives.

REMARKABLE CASE

OF

INFLAMMATION AND SUPPURATION OF THE PLACENTA.

THERESA RAFFO, of Leghorn, aged 32, of a good constitution, being pregnant for the seventh time, had miscarried in October, in the second month of pregnancy, in consequence of a blow which she had received upon the abdomen. She recovered with facility, and a month afterwards became pregnant again; nor did she complain of any ailment until the end of the sixth month. She was then attacked with pains in the loins, in consequence of over-fatigue and vexation; they became more and more severe, and on the

5th of June they extended to the uterus and thighs. On the seventh day, uterine contractions appeared, and the patient was obliged to keep her bed. M. Landini was now called in. He found her labouring under burning fever, anxiety, great thirst, want of appetite, difficulty of making water, sharp uterine pains, a slight sanguineous discharge from the vagina, headache, and vomiting. The midwife who attended the patient, believing that delivery was near at hand, made her exhaust herself by useless efforts, and gave her three glasses of Spanish wine. The abdomen was very painful when touched, and there were frequent but ineffectual attempts to make water. A consultation took place, and it was agreed that there was inflammation of the uterus. The measures ordered were the immediate introduction of the catheter; a large bleeding from the arm; leeches to the abdomen and the anus; emollient poultices; a purgative of castor oil; and cooling drinks. The bleeding was repeated three times, with a marked amendment of the symptoms; the fever, however, continued, though in a less degree. The patient complained of dull pain in the left side of the uterus, in the loins, and the thighs, which continued until the 19th of June. The patient now suffered from violent contractions of the uterus; moreover turbid and very fetid water flowed from the vagina, and afterwards putrid blood.

This flux lasted till the 23d of June, but it did not appear, from examination *per vaginam*, that delivery was about to take place. The antiphlogistic treatment was still continued.

On the 27th of June the woman seemed extremely exhausted; the abdomen was very painful when touched; there was difficulty in making water; diarrhoea, with very fetid stools; and sores on the sacrum, from the recumbent posture. On examination, the uterus was found to be very high, and its cervix very narrow. A second consultation was held, and M. Landini was of opinion that the disease had been originally an inflammation of the placenta, which had afterwards spread to the uterus, the intestines, and the peritoneum. The continuation of the antiphlogistic treatment was advised.

On the 29th of June the patient was worse; there were uterine contractions, short, but very painful; and frequent desire of making water. In sitting on the pot for this purpose, she voided a soft substance from the vagina; this was the placenta in a state of suppuration.

M. Landini ascertained, by attentive inspection, that it really was the placenta. The suppuration extended over the whole

* Mary Preston, æt. 22, admitted June 29, 1831, with chorea of five years' duration.

† Lucy Blaydon, æt. 25, admitted Jan. 30, 1833, affected one year with chorea.

surface; its form was not lobular; the chorion was perfect, and served as a bag for the whole puriform placenta, which was contained in it; and a portion of the funis was to be seen, half a foot long, which had almost become ligamentous.

On examination, the cervix uteri was found to be lower than on the preceding days, but hard and resisting. The ergot of rye was prescribed with the intention of promoting parturition; the pains became more frequent, but were neither lasting nor expulsive; the contractions were excessively painful, especially on the left side of the uterus, where it was supposed that the placenta had been adherent.

Meanwhile, the patient grew worse; in the evening she was covered with cold sweats all over the body; there was general oppression; ardent thirst; very great anxiety; derangement of the cerebral functions; ringing in the ears; vomiting; a very small and frequent pulse; and fainting fits. The vagina was very hot to the touch, the os uteri soft and dilatable, and the child's foot was to be felt in it. An ethereal draught was prescribed, with warm fomentations to the extremities, and on the abdomen; clysters of mallow water and olive oil, and the same injected into the vagina. It was thought that the patient would sink in the night. Nevertheless, the next morning she was rather better, having slept three hours, and perspired copiously; she made water easily, and had had very fetid stools; felt stronger, and less thirst; the pulse, too, was better.

M. Landini attributed the violent symptoms of the previous day to the four doses of the ergot which had been administered. It is well known that the most prominent effect of this medicine consists in lowering the vital powers, like all contra-stimulant remedies.

The child's hand having passed through the cervix uteri, M. Landini waited till the patient's strength was sufficient to allow him to turn, which he did with ease in the course of the day. The child was putrid. Having again introduced his hand into the uterus, M. Landini found a small portion of placenta strongly adhering to the fundus, which he did not force away. The left side of the interior of the uterus seemed to him covered with fungous growths.

The consequences of the operation were at first alarming; there was hæmorrhage, very intense inflammatory reaction, with anxiety, delirium, a small pulse, cold extremities, and the abdomen painful and tympanitic. The treatment was regulated accordingly, and these symptoms were gradually dissi-

pated. The woman seemed out of danger on the fifth day, when the right leg was attacked with *phlegmasia alba dolens*, which was ascribed to the diseased state of the uterus. The leg was ordered to be fomented with an infusion of digitalis leaves and belladonna, and improvement took place.

The lochial discharge was bloody, and as if putrid; small bits of placenta were distinguished in it, supposed to come from the breaking down of the remaining portion mentioned above. Injections of mallow water into the vagina were ordered, and oily clysters.

The 8th day after the operation the state of the woman was sufficiently satisfactory. After this period, however, she began to complain of giddiness, buzzing in the ears, and fever. Leeches were applied to the nape of the neck with success, and the patient's convalescence was no longer doubtful; indeed, she began to eat with such appetite, that there was some difficulty in checking her voracity. On the 15th of July she complained of dyspnoea and fever; and the left leg was attacked with *phlegmasia alba dolens*. Fomentations of digitalis and belladonna were ordered, and a gentle purgative. Two days afterwards the oppression increased, especially on the left side of the chest, and there was orthopnoea. The diagnosis was, that the disease was acute hydro-pericarditis: pills of digitalis and squill were prescribed, with a grain of extract of aconite in the evening, and milk diet. She now grew better; two blisters were applied to the calves; convalescence again took place, and the patient left her bed. The lochial discharge continued to be fetid and purulent, but less so than before. The patient's health continued to improve.

Some days afterwards, the woman, who was now far advanced in her convalescence, underwent a strong mental emotion by the unexpected return of her husband from Rome. The fever and dyspnoea returned; the legs became swelled and anasarcous; the lochial discharge stopped; there were vomitings, and symptoms of meningitis. She died on the 7th of August.

Post-mortem Examination twenty-four Hours after Death.

1. *The lower extremities.*—These limbs having suffered from *phlegmasia alba dolens*, first engaged the attention of M. Landini. An incision was made on the inside of the right leg, extending from the malleolus to the groin; and the sub-cutaneous cellular tissue was found to be copiously infiltrated with a yellowish serum, which flowed forth at each stroke of the bistoury.

The aponeurosis and subjacent muscles were healthy. The vein and corresponding artery adhered to the surrounding cellular tissue, which was itself thickened, and soaked with water. The external surface of the vein was of a dull red throughout its whole length; the artery was in its natural state.

The left leg afforded exactly the same appearances. In continuing the dissection of these vessels from the foot to the groin, it was seen that the inflammation of the cellular sheath was greater the nearer it was to the crural arch; that is to say, its thickening, its adhesions and the infiltration, were more obvious in proportion as the spot was higher.

2. *The abdomen.*—A vertical incision, which was extended as far as the vulva, and another one in a transverse direction, divided the skin and muscles, without injuring the peritoneum. It was attempted to dissect their layers without touching the serous membrane, but this was found to be impossible, for the peritoneum, which seemed much altered by disease, adhered strongly to the corresponding parietis of the abdomen. The liver was in a state of extreme atrophy, particularly the right lobe, which filled the upper half of the abdominal cavity. The lymphatic vessels meandering over its surface, and filled with a coloured fluid, were easily distinguished upon it. The right lobe was of a deep yellow, and so soft that the pressure of the finger was sufficient to break it down. Its internal tissue was very yellow, and seemed formed by the union of a multitude of small bodies of a shining yellow. On cutting it in different directions not a drop of blood flowed out, its blood-vessels being very contracted and quite empty. The gall bladder was larger than natural, and full of air, but not containing a drop of bile; its parietes were very thin, transparent, and whitish. The hepatic and cystic ducts were small, indurated, and obstructed; the *ductus choledochus communis* was wasted away, and entirely closed at its duodenal extremity. The two other lobes of the liver were not so much disorganized. The whole organ adhered strongly to the diaphragm, which was itself red and thickened. The vena porta and its ramifications had the same structural alterations as the diaphragm.

The spleen was blackish, very small, and contained a minute quantity of very black blood.

The stomach was distended by very fetid gases; its external surface was of a yellowish white colour; its cavity contained a little ptisan. The mucous membrane bore no trace of disease, and its vessels were not even filled with blood. The

mucous membrane of the œsophagus was also healthy.

All the intestines were of a yellowish white colour externally, and they were distended by gases, especially the colon.

The mesentery was healthy, but the peritoneum, reflected over the fundus of the uterus, the bladder, and the mesorectum, was decidedly gangrenous. The interior of the bladder was healthy; the uterus was of the regular shape and size, but its external tissue was denser and redder than in the natural state; the left fallopian tube and ovary were completely decomposed. The inside of the uterus and the vagina bore no marks of structural disease, except that the uterus was lined with a false membrane of a blackish colour, which was easily scraped off with the scalpel, the subjacent membrane of the uterus was slightly thickened, but was otherwise of the natural appearance. At the orifice of the left fallopian tube there was a smooth and shining tumor, like the kernel of a peach, and this tumor was surrounded by a rim, formed by the swelling of the uterine membrane. When cut into vertically, the uterus showed numerous openings of vessels, which poured forth blood.

3. *The Thorax.*—The pleura was thickened, and adhered to the ribs. The lower lobe of the right lung was very small, and manifestly gangrenous; the upper and middle lobes were hepatized. The mediastinum was disorganized like the pleura. The left lung was diminished in size, and full of blood; its lower lobe was gangrenous.

The pericardium, which was yellow and much thickened, contained a glassful of yellowish serum. The heart, which was very small, was softened, flaccid, and brownish; the right auricle was inflamed, large, and lined with a great quantity of plastic lymph.

4. *The Blood-vessels.*—All the principal vessels of the limbs and internal cavities were examined. In the legs and thighs the veins were very red internally, decidedly inflamed, and lined with plastic lymph, like the right ventricle. The internal iliac veins, and the ascending vena cava in a still more marked degree, bore the clearest traces of intense inflammation; they, too, were lined with lymph. The aorta, the arteries of the abdomen, and those of the thighs and legs, were healthy.

5. *The Head.*—The dura mater was thickened, and very red; its vessels were filled with blood. The cerebellum was covered with numerous vessels full of blood, but was of the natural size. The pia mater was red, dense, thickened, and

vascular, and it adhered to the brain. The ventricles contained much yellow serum, and the plexus choroides was very vascular. The arachnoid was much inflamed and thickened, and was separated from the pia mater by sanguineous serum. The grey substance of the brain, the corpus callosum, and still more the cerebellum, the pons varolii, and the medulla oblongata, were of a reddish yellow colour, and steeped in red serum. All these parts were considerably softened; and the substance of the brain stuck to the fingers, like so much pulraceous matter.

The medulla oblongata [the spinal marrow?] could not be examined, as night was coming on. — *Gazette des Hôpitaux*, Feb. 13, 1838.

CASE OF LEAD COLIC FROM SWALLOWING SMALL SHOT.

A MAN, named Pezonzino, aged 45, a husbandman, at Celavegna, in the Sardinian States, having used too much cinchona in the intermittent fevers with which he was attacked almost every year towards the autumn, was seized with a violent gastro enteritis. He got well, but such an irritability of the alimentary canal remained behind, that the slightest cause brought on colic and diarrhoea. In 1828 he was attacked with a severe pneumonia, and after it was cured, he changed his occupation, and became a pedlar. In this new course of life he took to drinking, and thus revived the gastro-intestinal affection, which from this period grew worse, under the influence of the smallest atmospheric change. After a variety of treatment, the patient not being cured as soon as he wished, applied to a professed wizard, who promised to cure him, and made him swallow six ounces of shot*.

The patient immediately felt an uncomfortable weight in his stomach, accompanied by cructations, with a disagreeable metallic taste. These were soon followed by dreadful colic, which did not leave him till the sixth day, in consequence of the evacuation by stool of the lead which he had swallowed. As he was relieved by this salutary evacuation, and attributed it to the effect of the remedy,

he suffered himself to be persuaded to swallow some more the next day. But this time he was immediately attacked anew with the most violent pains of the bowels, with vomiting, and painful sensibility of the abdomen. His state became alarming, and he was obliged again to call in Dr. Ruva.

He was now labouring under violent headache, with profound drowsiness; his tongue was foul, with a bitter taste in his mouth; the skin burning; the pulse full, but not frequent; the expression of the face extremely altered. Every now and then there came on genuine paroxysms, accompanied by violent cramps in the legs, and retraction of the testes towards the inguinal ring. There had been obstinate constipation for six days; the urine was voided but seldom, and in small quantity. The patient vomited all that he swallowed.

The first indication that Dr. Ruva endeavoured to fulfil, was to relieve the bowels from the lead which they still contained, by means of purgative clysters. After two bleedings, twelve leeches were applied to the anus, and, at a later period, to the epigastrium; fomentations and poultices were applied to the abdomen. Under this treatment the pains diminished, the stomach was able to retain some spoonfuls of cherry laurel water, and soon afterwards a draught containing castor-oil. At last a stool was procured, containing porraceous and fetid matter, from which about three ounces of shot were collected. From this moment the state of the patient changed; intolerable pain was followed by refreshing tranquillity, and he was able to enjoy repose. Every symptom now grew better, and disappeared; the hiccup, which previously was excited by the smallest quantity of drink, yielded to the employment of magnesia, and of sulphuric acid diluted with a large quantity of water. The fever, too, went off, and with it the sharpness of the abdominal pains. Some wandering pains, however, with a sensation of weight, were still felt, sometimes in the region of the cæcum, sometimes in that of the descending colon. Moreover, the return of the cramps, and of some of the preceding symptoms, gave reason to believe that the whole of the lead swallowed had not been expelled; the use, therefore, of the castor oil, and of the magnesia, was continued.

Forty-six days had now elapsed since Pezonzino had swallowed the first dose of shot, and he thought himself quite cured, when a slight excess in eating brought back all his symptoms with such violence that it was necessary to have recourse again to bleeding and the other remedies

* This remedy is of long standing in the treatment of volvulus. Van Helmont, in particular, made the practice general, by laying down this dangerous aphorism:—"Neminem illo perire si globuli plumbei scolopetarii deglutiantur, ut sub pondere propellant impedimentum in intestinis hærens."—(*De Flatibus*, § 31.) But Sydenham, with more reason, disapproved of it, as dangerous:—"Hæc parum conducere, et noxam sæpe haud contemnendam inferre."—(*Op. Med. Sect. 1. cap. xiv.*)

above mentioned. This relapse produced an alvine evacuation, from which two more ounces of shot were collected, making ten altogether. His convalescence was very laborious, and lasted two months; but it was followed by complete recovery. Pezonzino has now been cured eight months, and has ever since enjoyed perfect health.—*Annali Universali*.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Feb. 28, 1838.

THE PRESIDENT IN THE CHAIR.

A PAPER was read, from Mr. Hadwen, house-surgeon of the Lincoln Hospital (communicated by Mr. Quain) detailing the particulars of

A Case of Popliteal Aneurism,

for the relief of which Mr. Hewson, the surgeon of the hospital, tied the superficial femoral artery on the 18th of July last. Hæmorrhage having taken place from the wound to a large amount, on the 13th day, the common trunk of the femoral artery was tied immediately below Poupart's ligament. Notwithstanding the second operation, however, hæmorrhage recurred two days afterwards, from the situation of the first ligature, which rendered amputation necessary on the fifteenth day after the first operation. From this time the case proceeded satisfactorily, until the eighteenth day after the operation, when blood began to issue from the wound in the groin. The hæmorrhage becoming more alarming during the night and on the following morning, Mr. Hewson determined on tying the external iliac artery, as the only means of saving the patient's life. The operation was accordingly accomplished by Sir Astley Cooper's method, and the patient afterwards recovered with scarcely a bad symptom. The relation of the case is followed by some observations on its principal points of interest.

The author takes occasion to observe, that the common femoral artery, from the uncertainty of the points of origin of the profunda, epigastric, and circumflexa ilii, as well as from the probability of the internal circumflex arising from it instead of from the profunda, is singularly ineligible for an operation of this description. In confirmation of this opinion, he cites six recorded cases in which this artery has been tied; two of which were followed by fatal hæmorrhage, which would probably have also occurred in the

other form, had not the external iliac been tied. The author contrasts this mortality with the success which has attended the ligature of the external iliac artery, which, we believe, is universally admitted by surgeons of experience. Mr. Holmes relates twenty-two cases in which this artery has been tied, in none of which was the operation succeeded by secondary hæmorrhage. Indeed, it is the opinion of that distinguished authority that the external iliac may be tied with as much security as any artery to which a ligature has been applied. From these premises, the author deduces the conclusion, that the operation of tying the common femoral artery should be entirely exploded.

A paper was afterwards read—

On Division of Stricture of the Rectum high up in the gut. By R. A. STAFFORD, Esq., Surgeon to the St. Marylebone Infirmary.

The author describes two cases in which he has performed this operation—the first in 1831, the latter in the last year. In the former case the stricture existed at about two inches and a half from the anus, and was of nine years' standing when the patient was admitted into the St. Marylebone Infirmary. The contracted part was indurated, and would only admit a No. 12 urethra bougie. The author divided the contraction towards the sacrum with an instrument which was shown to the Society, and was enabled to pass the middle finger through the stricture immediately afterwards. The operation caused very little pain, and only a few drops of blood were lost. The case went on favourably for more than three weeks, after which the patient was seized with erysipelas of the face, of which she died in a few days. Dissection proved to the author that disease of long standing which had existed in the whole course of the intestinal canal had been in a great measure relieved by the operation, and he expresses a conviction that had it not been for the occurrence of the erysipelas, the patient would have been entirely cured.

In the other case, the author divided two strictures by the same instrument—the first so contracted as only to admit a bougie of the size of No. 10. Slight hæmorrhage followed the division of the second obstruction, and in two hours afterwards the bowels began to discharge fæces of a very offensive character, which continued to come away in large quantity for two or three days. In this case diarrhoea continued for some time, but the patient was ultimately discharged perfectly well, the passage of the rectum being completely open.

PHYSICAL SOCIETY, GUY'S HOSPITAL,

Saturday, Feb. 24, 1838.

DR. GUY IN THE CHAIR.

MR. BIRKETT read some

Cases of Syphilis, with Remarks.

The cases were of superficial sores, in one instance followed by secondary symptoms. Mr. B. alluded to the few cases of Hunterian chancre met with in the present day, and was inclined to attribute this to the immediate use of mercury, which the lower classes now adopted on the first appearance of pimples or excoriations on the genital organs. The primary sores he believed to be indications of absorption of the poison into the system; he could not imagine that the peculiar suppurating surface was produced as a local effect by the irritating nature of the poison. The author gave it as his opinion that there was but one kind of syphilitic virus, and that the varieties of sore observed were the results of differences of constitution and habits among patients. When speaking of treatment, Mr. Birkett recommended practitioners to wait a day or two before they exhibited mercury, as he thought by that time a correct judgment might be formed as to whether or not that remedy was needful for the cure. The discussion which followed the paper was quite of a practical nature.

At the next meeting of the Society, Mr. Chapman in the chair, Mr. Brereton will read some observations *On Cerebral Physiology derived from Cerebral Pathology.*

MEDICO-BOTANICAL SOCIETY OF LONDON.

Feb. 28, 1838.

EARL STANHOPE, PRESIDENT, IN THE CHAIR.

A PAPER was read, by Edwin Saunders, Esq. one of the secretaries,

On the Employment of Creosote as an Odonalgic Remedy.

After giving a brief account of the drug, its discovery, qualities, and the various diseases in which it has been found useful, the author proceeded to distinguish tooth-ache into two or three distinct species, each requiring different treatment. In only one of these is the creosote useful, —viz. that which arises from sudden exposure of the internal membrane, or

nerve, which may be termed the acute form of tooth-ache. The rheumatic form of tooth-ache, in which pain is experienced over the whole side of the face, in neighbouring teeth, the ear, temples, &c. is not susceptible of relief from it; at least, in its undiluted state. The cotton, or wool, which serves as the vehicle for its introduction, should be small, and care should be taken to prevent any portion of the drug from falling upon the gums and lips. The oil of burnt paper, an old and popular remedy for tooth-ache, was supposed by the author to owe its virtue to the creosote which it contains.

INSURANCE OFFICES.

To the Editor of the Medical Gazette.

SIR,

As the subject of remuneration to medical practitioners by Insurance Offices is now becoming very generally commented upon, there is no occasion for apology in offering the following remarks.

What has been the result of the "resolution" adopted by the medical practitioners at Leeds I have not been able to

ascertain. If such a resolution was to become general, the Insurance Offices must eventually succumb. Unfortunately the profession is composed of too discordant materials to anticipate such a conclusion; however, "*stillicidii casus lapidem cavat*," so may such a commencement as the Leeds resolution.

In my opinion the offices ought to remunerate the medical practitioners, not only because "they require" the information, but they can well afford to do it; for, maugre their sentimentality about a man providing for his family, &c., the advantage to those connected with these offices is as valuable (if not more so) as to the insurer himself. If the profits were not very considerable, would so many of these offices be starting every day, and so few which do not succeed? and every one acquainted with their proceedings is fully aware of their immense returns. At the present time there are offices whose "subscribed capital" is only a few thousands, one I am acquainted with is under 20,000*l.* and have a floating capital of hundreds of thousands. Now I would simply ask, what diminution in the profits of the shareholders or assured would arise from this act of justice to medical practitioners? The Directors know very well it would be a mere trifle; still they have the "assurance" to demand a favour which they are certain medical practitioners cannot generally refuse.

As for the patient paying his medical attendant, it is unreasonable; a patient naturally says, I do not wish to trouble you for a certificate, the medical officer at the office examines me, and they have likewise the testimony of two friends as to my habits, &c.; and as they require, after all this, the certificate of my medical attendant, they are the parties who are bound to remunerate him.

The offices are, I understand, expressing surprise that there should be so much feeling displayed upon the subject by the profession, as they state the amount would be so inconsiderable to any individual practitioner in the course of a year; but the Directors of these offices should bear in mind, it is not the amount, but the 'principle involved' that the profession 'is contending for.' Would the Directors think of sending a parcel of questions to a solicitor (and the solicitor's client relatively quite as much interested as the practitioner's patient) (without intending to remunerate him)? No. They go further than this; they actually pay the solicitor a per centage for merely recommending parties to their offices.

Finally, I am convinced medical men

would be more highly esteemed and better spoken of, if they were more chary of doing so much gratuitously; for what is the necessary result of being so liberal? Why, that the public consider it no favour to require what they would otherwise be ashamed to ask. Let us hope that those who are solely dependent upon their profession, and those who from their station and practice can support their medical brethren, adopt the "Leeds resolution." As for any general resolution of the profession in London, it is, I am afraid, hopeless. much may be effected by those who have the respectability and well-doing of the profession at heart; for the rest, we must trust to time and more liberal feelings on the part of the public towards (in reality) a too liberal profession.

I am, sir,

Your obedient servant,

MEDICALS.

TRIBUTE TO MR.

To the Editor of the Medical Gazette.

SIR,

In reply to the letter of Mr. Middlemore, in your number for Feb. 24, I am directed to state that the committee for managing the fund subscribed to raise a tribute to the late Mr. Earle, have resolved to extend the period for receiving subscriptions to the end of the present month.

I am, sir,

Your obedient servant,

HENRY SMITH,
Hon. Sec.

St. Bartholomew's Hospital,
March 1, 1838

OSSIFICATION OF THE CRYSTALLINE LENS.

PROFESSOR GRILLO, of Naples, has communicated a curious case, that of a sailor who had suffered from gout for twenty-five years, and who from it was affected with an obstinate gouty inflammation of the eyes, opacity of the cornea, general atrophy of the eye, and perfect blindness, and both eyes were by degrees converted into white balls. This man died of apoplexy. The remarkable part of this case is, that it was not alone the external surface of the crystalline body which was ossified, but the whole substance was perfectly converted into solid bone.—*Observatore Medico di Napoli*; and *Dublin Journal*.

COLLEGE OF SURGEONS.

PROPOSED CHANGES IN THE
ROYAL COLLEGE OF SURGEONS IN IRELAND.

To the Editor of the Medical Gazette.

SIR,

I HAVE delayed a second communication, expecting that a reply would have been made to my former one, in which the offensive imputation complained of would have been either justified or retracted by its author. He, however, has not condescended; and I am left at liberty to conclude, that he had advanced a charge which he was either unable or unwilling to maintain. A letter *has* appeared from "A Member of the Royal College of Surgeons in Ireland," professed to be "a comment," rather than "reply," to mine, and, however strange it may seem that one of the party, who have assailed us, should endeavour to escape under shelter of a comment, I am yet willing to take it for what it professes to be, and, before I proceed further in the case, to offer a comment in return.

The *animus* of the writer is sufficiently manifest from his use of the epithet, "*the soi-disant professor*," &c. But I regard not such provocations as these: they are beneath my notice. However, as I consider myself engaged in a contest rather of general than individual concern, I dismiss them with the wise though homely admonition, "that those who live in houses made of glass, ought not to throw stones." "Member of the College of Surgeons," as he subscribes himself!—why not, manfully, Professor in the School of the Collège?—he has, doubtless, no desire to humble the pride of its professors; and I repeat, that the school of the Collège was established without any authority of charter, and neither in its present nor its former one is there provision for the foundation of a single professorship. Therefore, the teachers of the two schools hold precisely

the same position, and may hail each other as *soi-disant professors* all, if it so please the Member. Meantime, if he will take the trouble to consult Johnson, he will find that it requires neither charter nor act of parliament to make a professor. The second paragraph of the Member's letter sets forth, that the great bulk of my letter "being purely of a personal nature, does not, in his opinion, demand either notice or reply." This, I must admit, is very proper and dignified, and becomes amazingly a gentleman who, in the very next sentence, casts a personal and individual aspersion upon myself. The express object of my letter was to prove that the charge against which I protested was a calumny, and an unfounded one. It was of a personal nature doubtless. What else could it be? Of what kind was the wanton assault? Personal, purely personal; and must not the defence be the same? But it shall not pass. He that attacks and chooses his weapons is not at liberty to decline. He is bound either to submit or see it out, and the announcement, coming as it does from the reserve champion of the party—for be it observed, that it is no longer the original calumniator, "the Graduate of three Colleges," who writes—amounts to an acknowledgment that he was unable to grapple with that which he affects to disregard. He is too magnanimous, indeed, or else too well assured, to "hairsplit the letters of an official oath," in order to prove another a renegade! Yes, yes—but though he will not hairsplit, he seems not to consider it beneath him to gloss and to pervert. It is enough for him to know, that I have "thought proper to unite myself in intimate relation with the bitter and avowed enemies" of the Collège! Alas! this is but a sorry shift. Were it true, I should agree with him.

But it is *not—emphatically* not. I have not united myself with the bitter and avowed enemies of the College; but the party, of which the Member is the champion, have thought proper to make enemies to themselves of the Members of the Corporation, which *had* elected me and my colleagues their professors. And am I to be responsible for their misconduct? or to be the victim of their cunning? Assuredly not. Nor shall any power make me so. The enmity of which they complain has been raised by the men themselves; and as they have raised, so let them allay it. They commenced their hostilities at the beginning of the present session with the lecture to which I adverted in my last,—a lecture introductory to a course of Anatomy, delivered by a professor and *president!* of the College, the object and end of which were, as I stated, the malpractices of Apothecaries, and the consequent necessity that the Members of the College should make Apothecaries of themselves! What could have been the design of this proceeding, if not to create enmity between the two bodies? What other effect could it have but to commit the College and the Hall, and to render it, and every man connected with it, hostile to the College? I cannot say that such was its design, but had it been, the means for its accomplishment could not have been better devised. And now let the party who allowed themselves to be betrayed into so rash and unseemly a step retrace it as they best can, for it was altogether their own doing. If not, let them pay the penalty, and pay it they will.

But I must hasten, else my friend the Member will have fallen asleep. I see him nodding already. The next paragraph of his letter furnishes matter for much and grave comment. He must therefore extend his indulgence, and shake off the anodyne (!) effects of the preceding remarks. In my former letter I stated that the apothecary is compelled, as well by the wants of society, as by the position in which he is placed by others, rather than by himself, to act as a general practitioner. From this the Member dissents, and he requests that he may be permitted to state the case as it *really* is. Can you, sir, after this, have any doubt that my statement is incorrect, if not false, and that that with which he has favoured you is the true one. I really feel it necessary, be-

fore I proceed, to bespeak the patient and impartial attention of your readers, for it can hardly be suspected that any man would so commit himself as to contradict another, and even to cast a polite imputation of duplicity or falsehood upon his statement, without being assured that he was himself in the right, or that he would expose himself to be convicted of absolute and inexcusable ignorance—for I cannot suppose that he knew better—of a subject upon which he has undertaken to guide public opinion. He asserts that “the medical profession in Ireland has been hitherto entirely composed of physicians and surgeons who are in the habit of practising only as prescribers or consultants: no class equivalent to the general practitioner or apothecary of England having ever been sanctioned by law or custom in this country.” This statement contains two errors so monstrous, that it is impossible any man who knew better could have ventured to assert them. 1. It is an error that the medical profession in Ireland has been hitherto *entirely* composed of physicians and surgeons, the profession containing, even according to the writer’s own shewing, since 1791 at latest, a third estate; viz. the Apothecaries. 2. It is an error, that “no class *equivalent* to the general practitioner or apothecary of England has ever been sanctioned by *law* or *custom* in this country.” 1. Every graduate in medicine, or licentiate in surgery, who has taken the license of the Apothecaries’ Hall, Dublin, is *by law* entitled to practise both as apothecary and physician or surgeon throughout Ireland, except in Dublin, or within a few miles thereof. 2. It is notorious that Ireland abounds with men who practise in the double capacity—that in the north the practitioners are chiefly of that class, and that in Dublin and the south they are numerous also. How they must have stared at the Member’s assertion! And further, that apothecaries do, and have long acted in that capacity—according to the licentiates of the Dublin College of Surgeons resident in Sligo, “from time immemorial.” In the next statement to which I shall refer, the Member asserts himself one half of my statement, for he admits that the medical profession itself had consigned to the apothecary the offices of applying leeches, &c. Next he asserts, that the

apothecaries "have boldly set themselves forward, not merely as general practitioners, but as *the sole licensers and instructors of that class of the profession.*" What his authority may be for the latter part of this assertion I cannot even imagine. Every member of the College of Surgeons, at all conversant with the matter, must know that the Hall were willing to receive, and did receive, the certificates of the Professors of the College School so long as they were allowed to do so; *i. e.* until the College were induced to reject theirs; that the Hall do receive the certificates of the Professors of the School of Physic, and of others; and that the body of the apothecaries are desirous that the general practitioner shall be licensed by a Board, in which each of the three Medical Corporations shall be represented. I cannot permit myself to comment at length upon the assertions which I have adduced. Wilful misrepresentation I do not impute to the gentleman; ignorance of such familiar circumstances I cannot, without his own authority, admit; but the man must be silly indeed, who could persuade himself that such errors would be permitted to pass without exposure. I have left only the alternative, *aut insuit homo, aut versus facit*; and those who have perused his succeeding paragraph will, I suspect, entertain little doubt upon this point. What does it say?—Hear, College of Surgeons in London!—Hear, College of Surgeons in Ireland!—Hear, ye sister and hitherto rival institutions, now such no longer! "The apothecaries of England are the brethren of the Irish surgeons," and of course the Apo-

thecaries' Society at London is the sister institution to the Royal College of Surgeons in Ireland! This speaks for itself, and needs no commentary. But will the College of Surgeons in Ireland permit the statement to pass without notice and without contradiction? If it be true, it is time to admit that all her past claims have been but pretensions; that she has robbed alike the public and the profession; and that she has been as dishonest as pretending; for the Society of Apothecaries neither profess surgery, nor even require attendance upon a surgical lecture. It cannot be. The institution which could be so degenerate as to sanction such a disavowal of duty and station has fulfilled its destinies, and is unworthy to continue. Its sun has gone down, and the hour of its dissolution has arrived. But let us hope for better things. The profession can now, indeed, decide whether in what the party, of which the Member is the spokesman, are doing, they are desirous or not to degrade the College and its members from the station they have hitherto held.

I beg to conclude with an apology to the Member for the length of this epistle; at the same time reminding him of his pledge to expose the "calumnies" of my letter. Or shall we have the third of the Curiatii?

I have the honor to remain,

Your very obedient servant,

A PROFESSOR IN THE SCHOOL OF
THE APOTHECARIES' HALL.

Dublin, Feb. 10, 1838*.

LECTURES ON TUMORS,

Delivered at St. George's Hospital,

By CÆSAR HAWKINS, ESQ.

LECTURE IV.

III. SARCOMATOUS TUMORS (*continued.*)

1. Conglomerate or Pancreatic Tumors.
5. Conglobate Tumors.
 - a. Simple Conglobate Tumors.
Tumors in the Parotid Gland.
 - b. Tubercular Conglobate Tumors.
6. Scrofulous Tumors.
7. Cystic Tumors.
8. Tubercous Cystic Tumor.

Circumstances in which Cysts are met with in Tumors.

Theories with regard to Cysts in Tumors.

III. SARCOMATOUS TUMORS (*continued.*)

III. 4. THE next genus of sarcomatous tumors we will call the *conglomerate tumors*; by which term I mean to designate the kind of tumor which Mr. Abernethy has termed *pancreatic*, i. e. a new substance, consisting of numerous small portions, each resembling the rest, and the whole bearing some similarity of appearance to that of the pancreas or salivary glands. Some tumors, however, of apparently the same kind, consist of much more minute elementary particles, more like the acini of the liver in size, than the separate portions of the salivary glands; and I therefore prefer the name *conglomerate*, implying, as with the conglomerate glands of all kinds, that the tumor is composed of a great number of similar elementary portions firmly joined together, so as to compose one mass.

This tumor possesses a firm texture, it is of a whitish colour, and it has little vascularity; it has a general coat or covering

of cellular membrane, from which it may be dissected, or pulled out, so as to shew as in this preparation, the separate portions of which it is composed; and on making a section of the tumor, it has a granulated appearance, which is here very distinct, from the number of packets which are cut across; and in some, which are softer than others, you can squeeze out the granular bodies from their cellular beds. They sometimes attain a considerable size, as in this case, where the tumor is six inches in diameter; but in other cases the growth of several years may not be larger than a marble.

When the tumor is tolerably large, it feels irregular, and lobulated, and hard; it is separate from the part in which it is embedded, but the cellular connexion is sometimes so strong, that you cannot trace its boundaries very accurately. When thus firmly bound down, it feels almost of a scirrhus hardness; but its more irregular surface is very different from that of a cancerous tumor. There is also no attachment to the skin, unless it be of very large size, and it is moveable upon the deeper parts; and it generally gives little pain or inconvenience, though this circumstance is not always the case; so that it sometimes requires a good deal of care to distinguish it from a cancerous tumor in its early stage. If the tumor is composed of smaller elements, it is smoother than usual on the surface, so as to make it in some situations impossible to be distinguished without dissection from the next, or conglobate tumor. It is a disease of middle age chiefly, not appearing to attack children or young persons, and seldom coming for the first time at an advanced age.

Mr. Abernethy supposes that this tumor originates in an absorbent gland; but it hardly seems to do so, and certainly is, in general, in parts where no absorbent gland is known to exist. Mr. Lawrence conjectures, with apparently more probability,

that the conglomerate or pancreatic tumor is a new structure, deriving its peculiar appearance from its being like the structure in which it is situated, just as a bone will give an osseous texture to a tumor upon or near it. If this conjecture be well founded, the conglomerate tumor would be nearly confined to the breast, in which it is most frequently met with; to the parotid and submaxillary glands, in which it occurs next in order of frequency; and to the orbit near the lachrymal gland, where it is occasionally, though not often observed. I am not certain, however, that the tumor is really confined to these situations; for instance, here are some tumors apparently of this nature, said to have been situated near the thyroid gland; but I do not know their exact history, nor whether they were high enough to be near the submaxillary gland, as well as the thyroid, to which latter structure they have no similarity.

Sir A. Cooper has called this kind of tumor, when situated in the breast, the chronic mammary tumor; but the term mammary tumor, you will recollect, as it is employed by Abernethy and other persons, means a form of growth like udder, rather than what we are now considering, and which occurs in any part of the body, and is, in fact, a kind of cancerous structure. Dr. Carswell also, in his admirable plates of morbid structures, places the mammary tumor of Sir A. Cooper, *i. e.* the conglomerate tumor now before us, among the forms of cancerous tumors, as if it were exactly the same as the udder-like tumor. I am myself, however, strongly inclined to believe, that the true conglomerate tumor is not in any respect malignant; I never heard of its returning in the breast, though it is very frequently removed from that situation, and not seldom from the neck also, with perfect success.

You will find in practice that the growth of this tumor, and the pain or inconvenience it occasions, are materially dependent on the general health, and consequently that you can relieve it, and check the rapidity of its increase, by alterative treatment. When painful, a few leeches may now and then be employed, with cold or tepid evaporating lotions; at other times a warm plaster over the tumor is of service; but the subject will be mentioned to you again with the diseases of the breast. When large, or when inconvenient and harassing to the patient, it may be removed with perfect safety, and without fear of a return; and the best method of operating, though somewhat more difficult, is to cut into the cyst which surrounds it, and tear and dissect it out of its bed, this plan occasioning less hæmorrhage, and affording consequently

more chance of union, than if dissection is made round the tumor. In the operations for the removal of these tumors from the neck, more difficulty is experienced, and more caution necessary, from the irregular processes which sometimes dip down among the important vessels of this region. Mr. Lawrence has published the particulars of one case, in which the tumor passed behind the pharynx, and between the external and internal carotid arteries, both of which were laid bare, while the portio dura was also divided, so as to cause permanent paralysis; and I mention this case to you as a great encouragement in even extensive tumors, since that gentleman saw the patient five years after the operation, at which time there had been no return of the disease, although the tumor had been of the extent described.

III. 5. *Conglobate tumor*.—As the last genus of sarcomatous tumors is connected with, or similar to, the conglomerate glands, so is the next either situated in, or it resembles, the conglobate or absorbent glands; and I will divide the genus of *conglobate tumors* into two species.

a. Simple conglobate tumor.—This tumor is chiefly found in middle life from the age of 35 to 50, at which time one or two bodies are found, round or oval in shape, firm, hard, or slightly elastic, in the situation of some of the absorbent glands. Not unfrequently it is the sequel of the common serofulous enlargement of early life, in which case, out of a number of glands somewhat larger than natural, but which have remained perfectly quiet for years, one or two will suddenly increase and become painful, still being smooth on the surface, but feeling harder and less yielding than they had before been. When cut the tumor shews a firm uniform structure, something like scirrhus in appearance, but still looking slightly glandular. This one was situated behind the mastoid muscle, and I assisted Mr. Keate in removing it from a lady nearly 40 years of age, in whom it had thus suddenly begun to increase; it shews the structure very well. In this preparation is a larger mass, by the side of the larynx and œsophagus, which had obstructed the circulation, so as to induce apoplectic symptoms. After a time, the tumor, having perhaps increased to the size of a cricket-ball, becomes attached to the skin; it ulcerates, and an unhealthy bleeding surface is exposed, which is hollowed out by sloughing and ulceration, while the edges are thickened, everted, and fungous. The health now suffers considerably from the irritation of the tumor; the patient becomes weak and emaciated, and dies with hectic fever, worn out by the pain and irritation and

bleeding of the tumor; or perhaps a temporary respite is afforded by the greater part of the diseased mass sloughing away, after which the health is restored for a few months, till the part which is left again increases.

I have said that the tumor looks like scirrhus, and its termination locally is like that of a malignant and cancerous sore; yet I am inclined to think that it is not ordinary cancer, not malignant in its effects upon the *system*, but only *locally* malignant in its influence upon the neighbouring structures. Certainly, at least, the patient has not commonly any scirrhus or malignant disease in other parts of the body, and certainly the tumor may very often be removed without any return of the disease, and that, too, even after ulceration has commenced; and it ought undoubtedly to be removed by operation as soon as its nature is ascertained, whether, on the one hand, I am correct in placing it thus by itself as a separate disease, or whether, on the other, it is only scirrhus modified by its originating primarily in an absorbent gland.

The situation in which the conglobate tumor is most frequently met with is in the submaxillary and parotid glands; and in the latter place it is bound down by fascia, so as generally to ulcerate early. Now you will find in surgical writers numerous descriptions of diseases of the parotid gland, for which that gland has been removed by operation. But the real fact is, that the salivary glands are very seldom altered in structure, so as to require removal; and the greater number of the tumors here met with are not enlargements of the parotid glands, but of the absorbent glands attached to them. In general the tumor is therefore on the surface of the parotid, or slightly covered by it; but after a time the pressure of the tumor may cause the absorption of the salivary gland, and the new structure will thus occupy its place. In many of the reports of cases in which the parotid gland is supposed to have been removed, there is no mention of paralysis of the face, nor of great hæmorrhage, nor of deep and intricate dissection, which almost always present themselves when the parotid itself is intimately connected with the diseased mass; and in many I have no doubt the operators have deceived themselves, and have removed a tumor, which has pushed aside the parotid, when they imagined they were dissecting out the salivary gland also.

Certainly no one should attempt to remove the parotid, or a tumor which has produced absorption of that gland, who is not conscious that he possesses considerable anatomical skill, and the boldness

which is derived from such knowledge, for it is undoubtedly a formidable operation. I have seen very good surgeons obliged to desist in the middle of the operation, from the impossibility of dissecting out the whole of the tumor, from its passing below the jaw, or behind the pharynx, with an intimate connexion with the important arteries, and vein, and nerves of the upper part of the neck. In other cases, on the contrary, the removal of a tumor from this part is an easy operation, and you have nothing to do but to dissect out the tumor from its bed in the parotid gland, without inflicting any injury upon the portio dura or the carotid arteries. Let me caution you, however, not to be deceived by the apparent mobility of this tumor, into a belief that it is superficial, when it is really very deeply situated; for it has occasionally a sort of hour-glass shape, and you can move one-half of it freely, while the rest dips down among the important parts below.

There would seem, however, to be several kinds of tumors in the situation of the parotid gland, besides that which we have just been considering. Sometimes there is a serous encephaloid tumor, sometimes an osteo-sarcomatous or an osteo-sarcomatous tumor; and, of the solid structures, you may find a fibrous tumor, or a conglomerate tumor, or a conglobate, or a serofibrous tumor. Now all of these may usually be removed from the parotid safely and with facility early in their growth; they may also be dissected out at a later period, but with more difficulty, from the processes arising irregularly from the chief part of the new growth, or from their connexion with blood-vessels and nerves; but still safely, if the whole of the disease is removed. Here, for instance, are some large tumors, which were not followed by any return of the disease after the operation. But with regard to the conglobate tumors, if the least portion of the disease be left, a new tumor is likely to appear in the seat of the operation, and the patient will die of ulceration and hæmorrhage; such was the sequel of the cases from which these two tumors were removed, although they were much smaller than the others which I before showed you. I have seen several, however, in which, on a narrow examination, it was evident that a little piece was cut off in the operation. Still, even in these cases in which the disease returns, I believe the malignant action is confined to the part; that it is local, and affects the textures in contact with the tumor, but does not contaminate the glands, nor the whole system.

But, finally, there are other tumors in the parotid gland, which are really malign-

nant in a higher sense; which are of the nature of cancer, or of fungus hæmatodes, melanosis or medullary structure, and in which consequently the disease will in all probability return, as usual, in the glands of the neck, or in other parts of the body, or in the internal viscera.

b. Tubercular Conglobate Tumor.

The second form of conglobate tumor is in some respects like the former, but is yet distinct from it in other particulars. I suppose it is to this disease that Mr. Abernethy gave the name of tubercular sarcoma, and as I wish as far as possible to speak to you in the same language as other persons, I will adopt in this arrangement the term *tubercular conglobate tumor*.

The chief difference in the appearance of this disease from the simple conglobate tumor, is, that it begins not as a single mass, but consists of a great number of round bodies, like swelled absorbent glands, more or less joined together; in fact, they much resemble common scrofulous enlarged glands at first. Here is a cast which I had taken from a boy under my care in the hospital, but from an accidental delay it only appears of half the size it had been a short time before. These numerous round bodies vary in size from a pea to a walnut or hen's egg, and are connected together by loose cellular texture, which inflames from time to time, with a temporary increase in the bulk of the separate round bodies, which then form one uniform mass of an irregular and *tuberculated* figure; but on the subsidence of the disease, the globular bodies can again be moved upon one another. These tubercles are of a white or light brown colour, as you may see in these preparations, and possess a firm, hard, and uniform texture, not in the least scrofulous in appearance, nor so soft and white as cerebriform tumors. When hardened into one mass, and increasing much, the skin over the tumor ulcerates, and a painful intractable sore, with fungous edges, is formed, with occasional hæmorrhage, and the patient dies of irritation, with the aspect of a person labouring under malignant disease. I have seen great irritation and emaciation before the ulcerative stage commences, and when situated in the lower part of the neck and mediastinum, irritation of the lungs is produced; or when around the trachea and œsophagus, ulceration may proceed into those tubes with the usual symptoms of such a connexion, as seems to have been the case in the patient from whom this large mass was taken; and in the abdomen, ascites will result from a similar formation.

The disease may, in fact, occur in any part, though the neck is its most common

situation; as in the glands of the axilla or groin, or along the aorta, in the chest or abdomen. But further, during the progress of the complaint little round bodies may make their appearance under the skin in various situations, where no absorbent glands are known to exist. In this boy a great number existed over the front of the sternum and below the clavicles, which disappeared under medicine, while the chief mass in the neck was materially lessened in bulk. I have not usually seen the patients suffer much pain either in the chief tumor, nor in these separate globular tubercles (which, by the by, are not frequent); but Mr. Abernethy, under this name, describes one case, where the little tumors, which were numerous, were so exceedingly sensitive, that the patient, in describing the pain he experienced, employed the expressive simile of his lying on hob-nails. It would appear, finally, that the disease may exist at any age from ten to fifty, but the few I have seen have been in lads from sixteen to twenty years of age. I have recently met with an observation of Dr. Hodgkin's, in the 17th vol. of the Med.-Chir. Transactions, in which he mentions several cases of apparently this disease, and remarks that in every case except one he has found a number of little bodies of a cyst-like form in the spleen. I have not myself had an opportunity of verifying this observation since I noticed his paper, nor do I know (if it be well founded) whether the coincidence is of importance or not.

As to the nature of tubercular conglobate tumor, Dr. Hodgkin quotes a case from Dr. Carswell's valuable work, in which it is called cerebriform disease of the absorbent glands. I agree with Dr. Hodgkin, however, in thinking it a different disease to a certain extent; the tumors are harder and firmer than cerebriform formations, and they run a somewhat different course. I have, indeed, seen cases of fungoid disease of the cerebriform variety, which resembled the disease in question. Mr. Keate, for instance, had an elderly man under his care in the hospital with a great number of superficial tumors on the head and face and other parts of the body, but they affected the skin more intimately, and were whiter and softer than the superficial subcutaneous tumors of the tubercular conglobate tumor; and in this case the glandular mass in the neck had occurred secondarily by absorption from some of the other tumors, and there were tumors of fungous character in other parts of the body.

Still I am inclined to look upon it as to a certain extent a modification of malignant disease, if there is not confusion in the accounts related of cases of

the disease. As I have myself seen it, indeed, it appears to be a peculiar local disease of the absorbent glands, (and I have therefore placed it in this genus of tumors), confined generally to the glands, though, as we have seen, accompanied sometimes by small cutaneous tumors where no glands are known to exist. I have already observed, however, that Dr. Carswell does not distinguish it from cerebriform disease, and Mr. Abernethy describes a case in which a tumor supposed by him to be of this nature in the axilla was succeeded by tubercles in the lungs, heart, liver, omentum, and other parts. Now if this be so, we must evidently regard it as only a modification of cerebriform fungous disease, in which the whole body is less affected than is usually the case with a fungous tumor of that or any other sort.

In the treatment, however, of the disease there is sufficient to demonstrate at the least a very considerable modification of malignant disease, since it is sometimes very much influenced by medicine, which cannot often be said of fungous diseases. As it occurs in lads, and looks like serofulous enlargement, it will at least be right to try some remedies, before having recourse to operation. I have told you that in the lad of whom the case is before you, the tumors in the neck had become lessened to half the former size, and the separate cutaneous tubercles disappeared; when I saw him some months afterwards, however, the disease was again increasing, and his health a good deal affected, and I dare say the disease proved ultimately fatal. Now in this lad what seemed to do most good (when a great variety of means were tried), was the occasional employment of a few leeches, with collutions, whenever the tumor was attacked by the temporary inflammation I have alluded to (at which time, besides the pain in the tumor, he suffered much from pain in the head, as if the circulation in the brain was interfered with by the pressure of the tumor on the jugular veins,) while he took internally, during a long time, small doses of blue pill with sarsaparilla. Mercury, however, must not be given so as to affect the gums, for I have observed, that whenever the action of the medicine was greater than that of an alterative, the disease became worse, and I have been obliged to intermit its use. Some good was done at this time in this lad by liquor potassæ, of which he took as much as ʒij. three times a day. Some good is occasionally done by iodine, but not so much, I think, as by the other means, and sometimes iodine does harm, probably when there is a disposition to inflammation. This patient had been the servant of a medical man, who informed me that he had employed a tincture with

double the usual quantity of iodine, and that he had at least given as much as ʒij. of this strong tincture twice daily, while you know that five drops will be too much for some persons.

It only remains for me to speak of an operation, when your medicines fail, in checking the growth of the disease. Now in general this is useless; the disease is a constitutional malady, and while you remove some of the tubercular masses, others will continue to form. I had a consultation on this lad for instance, but both sides of the neck being immensely large, while tubercles existed elsewhere, it was considered out of the question. Where, however, the diseased mass is more local, and is troublesome, and the patient is desirous of an operation, it may be performed, though not always completely. In this preparation you may see a great number of the tumors which I assisted Sir Benjamin Brodie in removing from the upper part of the neck of a boy in this hospital; many were drawn out from their cellular beds, exposing the carotid artery and jugular vein; but even then, many small glands or tubercles were obliged to be left. In this case, however, I understand the tumors had not returned for a year or two after the operation; but in many other cases the removal of all the glands and tubercles then enlarged, has not prevented the subsequent formation of many others, and the death of the patient from ulceration or irritation.

III. 6. The next genus of sarcomatous tumors may be called *Serofulous Tumors*. Serofulous or cheesy matter is a secretion from the vessels of the body in a particular state of constitution, and may be deposited in various situations, and in several ways. You meet with it in the internal viscera, in the form of tubercles, cyst like in appearance—as in this preparation of the liver—the serofulous matter being a mere deposit from the cyst, which Dr. Carswell has demonstrated to be frequently at least an enlarged biliary duct in that organ, or an air-vesicle in the lungs; you find it, also, in the cellular structure below the skin, or in the cancelli of the bones, or in the absorbent glands, with or without swelling of the affected part; and thirdly, but more rarely, it is deposited more universally in the structure of any part, so as to constitute not merely an inflamed swelling with some serofulous matter, but a distinct chronic tumor, consisting in part of the unorganized matter in the cellular tissue of any organ, which tumor is sometimes of considerable size.

It is only in the latter form that it can be called a tumor; and you may here see such masses in the thyroid gland, the brain, (where it causes epilepsy and compression)

and in the testis and breast; and it occurs in other parts also. The serofulous tumor in any organ is a soft, elastic, globular, or oval mass, semifluid occasionally in feeling, though generally firmer in consistence, resembling a fatty tumor in this respect, but deeper and more globular; and often not single, but two or three are at once felt in the same part. Such tumors may be of the size of a nut or walnut, or small apple, giving very little pain, and possessing very little tenderness; nor have they much disposition to suppurate, unless the serofulous tendency be very strong, so that years may elapse without any abscess being formed.

Serofulous tumors are very much under the control of medicine, as you might expect, so that I have seen very large ones disperse when in the breast, or thyroid gland, or when the absorbent glands have been thus enlarged so as to form a large solid mass in the neck or axilla. The most useful remedies are, alternative purgatives, such as the hydr. c. cretâ, and rhubarb, with alkaline medicine, especially the liquor potassæ in large doses, continued for a considerable time. With potash you may combine bitter medicines, or sarsaparilla sometimes; or the potash may be given at the same time with small doses of the tincture of iodine, or hydriodate of potassa. I shall not dwell, however, upon the medicinal treatment at present, as I have recently spoken to you of the cure of serofula in whatever way it may be developed in the body. Locally, I think a mercurial or ammoniacum plaster alone will be of most service, or a stimulant lotion of salt solution, or the hydriodate of potassa ointment, or the strong solution of iodine in a solution of the hydriodate, applied daily with a camel's-hair pencil. Constitutional remedies have more influence, however, if judiciously employed, than any local application.

III. 7. We next proceed to the *Cystic Tumor*, which is composed of a vast number of cysts, united by more or less cellular substance, and varying in size from that of a pin's head to a pea or marble, or in the ovary to a greater size still. The cysts are vascular, and separate from one another, as you may see in these preparations, and secrete various fluids; generally thin and transparent mucilaginous water, like the fluids of the serous encysted tumors; sometimes opaque and dark brown, or green, or almost black; occasionally, a few cells of cheesy matter are mixed with the rest, and sometimes the contents are semi-purulent.

In speaking of this tumor in the breast, Sir Astley Cooper calls it the cellular hydatid disease; but, as you see, the cysts

are not hydatids, but are vascular, and highly organized; and if a few hydatids are found in some of the cysts, this is merely a coincident circumstance, just as you occasionally find these animals in fungus hæmatodes and other tumors.

Sir Astley attributes the formation of the tumors to the obstruction of ducts; this will account for their formation in the breast or testis where the tumor is sometimes met with, or in the kidney, as in this preparation and plate, where a vast number of watery cysts are seen with hardly any of the natural structure remaining. But it will not explain the growth of the tumor in the ovarium, where it is most frequent, and the cysts are, in this situation, a great deal too numerous to be easily attributed to enlargement of the Graafian vesicles. But here you will see a tumor of apparently this texture in the situation of a fractured and ununited rib: and Dr. McFarlane has met with such a tumor between the peritoneum and the abdominal muscles. Just, then, as we have already seen with regard to a single serous or aqueous encysted tumor, so with this cystic tumor also, if, as is no doubt the case, cysts of fluid arise from obstruction of the ducts of secreting organs, yet, if it is formed in simple cellular structure, where no ducts exist, we must at least look to more than one cause for its origin; and in the ovary, where the cellular structure is so tough, enlargement of these cells will scarcely arise very easily. But, after all, I cannot explain to you why in a certain individual all the ducts of the breast or testis, or all the cells of the cellular membrane in a given part of the body, and in that only, should be obstructed and enlarged, and secrete peculiar materials.

Examine the cystic tumor and you will find it soft, elastic, with obscure fluctuation, the fluid not being so evident as in simple cysts, from the numerous partitions of the tumors. It is not very heavy when poised in the hand, as a completely solid tumor of fungous disease would be. It is of slow growth, several years elapsing before it often attains a large size; and it has little disposition to inflame, or to adhere to the skin, or to ulcerate. It sometimes, however, has one cell after another in a state of suppuration, and bursting, as a small abscess, without the inflammation spreading to the mass of the tumor. This is a part of the cystic tumor which grew in the breast, and must have weighed several pounds; and yet it presents no mark of much diseased action. Sometimes enlarged veins are seen on the surface, as in malignant disease; but this may be observed in any tumor, in which the passage of the blood through it is retarded, without being necessarily a sign of

malignant action. In the ovarium the tumor grows to an enormous size. I have seen one of seventy pounds weight, which was tapped in three places, and the fluid of as many of the largest cysts evacuated, which immediately became as solid as jelly or glue.

Cravillier, in speaking of this tumor, I believe, in the ovarium, calls it the same disease as what has been termed *cancer aréolaire* or *gelatiniforme*, which disease I show you here in the stomach: even he, however, calls the cystic tumor a local disease, only affecting the neighbouring textures by continuity. For my own part, however, I have never seen any evidence of even the largest (not even the one I have just mentioned of seventy pounds weight,) which seemed to affect any part besides the organ attacked; and I am not inclined to attribute any malignant action at all to this disease, not even the power of contaminating the parts around; believing that it is not the same affection as the gelatiniform cancer.

Whenever, then, a part of the body is affected with this tumor, and is becoming inconvenient from its size and weight, you may remove it, I believe, if accessible, with perfect safety, and without fear of an unsuccessful result from any constitutional taint. I say little of any thing but removal, since local remedies have little influence, even upon the fluid part, and none whatever, I believe, upon the solid portion of it. You may try, however, some of the stimulant lotions I recommended for the single cysts, the muriate of ammonia, or the camphor spirit and goulard, and so on, or iodine applications. You may also try internal remedies for a time, at least early in the disease, such as potassa and iodine.

III. 8. The next genus of sarcomatous tumors on our list is more rare than the last, and I have been accustomed to call it, for distinction, the *tuberos cystic tumor*; and I scarcely know whether it should be placed by itself as a separate genus, or only considered as a species of the last. It consists, as you perceive, of a large cyst, which generally contains a yellowish or brownish fluid, into the interior of which cyst there project a number of bodies, like a bunch of grapes sometimes, of various sizes and shapes. These tubera look like portions of the cystic tumor, and are soft, of a white or yellow colour, and a section of them shows that they are also cells with a similar fluid or semifluid jelly inclosed in a membrane similar to that of the large cyst which surrounds the whole. In these preparations from the breast there seems little difference, except in the form and connexions of these portions, from the cystic disease, and both are not

very unfrequently met with in that organ. In the ovarium, the tuberos cystic tumor is not uncommon, of which this is a good example. Here is also a beautiful drawing, from Dr. Seymour's excellent work on the Ovaria (to which I may refer you for a detail both of this and of the cystic tumor, as they present themselves in that organ, which shows you the recent appearance of the same tumor, in a case which I have cause to remember, as it cost me three months' illness from a wound, after the death of the lady. There was a large quantity of fluid, which I drew off several times by tapping, and the section of the tuberos mass bears some resemblance to the areolar cancer of the mucous membranes. The tumor was remarkable before it contained much fluid, from the contradictory opinions given with regard to it by different medical men, whether it was the ovarium, or spleen, or liver, or some new structure altogether.

In speaking of this disease in the breast, Sir A. Cooper calls it a form of hydatid disease, and expresses his opinion that hydatids, having been subjected to pressure, have been killed, and subsequently become attached to the cyst around, into which they hang like polypi; there is not, however, the smallest evidence of the hydatid origin of the disease, nor, indeed, of hydatids in any part ever becoming attached when deprived of their independent vitality.

I cannot, then, explain the peculiarity of the appearance of this tumor; but I may add, that it would appear as if such pendulous bodies as are here met with did really become sometimes strangulated, as it were, so that they are bloody and soft, as if mortified, with coagulium in their substance.

The appearance of the tuberos cystic tumor in the living body is that of a generally smooth surface, but sometimes of more irregular figure than the cystic tumor; it has a sensation of more distinct fluctuation, but this will depend on the relative quantity of fluid; and when it is pressed deeply, it is generally easy to feel the mixture of solid matter presented by the projecting tubera. The skin is dark-coloured and purple, over a large space sometimes, and is more frequently attached to this than to the cystic tumor, and the enlarged and tortuous veins on the surface are more evident. In the several particulars I have just mentioned, the tumor bears much resemblance to one of fungus hæmatodes, nor do I know any positive distinction between the two before removal, in all cases. Here is one which Mr. Babington removed from the breast, which was extremely dark coloured, but from the perfect health of the patient, with some

trifling circumstances in the part, I believe we all formed a correct diagnosis before the operation, which was confirmed by the dissection and by the result; at least there was no evidence of any return three years afterwards. In the ovary you can often distinguish the tuberos cystic tumor from the aqueous eneysted tumor, and from the cystic tumors, by the irregular solid masses which you can feel through the parietes in a thin person, and which sometimes have hardly afforded me room to tap the patient. In the lady from whom this was taken, by the time of the fifth operation, hardly any space was left, as the tubera increased in size and number between the intervals of theappings.

There is no cure, I believe, for this disease; the quantity of fluid may be made to vary, but the whole tumor should, if possible, be removed, and the operation, as for the cystic tumor, may be undertaken with a fair prospect of success: at least I have not seen any more evidence of malignancy than in cases of the cystic tumor. I have mentioned, in this case from the breast, that the patient was quite well three years after removal: in the case from which this larger tumor, with more solid matter, was removed by Sir Benjamin Brodie, from the same part, a longer time, I believe, elapsed; and Sir Benjamin informs me (and Sir Astley Cooper says the same, in his work on the Breast), that the tumor has not returned, nor affected the system, in several cases where these gentlemen have operated on large tumors of this kind. It is true, indeed, that in the ovary, where it grows to so great a bulk, the patient suffers great irritation, and becomes emaciated, and dies worn out by her disease much earlier than is usual with other forms of ovarian cysts, and with a countenance sallow and sunk, as if with malignant disease; and it is thought by some for whose opinion I have a high regard that it is a malignant form of structure. But though I have seen cases of malignant disease, with cysts too, in the ovary, yet, even when the patient has died of the tuberos cystic tumor, with what has been regarded as the appearance of the system being impregnated with the poison of malignant disease, I have not seen it evinced in any tumor of the glands communicating with the ovary, nor in other parts of the body; and sometimes, when it is of great size even in this internal situation, the irritation is much less than usual. I tapped a woman, for instance, about fifteen times in nearly three years, taking away as much as 74 pints of fluid at a time, and yet, but for an accidental attack of erysipelas and inflammation of the sac, which had numerous tubera within the cyst, the patient

appeared likely to have lived some time longer.

I have now mentioned to you a great number of tumors, of which one or more cysts form the whole, or a part:—sebaceous cysts, serous cysts, congenital cysts, hydatid cysts; 2dly, osteo-steatomatous tumors; and 3dly (of the sarcomatous tumors), the cystic and tuberos cystic;—in all of which we have found that the disease is innocent, or rather not malignant. But further, cysts are often found connected with malignant disease, either in the same situation, or in some other part of the body; and tumors with such a combination especially resemble the two last genera of tumors. Here is a testis which I removed by operation, with a great number of cysts in its substance, and in many respects like a cystic tumor, but it is, on the contrary, a malignant tumor, and returned in the glands in the abdomen. Here, again, is a tumor like a case of tuberos cystic tumor, which I punctured in the neck, and dissected out after death; but which also followed fungus hæmatodes of the testis, like the other specimen, and was accompanied moreover by a large fungous tumor in the abdomen.

In the living body I do not think you can always distinguish one case from the other, where there are no constitutional symptoms to guide you, and no tumors elsewhere to indicate the malignancy of the disease. This is of less consequence, however, since wherever a tumor contains many cysts, or even a single cyst is joined to much solid matter, you must remove it, whether it be malignant or not; and having examined it after the operation, you can form, at least, a probable opinion of its nature, and give your prognosis accordingly to the patient and his friends. If, for instance, a tumor contains a number of cysts, the contents of which are the ordinary secretions of such cysts—watery, gelatinous, cheesy, and so on; and what solid matter there is in the substance of the cysts, and in the cellular membrane between them, appears to be the ordinary deposits of inflammation, you may assure your patient, with tolerable confidence, that he is safe from any return of disease; if, on the other hand, the secretions and the solid deposits have any signs of the various malignant deposits, cerebriform, melanotic, and so on—even if the solid materials bear a very small proportion to the cysts, yet you may feel assured of the malignant nature of the tumor; the existence of the cysts, in such a case, is an accidental circumstance only, that does not lessen the chance of the tumor returning. But further, when the solid matter bears a large proportion to the cysts, even

if you cannot quite satisfy yourselves of the exact nature of such deposits, yet you should, I think, always regard the combination with suspicion. And lastly, if a tumor containing cysts is growing rapidly, and is accompanied with severe constitutional disturbance, such as irritative fever, you will learn to anticipate the malignant nature of the tumor: for instance, a woman came under my care, with a tumor of only nine weeks' duration, in one mamma, but which was already two feet in circumference. I punctured several large cysts, with great relief to her sufferings, and felt the solid matter between them; but the tumor, growing thus rapidly, had caused so much fever, that, on consultation, its removal was not considered advisable. The circumstances I have mentioned led us to believe the tumor malignant; and when she died with fever and extensive gangrene of the tumor, three weeks afterwards, its solid substance was distinctly cerebriiform and hæmatoid, mixed with the large cysts, and the same disease was just commencing in the axillary glands.

The numerous circumstances in which cysts are connected with morbid growths, have led to the formation of numerous theories with regard to them. One of these theories is, that all tumors whatever owe their existence to the previous formation of cysts; and some theorists, going still further, affirm that these cysts are hydatids. Mr. Carmichael, for instance, proposes the cure of cancer by the use of carbonate of iron, to kill the hydatids of the disease, as that substance destroys the intestinal worms. I need say no more, however, upon this subject.

One of the most ingenious theories in connexion with tumors is afforded by Dr. Hodgkin, in the fifteenth volume of the *Medico-Chirurgical Transactions*. This gentleman, like the pathologists I have alluded to, attributes the structure of all tumors, even of solid scirrhus tumors, to the previous formation of cysts. This diagram, and the tuberos cystic tumors, will explain his theory to you. It is, that a cyst having been formed, a second is formed thus between the layers of the cyst, and projects into its interior; then a third between the layers of the second, and so on *ad infinitum*, so as to constitute a large mass. Now this theory would undoubtedly seem to be true as to this particular form of tumor (the tuberos cystic), to a certain degree; but he goes on to explain the solid structure of hard tumors in the same way. There is in them no fluid; but the secondary and tertiary cysts having been developed, are, according to the theory, pressed together and joined, so

that, on a section, the white lines and bands of solid substance then exhibited, especially in cancer, are the successively formed cysts, pressed together, which in this manner constitute the tumor. Now this theory does not appear to me to be at all well founded, as far as I have tried to unravel the tumors in question; nor is Dr. Hodgkin's opinion adopted, I believe, by any pathologist who has examined the subject.

ON THE

INTRODUCTION OF AIR INTO THE VEINS.

BY M. VELPEAU.

THE numerous incidental questions which have been raised on occasion of the discussion concerning the introduction of air into the veins, have made the original point be lost sight of. It was desired to know if air can spontaneously enter the human veins during surgical operations; if science possesses facts tending to establish the reality of this accident; and lastly, whether art has any method calculated to prevent or to remedy it: such were the points first debated. In spite of my efforts to keep the discussion within its proper boundaries, it left them almost at the outset, never more to return within them. As I shall not be able to treat the subject again, I think it will be useful to my colleagues if I publish in detail my researches on the direct question of the introduction of air into the human veins.

Surgical practice had long afforded examples of almost sudden death taking place during certain operations; but these occurrences had been attributed at one time to hæmorrhage; at another to the exhaustion of the patients by excess of pain; at other times to terror, and sometimes to syncope. I know myself that patients have died in a few minutes, while the operator was endeavouring to remove a diseased thyroid gland, or a tumor in the axilla; or, to give another instance, that the accident has taken place during tracheotomy, and that no explanation has been attempted except those which I have just given. Modern surgeons, however, not satisfied by these explanations, and recollecting the experiments of physiologists upon animals, have explained such cases by supposing that air entered the veins. The facts of this kind which I have met with are about forty in number. The question is, whether they can be really compared with those which are furnished by experiments on animals, or whether, in any other manner, they contain the proof

of the fact in favour of which they are quoted. I consequently think that it will be useful to review them, and give an abridged analysis of them. I shall take care to point out the work where they are to be found, that the reader may refer to all the details, if he thinks proper.

CASE I.—The first instance of the kind which was published in France, occurred in the practice of Bauchéne, at St. Antoine's Hospital, in July 1818 (*Piedagnel, Thèse*, No. 250, Paris, 1827). He was removing a large tumor on the right shoulder of a young man of 23; but little blood had flowed, and the clavicle had been turned outwards, when M. Piedagnel heard a noise like that which is caused by the entrance of the air through a small hole into the chest of a living animal. The patient cried out, "My blood is falling into my heart; I am dead!" The same sound was heard a second time, and the young man fainted, and died a quarter of an hour after the operation, which, moreover, had been long. The body was opened eighteen hours after death, and it was found that the external jugular vein had been wounded; *there was no blood in the heart*; its right cavities were flaccid and thin; all the vessels contained a considerable quantity of air-bubbles.

Here the external jugular vein was wounded. There was a hissing noise, followed by syncope, but no mention is made of convulsive movements; and there was air every where, except in the heart. Experiments made on living animals show precisely the reverse; in them the heart contains air more than any other part, and when air enters the veins, animals do not sink in this manner.

CASE II.—Before the fact just related had drawn public attention, another occurred at the Hôtel-Dieu. On the 19th of November, 1822, Dupuytren had to extirpate a large tumor from the right supra-clavicular region of a young girl, aged about twenty (*Arch. Gén. de Méd.* t. v. p. 430). During the dissection of this tumor, and before it was completely separated, a hissing noise was heard, as if air was entering a pneumatic apparatus. The patient, who had lost only a few drops of blood, exclaimed, "I am dead," sank upon her chair, and expired instantly.

The body was opened twenty-four hours after death. The right auricle, which was tense and elastic, was filled with air, but contained no blood; fluid blood, however, was found in the other cavities of the heart. All the vessels in the rest of the body contained a large quantity of air, mixed with a certain proportion of blood.

It cannot be denied that a fact like this has something strange about it; nevertheless, if we compare it with what happens

in experiments upon animals, we see immediately that the cases are dissimilar. In fact, there is nothing to show that the internal jugular, or even the external jugular vein, was opened during the operation; which, besides, was not finished. There was air alone in the auricle, and blood alone in the ventricle. But we have seen in animals that there was always a close union of blood and air, in the form of a bright-red froth, both in the auricle and the ventricle. In the case just detailed, death occurred suddenly, and without convulsions; but it never occurred in this manner in our experiments. Hence the case leaves much to be desired, even taking it as it is narrated.

CASE III.—At the same period it was said that a similar accident had happened to Gräfe, of Berlin; but I cannot find the particulars of this case any where, and believe it to be a mere *on dit*; unless, indeed, the name of Gräfe was confounded with the journal which he edits, and a case by Klein was really meant.

CASE IV.—We find, indeed, in Gräfe and Walther's journal (vol. i. p. 120), that Klein, of Stuttgart, while extirpating the thyroid gland in a deaf and dumb child, lost his patient in less than a minute. But in 1814, when this occurred, the danger of the introduction of air into the veins had not been thought of; and it was not till long afterwards that this case was referred to, in order to support Dupuytren's.

CASE V.—Dupuytren also quoted an instance of the same kind, as occurring in Sir Astley Cooper's practice; but nothing of the kind is to be found in his works, and M. Olivier, of Angers, alone has thought it necessary, on the strength of an *on dit*, to mention the case briefly, in the *Dictionnaire de Médecine*, tom. ii. p. 70.

I think I need not add, that, in so important a question, evidence of this kind is of no value.

CASE VI.—In 1826, M. Castara, a surgeon of Lunéville*, while dissecting out a tumor situated in the sub spinal fossa of the right shoulder, suddenly heard, at the bottom of the wound, a sound like the gurgling of a narrow-necked bottle which is being emptied (this sound is called, in French, *glouglou*). The patient, who was twenty-one years of age, fainted, and died suddenly, without any convulsive movement. Twenty-four hours after death, the right cavities of the heart were found filled with fluid blood, mixed with a great quantity of air-bubbles. The left cavities also contained some. The whole venous system of the right arm (including the fore-arm) was filled in the same way. The only vein which had been opened was a

* Sauerotte, *Thèses de Strasbourg*, March 1828.

branch of the sub-scapular, and the incision in it was less than a line in diameter.

There are some very remarkable peculiarities in this case; it is the only one of those we have hitherto narrated which can be compared with the results of experiments upon animals, with regard to the state of the blood in the heart. But the patient died suddenly; and this never occurs in direct experiments. So small an opening, and that too in a vein beyond the axillary, does not allow of the entrance of air enough to cause real danger, either in dogs or horses; nor can one understand how the air should be present in the veins of the right fore-arm, when none was found either in the vena cava inferior, or in the left arm. Hence M. Castana's case, though one of the most authentic, leaves some doubts in one's mind.

CASE VII.—Two years afterwards, in 1828, Mr. Mott, a celebrated surgeon of New York, who is now in Paris, published an account of the extirpation of a tumor, which extended from the parotid region to the face (*Journal of Surgical and Medical Science*, Nov. 1828, p. 127.) During the operation the facial vein was opened; a peculiar sound was heard; the patient uttered a cry of distress, and nearly fainted; but death did not take place. Hence there is nothing to shew that the symptoms were caused by air entering the veins, especially as the facial vein does not seem capable, anatomically, of allowing it.

CASE VIII.—Delpech, while extirpating the arm for a fungous tumor in a patient of about 30, heard two snuffling sounds (*rouffemens*) before he had got through the joint. The patient fainted twice, and died instantly. There had been but little hæmorrhage. The dead body was placed under water, and a considerable quantity of air-bubbles were found in the right cavities of the heart (*Mémorial des Hôpitaux du Midi, deuxième année*, pp. 231, 634.)

Here, again, we are immediately stopped by a number of serious difficulties. First of all, it is neither the axillary nor the subclavian vein which is in question, but merely the veins of the stump of the humerus; and we have already seen* that, at this distance from the thorax, the absorption of air appears to be impossible. Then it is not a snuffling sound which is heard in animals, nor do they sink suddenly; moreover, we do not learn what was the state of the air which filled the right cavities alone of the heart.

M. Clémot, of Rochefort, happening to be at the Hôtel-Dieu, told Dupuytren (who

had just been attempting to remove a tumor from the thyroid gland), the three following cases:—

CASE IX.—A woman, from whom he had removed a cancerous breast weighing twelve pounds, died a few hours after the operation; and air was found in the veins running from the wound to the heart, as well as in its right cavities (*Putegnat, Thèse*, No. 156; Paris, 1831.)

CASE X.—In another instance M. Clémot, while dissecting a tumor out of the axilla, suddenly heard a respiratory sound. It was thought that the chest had been opened; the patient fainted, but soon came to himself again.

Is it not clear that no one can be convinced by facts so vaguely set forth, and which, in addition, have not been published by their author?

CASE XI.—In the third case attributed to M. Clémot, the subclavian artery was tied. A small vein had been opened, and a respiratory sound was heard; but the sound was stopped by putting a finger on the vein, and it was thus allowed to reappear, and made to cease, several times. No bad symptom followed (*Gaz. des Hôpitaux*, tom. iv. p. 95; *Putegnat*, in the thesis above quoted, p. 38.)

Mr. Warren, a distinguished surgeon of Boston, published two cases in the American journals in 1832, and has again related them in an interesting work which he has lately published (*Surgical Observations on Tumors*, 1837.) They are to be found also in the *Gaz. Méd.* for 1833, p. 226, and in the *Arch. Gén. de Méd.* t. xxxi. p. 119. To me, however, they seem to have been admitted as evidence in the present discussion without sufficient reason.

CASE XII.—W. Buril, aged 60, had a cancerous swelling in the right parotid region and on the face. In laying bare the carotid artery, which he wished to tie, Mr. Warren opened a vein, on which he heard a sound like that of air-bubbles passing through water. The patient said he felt ill, and apoplectic symptoms followed. The temporal artery was opened, and the symptoms began to go off at the end of two hours. The next morning they had entirely disappeared (*On Tumors*, &c. p. 298.)

CASE XIII.—While dissecting a tumor out of the axilla of a patient named Nancy Barker, Mr. Warren heard an indistinct bubbling or clucking sound; the patient became insensible, and her respiration was apoplectic. In spite of stimulants, the introduction of brandy into the larynx, tracheotomy, and blowing air into the lungs, the patient died in a few hours. Post-mortem examination was not allowed (*op. cit.* p. 259.)

If I am not mistaken, these cases are

* That is to say, in the experiments on animals.
—TRANSLATOR'S NOTE.

not of a kind to satisfy all the demands of the critical. In the first one, we see hardly any of the characteristic symptoms which indicate the entrance of air into the veins of animals; and the patient did not die. In the second, only a small subscapular vein was opened, almost an inch distant from the trunk of the axillary. Moreover, those apoplectic symptoms lasting several hours in a patient who remained insensible, in whom the temporal artery was opened, who was exposed to the vapours of ammonia, into whose bronchi alcohol was introduced, and on whom laryngotomy was performed, have but little resemblance, as it seems to me, with the results of our experiments. All that one can say is, that the veins opened in these two patients were in a part where the entrance of air is, in truth, possible.

CASE XIV.—A case mentioned by MM. Putegnat and Guérétin, in their theses, and attributed to Mr. Hodge, or Lodge (*Gaz. Méd.* 1833, p. 27), seems stranger than any which I have hitherto cited. If we were to believe this physician, a patient died suddenly from the entrance of air into his veins, at the very instant that Dupuytren had opened the internal saphena!

This case, however, which nobody knew of at Paris, and which has come back to us from America, where it was communicated to Mr. Warren by the author, is too improbable to deserve discussion.

CASE XV.—M. Puydebat (*Gaz. Méd.* 1833, p. 498), and M. Forget (*Transact. Méd.* t. x, p. 75), have published the case of a young woman, aged 18, who was operated upon by M. Roux in 1832, for a lymphatic tumor in the parotid region. While removing the tumor a hissing noise was heard; the patient immediately cried out, and was violently agitated. A fainting fit followed, but did not last long. The patient went on well for several days, and did not die till the end of a week. Air-bubbles were found in all the vessels!

Although it is true that some of the symptoms which are produced by the entrance of air into the venous system occurred in this instance, still it is impossible to consider the thing as proved, and not rather to believe that it was merely a case of syncope. In the first place, we do not know what vein was opened; and as death did not take place till seven days had elapsed, it is unquestionable that it did not arise from the air which might have reached the heart during the operation.

CASE XVI.—In the *Gaz. Méd.* of 1833, and in the thesis of M. Putegnat, the following case is to be found, communicated by M. Duplat. M. Goulard wishing to remove a cancer which extended from the

breast to the axilla, injured a vein which he believed to be the axillary, from which, however, but little blood flowed. At the same instant the patient was seized with convulsive movements of the face, and died. The body was not examined.

I would not maintain, certainly, that the death of this woman was not caused by air entering the veins; but I cannot help saying that no proof of this is to be found in M. Duplat's case. When the particulars are so vague, it is impossible that a case can prove any thing.

CASE XVII.—I will say the same of a case taken from M. Ulrich (*Journ. des Conn. Méd.-Chir.* tom. ij. p. 91, or in the *Berlin Med. Gaz.*) In extirpating a tumor from the neck, the internal jugular vein was opened. A hissing sound was heard, and death ensued in a minute. The right auricle was distended with air, and contained no blood. There was black and fluid blood, but no air, in the corresponding ventricle.

Now, it is certain that in animals death never ensues in a minute; that the auricle contains both blood and air; that it is the same with the ventricle; and that, far from being black, the blood is always of a very bright red.

CASE XVIII.—The same remark may be applied, with still more force, to Mr. Barlow's cases. While removing a tumor from the cheek, he divided some varicose veins; a fainting fit occurred, which he attributed to the entrance of air into the veins, though the patient soon came to herself again.

CASE XIX.—In the other case, Mr. Barlow was extirpating a tumor from a woman's neck, and, while dissecting the skin, he heard a hissing, and a gurgling; the patient died suddenly, without sighing or convulsions. The body was not examined.

Thus, in one instance, it was in the cheek, and experiments show us that in this part the veins do not absorb air; in the other instance, the vein opened could only be the external jugular at most; death was sudden, and without convulsions; and yet it is never so in animals! Moreover, the absence of cadaveric examination makes the case quite incomplete.

CASE XX.—A case published by M. Rigaud (*Quelques faits de Pratique Chirurg.*: Paris, 1836) is less known than the preceding ones.

In exposing the subclavian artery to cure an aneurism in the axilla, he was enlarging the external incision, when he opened a vein which he believed to be the external jugular. A peculiar sound, a sort of respiration, was heard three times. Nevertheless, M. Rigaud, who was much alarmed (from recollecting Dupuytren's

case) found that no bad symptom supervened. The patient died six weeks afterwards, from causes which had nothing to do with the entrance of air into the veins.

We have evidence here of the existence of the sound, of the exit of air-bubbles from the ends of the divided vein, of a sort of bubbling at the bottom of the wound, and yet no particular symptom appeared affecting the visceral functions! We are, therefore, in some measure forced to conclude either that M. Rigaud was deceived, or that the introduction of a large quantity of air into the veins is not always dangerous.

CASE XXI.—In passing to the examination of the case which, next to that of Dupuytren, has most excited public attention, I mean M. Roux's, I meet with a mixture of circumstances amidst which it is difficult to find conviction.

A man of good constitution was admitted into the Hôtel Dieu for a burn, which affected nearly the whole right side of his head, a great part of the hip and of the thigh of the same side, and which had, so to say, sphacelated the whole of the arm up to a short distance below the shoulder. After having first refused to allow the disarticulation of the arm, he consented to it four days afterwards, namely, on the 30th of April, 1836, and was carried to the operating-room in the beginning of the period of re-action. M. Roux had hardly cut the posterior flap in the deltoid, when he perceived that the patient was pale, and seemed to be going to faint. The capsule was speedily opened; an assistant compressed the axillary vessels, and the disarticulation was finished by cutting the internal or anterior flap, after Desault's manner. But the patient had given no sign of life, and it was impossible to revive his circulation. Some of the bystanders afterwards said that they *thought* they had heard a sort of noise, a hissing. On examination, gases were found in the vessels and the heart.—*Journ. des Conn. Méd. Chirurg.*, t. iv. p. 108. *Revue Méd.*, 1836, t. ii. p. 417.

One cannot help remarking, that in this case a crowd of data are wanting, and that it does not fulfil the conditions mentioned in the account of the direct experiments relating to the entrance of air into the veins. It is not very certain that a sound was heard; and the opened veins were at most but scapular branches of the internal jugular. Death was sudden, without premonitory symptoms, and without convulsions. There was no frothy fluid in the heart, and the air spoken of is very imperfectly characterised. Lastly, is it necessary to have recourse to the entrance of blood into the veins in order to explain the death of a patient suffering from

so enormous a burn, while undergoing disarticulation of the shoulder?

CASE XXII.—While this discussion was going on in the Academy, M. Dupuytren was made to say, that Dupuytren had lost another patient by the introduction of air into the veins, while he was endeavouring to remove a tumor from the axilla (*Gaz. Méd.* 1837, p. 757; *Lancet. Franc.* 1837, p. 122.)

These journals add, that in this same operation the accident has happened six times to M. Roux and other practitioners; but every thing combines to shew that these are mere assertions, without proofs, arising from some mistake, or only founded on hearsay.

CASE XXIII.—The following extract is found in the *Bulletin de l'Académie* (t. i. p. 132). M. Delaporte, while removing a tumor from the neck of a woman, aged 60, was alarmed by a hissing sound, and the occurrence of syncope. However, this accident had no bad consequences, and the woman recovered perfectly.

In this case we see that the jugular vein may have been wounded, and that the air may have entered it. But allowing this to be established, we must conclude that this accident is far from being always fatal, being the same conclusion which we unquestionably derive from our experiments on living animals. On the other hand, it must be allowed that the case is insufficient for conviction.

CASE XXIV.—I must say the same of a case published by M. Malgaigne (*Gaz. Méd.* 1836, p. 167.) In removing the jaw, and the ganglia of the neck, he opened the external jugular. The hissing, which has been erroneously called a characteristic sound, was heard; but no bad symptom followed.

CASE XXV.—Let us see how far the case communicated by M. Amussat himself is conclusive. He was extirpating a tumor from the breast of a woman, aged 47, when a stroke of the bistoury, carried below the clavicle, in order to separate some scirrhous granulations, was followed by a jerking noise, as it were in a zig-zag direction. The patient said she was dying, and almost fainted. The wounded spot was compressed, and a jerking compression (*compression saccadée*) was also applied to the chest; the fainting was not followed by any bad symptom, and the operation was terminated without any other accident (*Bull. de l'Acad.* t. i. p. 894.)

Here the breast was operated on, and the incision was made several inches below the clavicle. Nothing could be opened there but some branches of the mammary veins; a zig-zag noise was heard; the patient said she was dying, and then came to herself again. It seems to me that all

this is far from proving that air entered the heart, and that it is difficult to find a less conclusive fact.

CASE XXVI.—At the same period a case of the kind occurred to me, which I communicated to the Academy. (*Bullet. t. i. p. 896.*) While I was removing by its base a tumor of the neck, which extended to the carotid vessels, in a woman of about 36, I opened the internal jugular vein. An evident hissing sound was heard; a kind of bubbling was then perceived at the bottom of the wound; and the patient, like the former one, cried out that she was dying, and fainted away. I made an assistant place his finger on the orifice of the vein, and finished the separation of the tumor with a stroke of the bistoury. I had immediate recourse to the remedies employed for common syncope, and the symptoms soon disappeared. The woman left the hospital a month afterwards, the very day that M. Amussat communicated his case to the Academy.

Undoubtedly this case has some points of resemblance to what is observed in direct experiments upon animals. The sound and bubbling caused by the agitation of a mixture of blood and bubbles at the bottom of the wound, this immediate tendency to fainting, accompanied by anxiety and slight convulsive movements, are altogether something striking and surprising. When I saw all this combined in this patient, I must confess that I was alarmed. Yet, would it be possible for me at present to demonstrate that these symptoms were produced by air entering the veins? Are all the elements of well-founded conviction present in this case? I cannot venture to affirm it.

CASE XXVII.—M. Malle has related a case nearly resembling mine (*Presse Méd. p. 463*). The internal jugular vein was opened, while M. Begin was extirpating a tumor from the neck, and a sound was heard like that which is caused by emptying a narrow-necked bottle (in French, *glouglou*.) No particular symptom, however, supervened!

CASE XXVIII.—According to M. Guérin (*Thèses, Paris, 1837, n. 191*) it would seem that an accident like Dupuytren's happened to M. Mirault, of Angers.

While dissecting out a tumor on the right side of the neck, M. Mirault, who had undoubtedly wounded the internal jugular vein, heard a hissing noise, followed by a second and third sound of the same kind. Tetanic movements took place; but the patient came to himself at the end of eight minutes, was comfortable afterwards, and had not lost twelve ounces of blood. Three hours afterwards he died suddenly.

I would not deny the possibility of air

having entered the heart in this instance, as the operation was performed near the internal jugular vein; but I cannot help remarking, that air does not kill animals after three hours of tranquillity. The want of a post-mortem examination, too, deprives this case of its chief value.

CASE XXIX.—In operating upon a woman for cancer of the breast, and while asking her to move the arm away from the body, M. Toulmouche observed, that the incision made by M. Duval was immediately followed by a hissing sound, resembling that of a loud respiration somewhat prolonged. The patient fainted, and the bystanders thought her dead; but she soon came to herself, and ultimately recovered all her senses. (*Bullet. de l'Acad. t. ii. p. 146.*)

Here a small vein only could have been touched, belonging to the trunk neither of the axillary nor the subclavian; so that it would be difficult to deduce any thing very exact from such a case.

CASE XXX.—Another instance is mentioned in M. Putegnat's thesis. He says, that a case had just been told him of a man, who being struck with apoplexy, was immediately bled from the jugular vein. After this bleeding he died suddenly, and air was found in the right auricle. (*Thèse, n. 156, p. 41: Paris, 1834.*)

One does not immediately see why this patient is supposed to have died from the introduction of air into the veins, rather than by apoplexy. Moreover, doubtful facts cannot be cleared up by examples of which the particulars are so vaguely given.

CASE XXXI.—Here is another case still more extraordinary. A woman, seven months pregnant, was attacked with flooding. M. Maugeis bled her in the arm; but eight ounces of blood had hardly flowed when the patient uttered a plaintive cry and died! Nothing was found upon post-mortem examination.

What can we say of a case like this? "If death was not caused in this instance by the entrance of air into the veins," cries M. Maugeis, "what could have caused it?" Were I in this practitioner's place, my answer would be an easy one; I should content myself with saying, "I know nothing about it."

CASE XXXII.—M. Dubourg has just communicated another, which is as little conclusive. M. Roux, who has brought it forward, says so too. Such are the principal facts which I have been able to collect concerning the introduction of air into the human veins. Assuredly, it would be possible to add others, if it were allowed to insert every case of sudden death occurring during a surgical operation without any satisfactory reason. We

might thus, for example, explain the almost instantaneous death of a patient on whom tracheotomy was performed at the Hôtel-Dieu, in 1835, by M. Trousseau; as well as of several of the persons who have died while it was attempted to remove a tumor of the thyroid gland; but as no one has spoken of the introduction of air in these cases, it is useless to dwell upon them. Animals themselves are sometimes subjected to operations which have caused the same accidents, and the same opinions, as in man. Veterinary surgeons have long known, for example, that opening the jugular vein of a horse may suddenly kill it, as I have already said.

CASE XXXIII.—M. Boulay, junior, long since published, in the *Journal de Physiologie Expérimentale*, a fact which he has again brought forward in the present discussion, and which M. Putegnat mentions in his thesis (p. 32;) a fact, too, which is not without its value. He had bled a horse in the neck, and at the moment when he was raising the vein in order to sew up the incision, he heard a peculiar sound, and the animal was seized with trembling, and soon fell down. The blood, however, by continuing to flow, gradually dissipated these symptoms, and the horse soon recovered itself.

CASE XXXIV.—An exactly similar case has been since reported by M. Gerard. (*Putegnat, Thèse*, &c. p. 32.)

CASE XXXV.—I have already said, that a similar example was related by Verrier, as long ago as 1806.

CASE XXXVI.—M. Leblanc has told me that he knows of six other cases of the same kind.

These are good examples of the first symptoms which follow the introduction of air into the veins of the horse; and it is difficult to avoid seeing in them, also, a part of those which have been pointed out in man. It will be confessed, however, that all this is not conclusive, and that facts like these could not be allowed to count in science unless the principal question were removed from the discussion.

CASES XXXVII. XXXVIII. and XXXIX.—Even before the experiments of Nysten, the elder Legallois pointed out, in 1809, symptoms which he attributed to the introduction of air into the veins, and which would be much more surprising even, than all that is asserted in the present day, if we were obliged to accept the interpretation which he gives of them. Thus, Legallois says, that he has three times seen rabbits die suddenly immediately after bringing forth; and this happened because the atmospheric air, penetrating as far as the cornua of the uterus, entered into the venous system and the heart. (*Putegnat, Thèse*, p. 25.)

I do not know whether Legallois is not the experimenter of whom Nysten says that he has to complain; but, assuredly, the facts which he puts forth will not convince any physiologist who has been present at modern experiments.

Nor do I think that much more reliance will be placed in Legallois the younger, who refers *en passant* to his father's experiments (*Journ. Hebd.* t. iii. p. 183, 181.) and who maintains that the cases of sudden death in some women, shortly after delivery, probably arise from air having entered the veins of the uterus. This is too much opposed to all that later researches have taught us, to be now admitted into science.

[To be concluded in our next.]

STRICTURES UPON

DOCTOR ARNOTT'S TREATISE UPON WARMING AND VENTILATING.

To the Editor of the Medical Gazette.

SIR,

SINCE the subjects discussed in the following strictures are attracting the attention of the public at the present time, and since they are of great importance to the community at large, any of the periodicals of the day which invite original communications would have been a suitable channel for the publication of these. Considering, however, the subject of warming and ventilating houses to be of more peculiar interest to the medical profession, through whom knowledge of the kind can best be diffused amongst the public, and being a member of the profession myself, I have been led to select your journal as the organ for submitting my remarks to the considerations of the profession and the public; if you will do me the favour of inserting them. My matter will be divided into three or four successive papers, each not exceeding the limit I suppose to be set in a hebdomadal publication.

I have the honour to be, sir,

Your very obedient servant,

JULIUS JEFFREYS.

Kensington,
3d March, 1838.

Throughout the wide range of sub-

jects to which the attention of educated minds is directed, in a civilized country, while those belonging to what are called the polite arts may be more attractive to many, few can be found of greater importance to the whole community than those upon which Doctor Arnott has lately favoured the public with a treatise. In this work he has undertaken a task, which any author, of less high reputation, would assuredly fail in, namely, to bring about an entire revolution in the opinions, feelings, and habits of the people, upon questions not only affecting their domestic comfort, but also highly important to the public health. The reputation of the author is such, that if this revolution would prove beneficial to the public health, there is strong ground for hoping it will be extensively, if not generally effected. On the other hand, if it would prove injurious to the health of the public, there is equal ground for fearing the influence which his authority may give to his doctrines and proposals.

In coming forward myself on these subjects, I shall entertain no fear of the charge of presumption from those who will afford me attention while I state the grounds upon which I venture to do so. I shall rather suppose, that every one must acquiesce in the opinion that a man cannot, without justly incurring the opposite charge of indifference to the public good, allow any love of retirement to keep back from them knowledge which he himself has received through study, followed out by a long course of experiments, when that knowledge bears directly upon questions occupying public attention at the time, and tending, in their decision, to the most important results.

About fifteen years ago, I commenced, in the East Indies, a series of experiments on the ventilating and cooling of buildings, employing in some instances an upward, and in others, a downward ventilation. I put to trial a variety of mechanical means, and among them a new instrument which, for reasons that will be explained in their proper place, proved to be the most effective of any kind of *pumping* apparatus for ventilation which I have ever seen. Subsequently, I was led to introduce several chemical arts into that country, which, while they were wholly new to India, had to be conducted in a very different manner from similar arts in

Europe. My operations were on so large a scale as to employ, sometimes, 1000 workmen, and were, for the most part, connected with the use of fuel. It became necessary to subject to trial most of the furnaces used in the arts, and then to modify them, or to devise others suited to the materials, fuel, and climate, of the country. By subjecting every operation to a series of unre-mitted experiments, complete success attended all of them in the end; although the difficulties, in some cases, proved such as could scarcely be credited. Indeed most of my experiments were directed to the improvement of manufacturing operations, but of many of them the object was purely scientific. In all these operations my agents were the rude workmen of the country, to whom every thing they saw was new. It became necessary for me to conduct the making not only of large boilers, and other vessels of iron, copper, and lead; of vats, of wood and iron; of pumps, and other hydraulic apparatus; of lathes, presses, and cogged machinery; of fire brick and stone ware of various kinds; but of furnaces also of almost every imaginable form, such as horizontal and dome furnaces; vertical, cylindrical, and prismatic kilns; reverberatory furnaces: one of which, in my saltpetre manufactory, was 12 feet by 10 inside; furnaces with the fire in the centre; furnaces with side chambers; boiler furnaces of many kinds; vaporizing kilns; and a great variety of experimental furnaces, and fire places, much too numerous to detail. In many of these, as is the case in many of the arts, the same circulation of hot air obtained, and upon the same principles, as in Dr. Arnott's thermometric stove.

Having long practised mechanical ventilation, and been extensively engaged in the use of fuel, my thoughts were, at times, turned to plans for warming and ventilating buildings in Europe. In the tropics, the occasion for employing any of these did not exist, but upon my return to England, three years ago, having matured one of them, I had the apparatus necessary made in Birmingham. I had not, however, the opportunity of erecting it at the time, and I laid my plans aside for a while, and devoted my attention to the carrying into effect the principle of an instrument which is now before the public, and which was invented shortly

after my return to this country. About a year after this, I heard that Dr. Arnott had taken up the subject of warming apartments, and considering that it could not be in better hands, I determined to allow my own plans to remain at rest; but upon the examination of his stove, and the perusal of his work, I have been compelled to consider the different kinds of apparatus I have above referred to, of one kind of which the fire is open, and of the other enclosed, to be constructed upon principles so superior, that I purpose, ere long, bringing them before the public.

With the above experience, and as a member of the medical profession, I am justified in holding an opinion upon the matter of the work before us. This work undoubtedly abounds with clear statements of important and well-established truths in medicine and natural philosophy. Principles in these departments of knowledge have been made intelligible to the general reader, which, while they are thoroughly understood by many, have not been comprehended by the bulk of the people, for whose comfort in life it is desirable that they should be acquainted with, and form right judgments upon them. To the full extent to which the author has done this, and wheresoever his reasoning upon, and application of these principles, are in accordance with them, and manifest that most essential quality, practical experience, I would rejoice to add my humble meed of praise to the unbounded admiration which the work has drawn forth. But I am compelled to affirm, that in the most important instances, these principles, laid down in the commencement of the work, have been adhered to neither in the subsequent reasoning, nor in the practical details; while in other instances, contrivances are seriously recommended for adoption, which, it may be shown, are either indefensible even in theory, or wholly unpossessed of practical advantages.

In venturing to affirm these things, and to stand forth to prove the truth of my affirmation, I am aware of the unequal task I undertake. With so much of private worth, and standing so high as does the author in public estimation, I might well be disposed to maintain now that reserve which has kept me from appearing before the public till of late, and of late no more prominently

than the nature of my occupations has rendered indispensable. I am conscious, that weight of some kind is required to give to my observations stability against the midway tide of public estimation, and the force of the object borne upon its surface. Having lived in seclusion, it is not of course in the influence of a name this weight is to be found: I can look for it only at its proper source, namely, whatever of soundness there may be in my arguments, and of value in my experiments.

The revolution which Dr. Arnott would work in the opinions and practice of the public on the subject of ventilation, I believe to be, not undesirable only, but highly dangerous in its consequence; tending to make the visitations of epidemic and pestilential diseases far greater scourges than they are at present to our land: and, waiving even the question of ventilation, I am prepared, and therefore bound to show, that the instrument, which is the chief object of his work, is by no means the one best suited to the purposes it is intended for, and that the modified forms proposed for open fires, to which he returns at the close of the work, are singularly defective.

Wherever the point on which I am compelled to be at issue with the author is a question for reason, my argument is before the reader, and I submit it to his judgment: wherever it is one for trial, a disciple, though a very humble one of Bacon, and a keen experimenter, I call for an experiment.

As I purpose occupying my reader's attention upon those subjects only upon which I consider it necessary to comment, it will be allowable, and it will be conducive to brevity, if I take up these subjects in a different order. Accordingly, they will be discussed under the following heads:—

1. Ventilation in general. 2. Ventilating and warming by recovered animal heat. 3. Ventilating and warming by the aid of combustion. 4. Mechanical ventilation.

1. *On ventilation in general*,—viz. on the quantity of air desirable for man.

If the present state of the public mind is to be disturbed upon this highly important subject, it is of the greatest consequence that the disturbance should take place in the right direction.

The subject of ventilation is so much involved at all times with other questions

which force themselves before our view, demanding prior consideration, such as cold draughts, trouble and expense of warming air, mechanical difficulties, &c. that however rigidly we may commence our task upon right principles, we are in much danger of being forced from our principles, or of seriously compromising them, when the tide of such considerations sets in upon us.

In the commencement of his article on ventilation, while treating of it generally, Dr. Arnott lays down the grand principle of *abundance* in the supply of air, in language so forcible and just, that any reader would consider him the zealous advocate of a system of liberal and copious ventilation, as will appear from the following quotation, Art. 76 and 77, p. 57 :—

“The nature of man's breathing, and the conversion by it, of the pure air which is life to him, into foul air which is poison, have already been explained in Art. 10, as also the beautiful provisions of nature for ensuring the required supply of air; first, by the heating, and consequent rising into the atmosphere above, of air which has been breathed, to be replaced by fresh air from below; and secondly, by the never ceasing greater motions, called winds, of the atmosphere itself, which mingle the whole, and submit it to influences maintaining its general purity. These aerial movements are to man, what the constant gliding past of a clear river stream is to the fishes which inhabit it; and as certainly as we should destroy the trout of a stream by confining them in a small portion of their watery element, until it became a dirty, putrid puddle, or as we should distress and injure them by confinement and privation in a less degree, so do we destroy, or injure, human beings when we too closely confine around them a portion of their aerial element. The arts of life, and usages of society, have led, in many parts of the earth, to the practice of forming apartments, which thus confine the air; but because the air become unfit for breathing is still as invisible as before the change, and the cause of the consequent distress and disease is not obvious, it has been, and still is, in innumerable instances, allowed to continue working its fatal results, without awakening suspicion. Science, however, having at last detected the concealed destroyer of so much life, and

health, and happiness, the mass of the people are beginning to deal with it as it is befitting. A striking instance of popular ignorance with respect to this subject, and of mischievous practice, founded upon that ignorance, was to be witnessed very lately, if it is not still, in Buckinghamshire, among the poor girls who gain their livelihood by lace-making. To save the expense of fire, they were wont, in winter, to choose among the rooms belonging to their families the smallest, which would contain to the number of from twenty to thirty of them, and there to congregate, and keep themselves warm by their breathing. The odour of their breaths, though unperceived by themselves, soon became to a stranger exceedingly offensive. The pale faces, broken healths, and early deaths, of many of the ignorant self-destroyers, told to a better informed observer what they had been doing; but it was very difficult to convince themselves of their folly. Proving how much is yet to be done to inform the public sufficiently on this subject, I need only add, that even now, many schools, manufactories, churches, ball-rooms, courts of law, and other rooms of assembly, are, for hours together, in a state little better than the rooms of the lace-workers above described; indeed, sometimes in a worse state, as shown by the carrying out of persons fainting and half suffocated, and the cry among the company left for open windows. The scene of death in the Black Hole of Calcutta was the consequence of confinement, without ventilation, carried not very much further than has been witnessed, for a short time, in some voluntary English crowds.” And in Art. 77, the author proceeds to the same effect.

These passages should be written in gold. They are, in my humble opinion, by far the most valuable portion of the work. They may well place the reader's mind in a position of confiding security, that whatever Dr. Arnott shall write or propose in his details, an abundant ventilation is his primary object. Although this impression on the mind of his reader may be powerful and lasting, it nevertheless may be but of an indefinite kind. The facts, also, which he relates in the admirable passages quoted above, may not fail to influence the mind of the reader; and yet their influence may only be of a general cha-

rafter, unless he has paused well and measured carefully the quantities denoted by these facts. And it will appear presently that the reader is soon called upon, in our author's work, to admit arguments and adopt opinions of so different a kind, that, in order his judgment may not be offended by them, it is necessary that these first impressions should be only vague and general, involving no measurement of quantities. If the new doctrines to be acquiesced in had followed close upon the first,—if the matter in Art. 82, quoted below, had joined hard upon that in Art. 76, quoted above, while the reader was fresh from the perusal of it,—his mind could scarcely have followed the bias of the author's. In that case, he ought, upon coming on the new arguments, to start back upon the first, and to observe how irreconcilable was the one set with the other; but, unfortunately, the author is led from the grand subject of *quantity* of air suitable for man, into a long digression upon mechanical questions respecting the method of supplying air. Important as these questions are, they ought to have occupied another place. The too probable effect of this digression may be—nay, in order to make it possible for the reader to fall in with the new arguments, its necessary effect must be—such an occupation of his mind with mechanical subjects that it shall retain no more than general impressions upon the previous physical questions, especially if, confiding in his leader, he shall have neglected to study well his facts and the arguments connected with them. Thus, by reducing any clear and particular impressions regarding the quantity of air constituting wholesome ventilation into such as are but vague and general, the long digression from Art. 77 to 82 performs a sophistical part, though not intended to do so by the author: it serves as a bridge for carrying the reader gradually, and without a shock to his understanding, from the pleasant and airy ground he was first placed upon, to the very opposite side, as will now appear.

Art. 82, p. 66:—"There is, with respect to ventilation, a popular misconception and erroneous practice, of a nature the opposite of the total neglect described in the former paragraphs: because ventilation is important, there are persons, not satisfied with enough, but who demand, at heavy sacrifices,

what is excess. It would be a similar error, if a man, from knowing that water is a necessary of life, should abandon the never-failing well in his garden and his convenient home, that he might drink always from the Nile or the Ganges. A man needs, per minute, as explained in Art. 10, the oxygen of one-sixth of a cubical foot of atmospheric air; but, because of the mixture of his breath with the air around him, he requires, to be safe, a ventilation supply of from two to three cubical feet per minute. Now, the ordinary workmanship of house-builders in England, leaves, as crevices round the doors and windows, passage for many times three gallons per minute; besides, that there is the powerful ventilation of the frequent openings of the door when persons come and go. Yet there are in England many persons, who, under all circumstances, call out for open fires and open windows, and by the cold currents and other concomitants of a ventilation, twenty or a hundred times more than necessary, prodigiously waste fuel, and injure or kill their children and friends by catarrhs, rheumatism, pleurisies, &c. To these persons it must appear wonderful, that in Russia, where, all through the winter, there are only close stoves and double windows carefully closed, and no provision made for ventilation beyond accidental crevices, the people are very healthy, and more individuals attain a very advanced age than in almost any other country in Europe. In a room of 12 feet in all its dimensions, and containing therefore 1728 cubical feet of air, there is, without any ventilation whatever, an allowance of 2 feet a minute, for one person, for more than 14 hours."

This paragraph is perhaps the most influential in the book, on account of which, and of the doctrine it inculcates, it may be considered by far the most important. The reader who carefully studies each successive sentence, will perceive a gradually progressing departure in the mind of the author from that demand for copious ventilation expressed formerly, until he at last closes, by giving countenance to the Russian system of what we should call suffocation in England. Impressed with a conviction of the prodigious importance of a right settlement of the question upon which the author has agitated the public mind, I must request

my reader's attention to an analysis of each sentence in this paragraph.

"There is a popular misconception, and erroneous practice, of a nature the opposite of the total neglect described in the former paragraphs."

First, let us consider what is the thing here predicated, what is affirmed, by "the popular misconception, and erroneous practice." The popular misconception, and practice, is something which the people in general *think*, and *do*, in regard to ventilation. Now what they *do* in almost every house in the land, is to close the doors and windows in cold weather, allowing more or less leakage through the crevices, and to employ a fire under an open chimney, which, while it warms the apartment, excites such a steady and powerful draught in the chimney, as to ensure a pressure inwards of fresh air into the room at all the crevices; and what they *think* is, that this fresh air, if inconvenient, is at least highly salubrious to the majority of persons. This, then, is "the popular misconception, and erroneous practice." Again, in the former paragraphs, the "total neglect" of supplying air was not the only thing described; salutary ventilation was also described by comparing it to the constant flowings of a trout stream, and a copious supply of fresh air was contended for, by shewing how the fishes would perish if deprived of this wonted supply of their native element. If illustrations mean any thing, if a long line of argumentation means any thing, the "misconception, and erroneous practice" of the people of England is a demand for, and a command of, a quantity of fresh air in their dwellings, which does, in reality, fall far short of the quantity advocated in those former paragraphs. It is next said, "because ventilation is important, there are persons not satisfied with enough, but who demand, at heavy sacrifices, what is excess." It was formerly argued in those paragraphs, not that ventilation only was important, but that *copious* ventilation was so; the "enough" ought then to be understood as meaning such copious ventilation; but "the demand, at heavy sacrifices, for what is excess," means, by the whole context, only that demand which is usual in England, namely, the common quantity which enters by the crevices, and passes up our chimneys. If the copious ventila-

tion contended for at the beginning of the chapter, meant a less quantity even than this, to what purpose was the strong language there employed, and the still more striking illustrations? Again, as the author is, throughout, contending against things which are popular and general, and not merely against individual cases of eccentricity, it is a great pity that the poignancy of the doctrine now enforced against the usual supply of fresh air, should be softened down by employing the expression, "there are persons not satisfied with enough;" instead of saying, "the people in general are not satisfied with enough." By the latter expression, the reader would at once perceive that the ordinary quantity of air which it has been considered wholesome to let into our houses in the usual way, namely, through the crevices, aided by the chimney draught, is the quantity which he is here required to consider as excessive; so excessive, indeed, that the following comparison is employed to set it forth:—"It would be a similar error, if a man, from knowing that water is a necessary of life, should abandon the never-failing well in his garden that he might drink always from the Nile or the Ganges." The using of this comparison is no other than begging the question. Let it first be shewn by right reason and rigid experiment, that the air we are accustomed to let into our rooms bears a proportion to that we need, even as large, as does the water in a never-failing well to the little that a man can drink. The experiment may appear not practicable, but it is, in fact, being made every day by thousands; and it tells wonderfully against the author's comparison and argument. A man very soon drinks to satiety, and can take no more with benefit: any more water is useless, or injurious to him at the time. The quantity of air a man breathes has also its limit, but there would seem no limit to the quantity of fresh air* which is beneficial, as is proved by every comparison between those who occupy themselves within doors, and those whose occupation is in the open air. All the air, therefore, we ever have at

* The care to have it warmed when it is to be enjoyed within doors, is quite another question; and I engage to present the public with apparatus which shall effect this thoroughly and with abundant economy, and no over-heating of the air.

any one time entering our houses, falls short of the quantity which can do us good; but the water entering a never-failing well greatly exceeds the quantity which can do a man good at any one time; so that the air entering our houses falls short in comparison with the water of a never-failing well even, and how incomparably short of a Gangetic or Nilotic ocean. Before such a comparison had any reality in it, it would be needful to shew that the people of England had left the insides of their houses to live upon the house-tops, or in open sheds. The author proceeds—"A man needs, per minute, as explained in Art. 10, the oxygen of one-sixth of a cubical foot of atmospheric air; but, because of the mixture of his breath with the air around him, he requires, to be safe, a ventilation of from two to three cubic feet per minute. Now, the ordinary workmanship of house-builders in England, leaves, as crevices around doors and windows, passage for many times three gallons per minute; besides, that there is the powerful ventilation of the frequent openings of the door when persons come and go."

I will remark upon the latter part of this sentence first: since cubic feet have been, throughout, the term employed by the author to measure the air by, and, as he had just said, "from two to three cubic feet were needed," it is a pity that the expression "many times three gallons" should have been used, when the actual supply was being spoken of, for the argument would lead a reader to suppose that many times three of the first measure were being promised him; and, unless watchful, he would overlook the new term "gallons." It is therefore to be regretted that, having commenced the argument in *cubic feet*, the author should have closed it in *gallons*. Now, a gallon being barely the sixth part of a cubic foot, many times three gallons may still be under one time three cubic feet. The quantity must exceed four times three gallons, or it will be under two cubic feet even. What the leakage really amounts to, in any one case, or whether the author meant cubic feet, and not gallons, as the measure of it, it is not possible to form any judgment of, without knowing what crevices there are, and what the pressure from without is. The quantity of air entering will vary according to the form and collec-

tive amount of all the crevices by which it is entering the room, and the facility by which it can pass out again, and also according to the square root of the difference between the external and internal pressure. In how disadvantageous a light this law places Dr. Arnott's stove, when compared with open fires, will be shewn hereafter. In the former part of the passage just quoted, reference is made to Art. 10 of the work, where we find it stated:—"In respiration or breathing a man draws into his chest, at one time, about twenty cubic inches of air, and of that a fifth is oxygen, of which again there is converted into carbonic acid gas nearly one-half." To suppose that the lungs employed so much as one-half of the oxygen of the air of ordinary respiration would be to familiarize ourselves with the idea that our lungs are tougher-working organs than they really are; and it might be argued by some, if they can endure to retain air in their vessels until one-half of its oxygen has been vitiated, they cannot be very sensitive,—very needful of perfectly pure air; whereas, if only one-sixth or one-eighth of the oxygen of the air we inhale is employed—if the air vessels, which the air of our ordinary respiration traverses, reject and have done with air, of which, being so delicate, they can only make use of this small quantity; how very pure ought the air to be in the first instance! I am aware of the experiments, on record, of able chemists, showing that, while in the chest, air loses from a fourth to one-half of its free oxygen; and from these, it is to be presumed, the author has drawn his information. If he had afforded the subject more attention he must have been led to draw a distinction between the two very different conditions in which the air in our lungs is. One, and by far the larger portion, is that which is deep seated, occupying the finer ramifications and extremities of the air vessels; its quantity varies, probably, from 100 to 200 cubic inches. With this air the lungs are more or less distended during life; and it manifestly must undergo but a very gradual renewal; for, since a very little of it only is discharged with the air of each respiration, very many acts of ordinary respiration must be performed before this air can be changed. If *this* air should be breathed out into a vessel, I have no doubt that one-half

of the oxygen it had contained would be found converted into carbonic acid; and, I imagine, that it must have been upon this deeper-seated air, which comes forth only by a forced expiration or sigh, that the experiments referred to have been made. Indeed, for the purpose of catching a quantity of the air from the lungs, it is highly probable that a long and deep expiration was practised in those experiments, which were doubtless very correct; but which cannot rightly be applied to the air of our present question: this last air is in a very different predicament; being changed at every ebb and flow of each act of respiration, it is but a short time in the chest, and appears only the upper part and the larger vessels. In quantity it may not exceed from 15 to 25 cubic inches, and it is *this* air, of course, which, being the air of ordinary respiration, is that of which the author is treating.

At his low estimate of fifteen respirations in a minute, about 300 cubic inches of air would be breathed each minute, or nearly 93 grains in weight; and in 24 hours, 133,920 grains, of which, the oxygen would amount to 31,471 grains; if half of this, or 15,735 grains, were converted into carbonic acid, it would require fully three-eighths of its weight, or 5900 grains, of carbon to combine with it, in order that it should be converted into that acid. Now, taking our driest food, bread, even it has so much moisture and other elements in it, that we shall find it does not contain, as it comes from the oven, more than about one-fifth of its weight of pure carbon. A quartern loaf, therefore, may contain about the above quantity, 5900 grains of carbon. In order, then, to supply the carbonic acid generated in his lungs, at the rate stated by the author, a man would have to eat a quartern loaf daily, for this purpose alone, in addition to all the food necessary for his nutrition, and to supply the ordinary excretions of the body; and fearfully rapid would be the emaciation of those whose appetites fell short of such voracity! Had such an out-going of carbon been really necessary for our existence, we should certainly have been constituted, like the termites, or white ants, of the tropics, with appetites to enjoy, and powers to digest, ligneous fibre itself; otherwise, a man's whole labour devoted to tillage would barely

supply him with the primary necessary of life alone. All civilization and philosophy would be sacrificed to a furious and unproductive out-breathing of carbon. The author proceeds—

“Yet there are in England many persons, who, under all circumstances, call out for open fires and open windows, and by the cold currents, and other concomitants of a ventilation twenty or a hundred times more than necessary, prodigiously waste fuel, and injure, or kill, their children and friends by catarrhs, rheumatism, pleurisies, &c.” Open fires are one thing, and open windows another. I confess myself to be a warm advocate for open fires, (though I would have them employed in a different manner) but I do not know of any persons, who, under any circumstances, excepting, perhaps, to sweeten a house of a morning, call out for open windows from the month of October, at least, to that of April; and under certain circumstances only in the summer. It is, indeed, a pity that the author should connect together so very different desires, as that for open fires, and that for open windows; and by the help of an alliteration, by repeating in the reader's ear the sound of the epithet open, should endanger in his mind such a connecting of the two, as would charge the one with the absurdities of the other. Is it the ordinary ventilation excited by open fires through the crevices of *closed* windows and doors, or is it a ventilation unheard-of elsewhere, through windows thrown open, which is said to be so prodigiously more than necessary, and so destructive to the public health? It were far better for the subsidence of error in the public mind to let the subject rest, than to handle it in such a manner: the continuance of any existing error were preferable to that which must arise from interweaving two very different categories—a state of things with open fires, and that with open windows, in such a manner, as that the former shall have to bear, by the implication, accusations which could with justice be applied only to the latter. Of the healthiness of country children, accustomed to ill-fitted doors and windows, I shall presently have occasion to speak; but who ever heard of sitting with windows thrown open, excepting in the dog-days? The context throughout, and the whole drift of the argument, clearly mean, that the

ventilation which prevails universally in England in our houses, is exorbitantly great, and the cause of all these diseases. The usual method of supplying untempered air through crevices only, is a practice no one can more earnestly desire to see altered than myself, as the public will in due time be satisfied; but while I would greatly desire a change in our system of ventilation, I would increase rather than diminish its quantity, convinced that these (the diseases of our climate) arise, in the great majority of cases, from that *occasional* and *unaccustomed* exposure, against which it is almost impossible to be always on our guard, but against the effects of which all our experience proves that we are rendered less and less susceptible, in proportion as we accustom ourselves to a more and more frequent renewal of the air in which we live; and there is no reason why it should not be renewed with tempered air; but in that case I am prepared to show that the thermometer stove is an apparatus by no means well calculated for the purpose. Of this, however, hereafter, under its proper head.

[To be continued.]

THE RESULTS OF TAPPING THE HEAD

IN NINETEEN CASES OF HYDROCEPHALUS.

To the Editor of the Medical Gazette.

SIR,
NEARLY *ten* years having elapsed since I was first induced to attempt the cure of chronic hydrocephalus by withdrawing the fluid from the ventricles, the time seems to have arrived when the profession has a claim on me for some account of the results of these operations; and, indeed, this has become necessary, in consequence of the numerous applications for information on the subject by practitioners, not only in Britain, but in many distant parts of the world. Still, it is a matter involving such important considerations, that until experience has thrown much more light upon it, I do not feel justified in advancing any thing beyond the mere statement of facts, such as the present position of my inquiries warrants, leaving to a future day a more methodical and full inves-

tigation of the origin, nature, and progress of this formidable disease, with its appropriate medical and surgical treatment.

The operation consists in passing a small and delicately constructed trocar into one of the lateral ventricles, and drawing off so much fluid as the powers of the constitution will admit of. The most eligible spot at which the trocar can be introduced, is in the course of the coronal suture, about midway between the crista galli process of the ethmoid bone and the anterior fontanel, so that the danger of wounding the corpus striatum is avoided on the one hand, and the longitudinal sinus on the other. The instrument usually penetrates about two inches, and in most cases the serum has been colourless, but occasionally tinged with blood. In one instance, and that was in the last child operated on at St. Bartholomew's only a few weeks since, a large and alarming quantity of florid blood escaped; most likely from a branch of the meningeal artery. Sometimes on withdrawing the trocar the water will not flow until a probe has been passed along the canula to remove portions of cerebrum which block it up. After taking away all the fluid that can be removed consistently with safety, the head, which should always be steadily compressed by an assistant during the operation, may be strapped with adhesive plaister, that it may retain its diminished size, and that the fearful consequences of suddenly removing long-continued pressure from the brain may be averted.

I have now tapped in *nineteen* cases, and of these *ten* were living when last heard of. Several of the children, before the operation, were reduced to the most deplorable condition, having frequent convulsions, with loss of sight, emaciation, &c.; but the diminution or disappearance of these symptoms has been very remarkable. In some cases the results have been triumphantly successful; in others, from the reluctance of the patients to have the operation repeated, only temporary relief has been afforded; but none of these children died either during or immediately after the operation, and those which, in the subsequent list, are reported as dead, survived weeks or months after the fluid was withdrawn.

All the operations were performed in

the presence of many medical men, and most of them before large bodies of students at St. Bartholomew's Hospital, and their progress has been watched by gentlemen who have felt a deep interest in their termination; and although exclusive dependence has been placed on the withdrawal of the fluid without the auxiliary assistance of any pharmaceutical or other medical means, yet I consider much of the success to be attributable to the kind and able superintendence of medical friends.

Having long entertained a conviction that this deplorable disease ought not to be left without something being done for its relief and cure, and not discouraged by the want of success that had followed similar attempts, and considering "*anceps remedium melius quam nullum*," it was in the autumn of 1828 that—

The *first* operation was performed, on Catherine Seager, aged 20 months, whose head had been gradually enlarging during the previous half year. Not more than two ounces of serum flowed; but on a probe being passed into the ventricle (by Mr. Harvey, of Islington), when the child reached home, a considerable quantity of fluid escaped *stillitio*, so that during the night it was calculated that the saturated bandages and napkins could not contain less than two pints. Only one paroxysm of convulsions followed the operation, and some symptoms of meningeal irritation which supervened were speedily subdued by leeches and cold evaporating lotions. Two years and a half subsequently I had the high gratification, in company with some friends, to see this child, when the parents left England for America, and it was not only in perfect health of body, without the slightest evidence of its having been the subject of so formidable a disease, but in the full possession of its intellectual powers.

The *second* case was that of William Honey, aged 8 months. The enlargement of the head had been perceptible about six weeks, and on the 20th of November, 1829, I tapped him, at St. Bartholomew's Hospital, and withdrew twelve ounces of colourless serum from the right ventricle. On the 2d of December, twelve ounces more were withdrawn; and on the 16th an additional ten ounces and a half: making the total

quantity thirty-four ounces and a half. This child was progressing most satisfactorily when it became the subject of whooping-cough, to which intractable disease it fell a victim some months after the last operation.

The *third* operation was performed on William Wilmer, a boy now (March 1838) under a course of education in the Orphan Working School, City Road; nearly *eight years* having elapsed since twenty-four ounces of water were taken away by twice tapping him. The history of this interesting case has been given by Dr. Caldwell, of the City Dispensary, whose patient he was. That the account may be authenticated and impartial, the following statement is an extract from that communication:—"William Wilmer, aged 4 months, came under my care in the month of July 1830. His head was of an enormous size, and had been so from its birth: the forehead was large and prominent; his eyes heavy, and somewhat convulsed; frequent hiccup and vomiting, &c. Several gentlemen had seen the case, and they all gave it up as hopeless. In the beginning of August Dr. Conquest performed the operation upon this child, and immediately the fluid issued forth in a stream, at first clear, and afterwards a little tinged with blood. During the remainder of the day the child continued rather weakly, but was more lively than he had ever previously been, and for some time afterwards the intensity of all the former symptoms greatly diminished. When a month, however, had nearly elapsed, it was considered requisite to repeat the operation, and on the 3d of September Dr. Conquest again extracted a clear liquid, to the amount of twelve ounces more. The child sleeps well, eats heartily, is very lively, and in full possession of all its mental faculties.

"(Signed) H. S. CALDWELL, M.D.

"September 6, 1832."

Amongst other things mentioned in the paper from which this extract is taken, is the curious fact, that the head, which was so enormously large at the time of the operation, remained stationary, although the size and strength of the body has gradually increased in proportion to the age of the boy; and now that nearly eight years have elapsed, the head, although dispropor-

tionately large, remains at about the same dimensions.

The *fourth* case, that of Elizabeth Forster, is referred to with more than ordinary interest, not only because it is the one from which the largest quantity of water was extracted (no less than fifty-five ounces), but more particularly because I had lost sight of the child for years, and thought it was dead, until, in September last, I received the following most gratifying communication, which I transcribe entire, as it will convey all necessary information of the case:—

“Dear sir,—Being lately on a visit in Buckinghamshire, I was enabled, through the kindness of Mr. Cowley, of Winslow, to see the child, Elizabeth Forster, residing at Little Harwood, on whom you performed the operation for hydrocephalus about five years since. Her countenance and general appearance are healthy, her appetite good, and her rest at night undisturbed; she has been attending a school in the village, where her progress has been equal to that of the other children; she answered questions which I addressed to her on this and other subjects, with a shrewdness for which her governess says she is remarkable. The greatest circumference of the head is twenty-two inches; the ossification is complete, with the exception of the posterior fontanel, and two other openings of the same size, two inches apart, on either side of the medial line, in the course of the coronal suture. Her mother shewed a lively sense of gratitude for the benefit she has experienced under the treatment to which you had subjected her.

“Yours, &c.

“FRANCIS COOK, M.D.”

It would be useless at present to detail the particulars of the other fifteen cases, as all that is important to be known will be found in the summary given at the end of this communication, and from which it appears that, of the nineteen children operated upon, ten were living when last heard of, and nine are dead; but it is only fair to state, that as most of these children were amongst the lower classes of society, who are continually changing their residences, several have been lost

sight of, and may now very probably be dead, although when last seen, some time subsequently to their having been operated upon, they were living.

Of course these operations have been attended with different degrees of success. Unquestionably some are cases of perfect recovery; but in every instance there has been a very marked diminution of suffering, and prolongation of life, and in no one case has a fatal termination been accelerated.

Dr. B. G. Babington has analysed the fluid with great care, and states its specific gravity to be 1004. It does not coagulate by heat, acids, or alcohol, and consequently does not contain albumen. Tincture of galls produces no immediate precipitate, but after standing some hours a few brown flocculi subside, proving that it contains a very little gelatine. On evaporation, 1000 grains yield 10 grains of solid matter, chiefly chloride of soda, proved by precipitation with nitrate of silver. The liquid therefore contains, in 100 parts—

Water.....	99
Gelatine.....	1
Chloride of soda	845
Other salts and loss	055
	<hr/> 100.000

In no instance has clearly marked congenital disease been permanently benefited, and those cases have done best in which effusion manifestly resulted from inflammatory action, and in which cerebral excitement followed the operation. The number of cases tapped, with the quantity withdrawn, will be seen in the tabular summary which concludes this brief notice of the subject. [*vide next page.*]

I feel no ordinary pleasure in thus simply recording the progress of my investigation of this momentous and interesting subject, and shall be most happy to receive from my professional brethren any suggestions that may assist me in attempting to diminish this one source of human suffering and death.—I am, sir,

Your obedient servant,
J. T. CONQUEST, M.D.

Finsbury Square,
March 1, 1835.

ON THE ANATOMY OF CERTAIN
STRUCTURES

IN

MYRIAPODA AND ARACHNIDA,

WHICH HAVE BEEN THOUGHT TO HAVE
BELONGED TO THE NERVOUS SYSTEM.

To the Editor of the Medical Gazette.

SIR,

THE communication of Mr. Lord, in the last number of the GAZETTE, respecting a structure observed in the centipede, *Scolopendra morsitans*, is one of particular interest, since the fact stated by him has immediate application to the controversy now pending between Dr. Grant and myself; this structure being that which Dr. Grant has hitherto described as the *true motor* tract, and which has also been considered by myself as analogous to the transverse nerves of lepidopterous insects. It now appears that the analogies between these different structures in Invertebrata, had not been correctly ascertained.

I had, however, long ago suspected that the structure in question in the centipede, and an analogous one in the

scorpion, did not in reality belong to the nervous system, and have stated my opinions, and shewed my preparations to many friends, but have been withheld from publishing them in consequence of my investigations of those structures forming part of a yet unfinished series of observations on the vascular system of invertebrated animals. I had not, however, traced the direct communication between the dorsal vessel in the centipede and the structure in question (*e*), which may be called the *supra-spinal vessel*, analogous to one in a similar situation in Crustacea, as described by Dr. Edwards. In addition to Mr. Lord's description of this vessel in the centipede, I must state that the central artery or continuation of the dorsal vessel on the upper surface of the œsophagus gives off a pair of branches almost immediately behind the brain, and these pass outwards behind the two lobes, while the middle artery is continued beneath the brain, as in insects and other Articulata. The branch described as originating at the side of the œsophagus from the *lateral communicating arches*, between the heart and supra-spinal vessel, passes forwards to the anterior part of the second segment, and then divides into two branches; the first

of which passes outwards, and enters the inner side of the base of the mandibles, while the other runs to the middle of the head, and passes beneath the muscles of the anterior part of the mouth and antennæ. From the posterior part of the communicating arches there appears to originate a branch, which I consider as the commencement of a venous lateral trunk; while the small branch which arises in the median line, on the anterior part at the junction of the arches, on the nervous cord, passes forwards to the first sub-œsophageal ganglion, and then divides into two branches, which proceed to the base of the antennæ. It was the course of these branches that first led me to suspect that this structure was not part of the nervous system.

I have now to state, that the structure which lies upon the nervous cord in the scorpion, *Scorpio afer* and *S. Europæus*, belongs also to the vascular system. I was first led to suspect this in the scorpion from this structure being always contracted irregularly in its course, being sometimes compressed from side to side, and sometimes flattened, and lying on the nervous cord, like a ribbon, and from its tearing, transversely, like a vessel, very easily; but was recently confirmed in this opinion on finding it was hollow, and often partially filled with granulated matter, and I have since more completely made out its anatomy and vascular nature.

The dorsal vessel or heart (*b*) in the scorpion may be said to originate from the superior caudal vessel (*c*), which runs along the dorsal surface of the tail to the base, gradually enlarging in its course, and giving off in each caudal segment a pair of lateral vessels (*l*), which pass around the sides of the tail, and anastomose beneath each ganglion of the nervous system, with a vessel (*f*) beneath the cord (*d*), and which I shall presently describe as the *sub-spinal vessel*. The heart or true dorsal vessel consists of distinct chambers, furnished with valves*, and runs along the dorsal surface of the body as far as the posterior margin of the cephalo-thorax (*a*), where it descends very suddenly upon the œsophagus, and spreads out behind and above the great ganglion into three pairs of branches,

and one single central one, which becomes very small, and runs along the median line of the œsophagus to the anterior part of the cephalo-thorax. The other vessels are again divided and given to the surrounding limbs. The second pair of these vessels appears to pass around the œsophagus, and unite beneath it in a sinus just posterior to the great ganglion, and from this the supra-spinal vessel (*e*) apparently takes its origin. It then passes under a bony arch in the cephalo-thorax, unto which it is so strongly attached, that it was considered by Professor Müller as a ligament. After this it pursues its course, gradually decreasing in size, as noticed by Dr. Grant, along the upper surface of the cords, as far as the terminal caudal ganglion, and appears to end in two small branches, which seem to take the course of the terminal nerves of the cords. Throughout this course it sends down from its under surface, both anterior and posterior to each ganglion (*e k*), between the nervous cords, a branch, which unites beneath the cord with another vessel (*f*) the *subspinal*, but which I am not aware has hitherto been noticed in the scorpion, although a similar one was noticed by Duges in the leech, and called by him the *subnerval*. I have been unable to trace this vessel to its origin in the cephalo-thorax, where I first observed it, and from whence it is continued along the under surface of the cords to the caudal ganglion. Beneath the first abdominal ganglion it gives off a branch which passes backwards along the middle of the under surface of the abdomen until it meets and anastomoses with a vessel which runs transversely across the body (*g*), and pursuing the course of the nerves, from the first abdominal ganglion, is distributed on each side to the base of the respiratory sacs; a similar transverse vessel is given off from the subnerval beneath the second ganglion (*g*), in the course of the nerves to the respiratory sacs; and a similar one beneath the third ganglion, which is distributed in like manner; while another single vessel also originates from the subnerval beneath the third ganglion, and passing forwards into the integument of the abdomen, divides into two equal trunks, which, like the preceding vessels, are given to the respiratory sacs. In the tail of the scorpion the subnerval vessel also gives off a branch

* Not figured in the drawing.

beneath each ganglion, which unites, as above stated, with a branch from the superior caudal vessel (*f/c*), or origin of the heart. Judging from the peculiar distribution of the branches of the subspinal vessel to the respiratory sacs, I am inclined to regard it as the true portal or venous trunk, and the

supra-spinal, to judge from its direction and direct continuity with the heart, as an aortal or arterial trunk. The blood, after being aerated in the sacs, is returned to the heart by four sets of vessels, which originate in the pulmonary sacs in small branches, and which, having formed distinct trunks, pass directly

ON THE ERUPTION ATTENDING
EPIDEMIC FEVER*.*To the Editor of the Medical Gazette.*

SIR,

SINCE the attention of the medical world has been directed to the exanthematic nature of what is called petechial eruption in continued or typhus fever, almost all the practitioners who have had the opportunity of observing such epidemics acknowledge a peculiar spotted appearance of the skin taking place in the first week of the disease, exhibiting spots of different colour, size, firm, and number, according to the different character of the epidemic, the age and constitution of the patient, the time which the spots themselves have existed, &c.; but having all the common character—that they disappear on pressure, or that they consist of a simple turgescence of the capillary vessels in the points in which they are seen. It is a matter of indifference whether we call them fever eruption, typhoid eruption, roseolæ, measles-like spots, and so on. I feel myself convinced, by a special attention which I have paid to the subject from 1833, when I first had the opportunity of observing an epidemic typhus, while attending the dispensary practice of the well-known clinical school in Halle, down to the present time—having attended the fever wards in Vienna for a few months, the Parisian hospitals for almost a year—having visited the fever wards of Birmingham, Manchester, and Liverpool, for a few days, attended carefully the Dublin hospitals for three months, and until this day the fever hospital of Glasgow (as often as my health allowed me) during two months—that, from the pale or rose-coloured spot (macula), which is called in France *tache typhode*, *éruption typhode*, to the papular spots, which have deceived even experienced practitioners at first sight, taken by them for measles, there is a regular gradation, that all degrees are observed, occasionally, in the same epidemic or endemic fever, but that there is no doubt, although, that either may be at one time the rule, and at another the exception.

from the sac to the inferior lateral surface of the heart. I suspect that there are also two lateral venous trunks; but these I have not satisfactorily traced.

These structures find analogies in insects and other Articulata. In perfect lepidopterous insects there is a large spinal vessel lying upon the abdominal portion of the cords. This was first noticed by Lyonet, but not as a vessel, in his posthumous publication, 1832, p. 595, (plate 52, fig. 18; and 54, fig. 2); and subsequently by myself, in the *Phil. Trans.* 1834, p. 395, plate xiv., fig. 9 (a). This is evidently the supra-spinal vessel. Duges, as above stated, shewed an infra-spinal vessel in the leech; but there exists also a supra-spinal, and I regard the like to exist in Myriapoda, although not distinctly traced.

These facts will prove that the supra-spinal structures in myriapods and arachnidans belong to the vascular and not to the nervous system, and controvert the opinion entertained by Dr. Grant, who regards them as the *motor* portion of the nervous system; while, I trust, they will tend to establish the opinion I have advanced, that the true motor structures in these classes consist, as described in my paper, 1834, of a series of fibres which form part of the longitudinal cords, and pass directly over the ganglia in all the classes.

I remain, sir,

Your obedient servant,

GEORGE NEWPORT.

10, University Street,
March 6, 1838.

* As there is some peculiarity of idiom in this paper, it may be proper to keep in mind that the intelligent author of it is a foreigner.—ED. GAZ.

† In an account of the epidemic typhus of 1833 in Halle (J. Staberoh, de typho exanthematico Halis epidemico: Halis, 1834), I was induced so to call the form, which I always observed.

In like manner the course which those spots follow differs in length, development, and termination. Sometimes they disappear in a few days; sometimes they become livid, and remain so until they disappear, or they become red again; sometimes they disappear while yet pink-coloured, and so on: but I must repeat that they continue to fade on pressure until they disappear.

The spots observed by Hildenbrand, Reuss, Bischoff, &c., and recently by Peebles, Perry, and many other medical authors, are described as following this course; and I may add, in the epidemic of 1833 above mentioned I never saw another termination.

What is called *Petechia vera* (*purpura*, Willan) are ecchymoses of different sizes in the rete mucosum, of which we have the best example in the *purpura hæmorrhagica* of Werlhof. We may compare them to flea-bites, because the resemblance is often very striking. Those spots were supposed until now, by a great many practitioners, to have characterized the typhus epidemics, which afflicted more or less, in the beginning of this century, all the countries which were the theatres of the French wars, and I refer to the very numerous accounts given of them in Germany (of which I have quoted in my thesis those alone who paid more or less attention to the existence of an exanthematous eruption). Many very accurate observers describe them as being petechial (*purpura*, Willan). Others, and I may refer to the most valuable paper of Dr. Peebles, in No. 125 of the *Edinburgh Medical and Surgical Journal*, suppose that those authors have been mistaken, and that they overlooked the circumstance that the true petechial spots (*purpura*, Willan) occasionally appeared among the exanthematous spots in the latter stages of the fever, depending upon the state of the skin, the general constitution, and the treatment, &c.* and appear to be convinced that those practitioners observed epidemics of continued fever similar to those which we see at this time. No person that my very learned and highly-esteemed friends in Glasgow, nor I, are aware of, mentioned a change of the first described exanthematous eruption into petechial spots—into spots which do not fade on pressure—a stage which I may

be permitted to call exanthematous petechiæ (ecchymotic state of the exanthematous spots). Dr. Peebles (*l. c.* p. 10), I understand, denies this change positively; and in the thesis above quoted, p. 30, I said, speaking of the roseola spots sometimes becoming livid—"minime vero, hic petechias me vidisse, quis suspicetur, quum macule hæcæ semper digito prementi cederent, ac circa eas rare apparerent, petechiæ veræ, colore ceterisque criteriis plane ab iis discrepantes."

But although I am satisfied that I was not mistaken with regard to those observations, which, however, were made in an epidemic of small extent, I shall be most happy to show to any man who will accompany me, for two or three days, into the wards of the Glasgow fever hospital, the above-mentioned change of the exanthematous spots into the petechial—into spots which do not fade on pressure—taking place in many cases of well-marked exanthematous eruption. While studying the fever in the Dublin hospitals I supposed this to be the case, and I think I mentioned it to my learned friend, Dr. Robert Law; but as I am not certain how far he approved of this opinion, I cannot avail myself of his authority: but in Glasgow, attending the same cases every day, and comparing the state of the eruption with great care, I found that petechial spots (which did not fade on pressure) were to be seen to-day in cases, were the day before exanthematous spots, fading on pressure, of the same form, and almost of the same colour, existed. This struck me, and I mentioned it to my very learned and very kind friends, Dr. Anderson (the physician of the fever hospital) and Dr. Cowan, who has favoured the medical world with the valuable pamphlet on "Statistics of Typhus Fever," partly the result of his attendance in the same hospital in 1836. Both acknowledged the possibility of the above-mentioned change, but they told me that they had never ascertained it. Hence I adopted, as well in their presence as in the presence of my kind companions, Mr. Carey and Mr. Stewart, clerks of this mentioned hospital, the following method to bring it to the proof. When I saw that, in a case of well-marked exanthematous eruption, some of the spots faded but slowly on pressure, while others disappeared easily (instantly); or

* I need not say that I observed also, repeatedly, this phenomenon.

when I found some of the spots not at all disappearing, but merely differing by a deeper shade of brownish red from the others, which still faded, I surrounded a certain number of these yet fading spots with a circle of dark thick ink, (better still with the nitrate of silver,) and I could, almost in every case, prognosticate with certainty that some of the marked spots would not disappear on pressure the next day, or the day after. It was always necessary to mark a number of spots, in which I supposed that the change would take place; as, very singularly, the change of one did not injure that of the others; and while I found that some of the marked spots became petechial, others continued to disappear on pressure, and followed the course formerly described, of a true exanthema, like measles and scarlatina. Yet, if I was not mistaken, I saw some of the spots, which became dark and faded but slowly to-day, regain a lighter colour, and fade promptly on pressure the next. Hence, by marking but two or three spots, I was very often disappointed, as the expected change did not take place in them, although the lividity or brown colour, &c. of the spots seemed to promise the success of the experiment. When the exanthema was very prominent, those pseudo-petechiæ preserved almost, I may say entirely, the same elevation above the skin*. But as to the relation of this change to the state of the patient, of the fever—as to the proportion between the different forms of exanthema—as to the relation of the exanthema in general to the epidemic at last, as to the comparison of the epidemic in Great Britain, Scotland, Ireland, France, and Germany; although I collected a great many striking facts, I'll not abuse the patience of my reader.

Professor Badham, before whom I had the honour to lay some of my observations, replied to me—"Well, but I hope you have not yet adopted any conclusion;" and certainly if there is any part of medical knowledge where the young practitioner gains, by cautious and repeated observation, it is in forming an opinion on essential (nervous) fever. I wish only to add, that the change of the eruption observed in that fever which I saw here (and I cannot speak, of course, of other epidemics with certainty until

I extend my observations,) strongly supports the idea, that the ancient authors, so remarkably well appreciated by Dr. Peebles, observed epidemics of continued fever of a character very similar to what we now see, both in this country and in Ireland. Further, that they may easily have overlooked the change of exanthematous spots into petechial, especially when the type of the epidemic caused it to take place in the earlier stages of the fever, as I think I saw it more than once the sixth or seventh day after the eruption of the spots; before attention was directed to the exanthematous nature of the spots by medical men, who observed epidemics, in which the appearance of petechial spots among the exanthema (or, perhaps, the change above mentioned also) was but the exception; as even until now it has not been proved by observers, in whom the medical world has the greatest confidence. I conclude these remarks with a few characters which could, perhaps, serve to distinguish the second (ecchymotic) stage of the exanthema (which may be partly a mere expansion of the capillary vessels), the exanthematous petechia, from the primary ecchymotic petechia (purpura) where they are found together; although I admit that, in many instances, only the complete attendance of the case, but particularly the experiment above mentioned, enabled me to distinguish them.

Purpura has its seat in the rete mucosum Malpighii; touches, at most, the level of the skin, but never rises over it: its colour has a well-marked blue shade in the red-brown, hence is the name purpura very striking. When examined with a powerful lens the colour is more or less uniform, although, especially some time after the appearance, paler towards the circumference. I may describe it as circumscribed by a well-marked edge*.

* I think I may ascertain it by very like casts taken by Dr. Paterson with his well-known dexterity.

* This condition of the purpura was most marked in a case of small-pox, in which the eruption receded a most entirely the third day. Purpura, as well as its larger variety, vibices, appeared throughout on the skin, and the conjunctiva appeared dark bluish red, purple, from extended ecchymoses, an appearance of which I have been favoured with a very good drawing by my friend, Mr. Anderson, clerk of the Royal Infirmary. The patient died the second day after the appearance of purpura, and on examining the body we found ecchymotic spots in the lungs, the stomach (my esteemed friend, Dr. Paterson, took a beautiful cast of it—the mucous coat appeared as well spotted as the skin in purpura hæmorrhagica).

The exanthematous petechia is always to be seen on the level of the epidermis. When the exanthema is very prominent, the corresponding petechial spot retains almost the same elevation—(further investigations are required); and on examining it with a lens, a granular appearance of the spots is observed, exhibiting an aggregation of more or less elevated brown red points on a paler ground. This dark red-brown colour has scarcely a shade of blue, and the edge of the spots is not so distinctly circumscribed as the purpura spots, which is easily ascertained by examining it with an armed eye.

JULIUS STABERON, M.D.
Of Berlin.

50, North Albion Street, Glasgow.

CASE OF HYSTERIA.

To the Editor of the Medical Gazette.

SIR,

FULLY conscious that the pages of your valuable journal are ever extended for the reception of aught that can benefit science or meliorate human suffering, I am induced to offer the subjoined curious case of Hysteria for publication in your columns, should your estimation of its merits entitle it to the favour.—I am, sir,

Your obedient servant,

JOHN JACOB,

Resident Medical Officer, Farringdon General Dispensary and Lying-in Charity.

March 12, 1833.

CASE.—On the 3d of September, 1834, I was requested by a gentleman to visit his daughter, a young lady, æt. 20, of rather pre-possessing appearance and

delicate constitution; the history of whose previous state of health I ascertained to be as follows:—She had been the subject of habitual constipation, to a great extent, two or three weeks having frequently elapsed without her having had any dejection from the bowels (an occasional head-ache, or nausea, being the only effects till then experienced). She evinced a somewhat capricious disposition, easily acted on by trivial causes. The catamenia had been little, if at all, interrupted; leucorrhœa had been more or less present for above a year past; her present suffering consisted (according to the notes I then took) of symptoms resembling those characteristic of colic—such as acute pain in the region of the left hypochondrium, extending towards the umbilicus; contractions of the abdominal muscles; costiveness; no febrile excitement; animal heat somewhat below par; tongue furred, but moist; pulse nearly natural; excretion from the bladder considerably diminished, &c. Notwithstanding these symptoms, I entertained some doubt as to the future progress of the case, and was therefore resolved to use much caution in its treatment. I merely, at first, cleared out the alimentary canal, which was not effected without some difficulty. The pain continuing for two days, and pressure on the abdomen inducing a degree of tenderness, I applied a few leeches, and advised the use of poppy fomentations. Meanwhile I prescribed a course of purgatives, anodynes, &c. A few days elapsed when the abdominal tenderness, &c. suddenly and completely vanished, and I found my patient suffering under considerable irregularity in the heart's action. It was now that my previous suspicions of the case appeared warranted, and I began to consider it a form of hysteria; of which opinion the subsequent detail will, I think, prove the accuracy. A state of considerable dyspnoea, identical in aspect with convulsive asthma, next engaged my attention. At some periods it resembled more a fit of whooping-cough, inasmuch as by frequently repeated convulsive expirations, the chest being exhausted of its contained air, and the respiration entirely arrested for the space of three or four minutes, the whole muscular system has been thrown into a state of rigid spasm, till a sense of the most dreadful suffocation being induced, the

rhagica Werlhofii), in the bowels, in the bladder, in the kidneys, and in the ureters. On examining the arm with a lens, while the light fell horizontally on the level of the skin, we saw at least a part of the epidermis unchanged above the dark purple colour of the spots. I could not ascertain whether, in the places where the papular elevations of the rising variola existed before, petechiæ of different kind from the purpura spots existed or not; but it would be interesting to examine whether, in small-pox, cases of this kind, as well as in measles and scarlatina, when petechial spots are observed, and, according to the general belief, all appear among the exanthematic spots, both exanthematous petechiæ and purpura spots are to be distinguished.

convulsion has abruptly terminated by a long deep inspiration, similar to the back draught in pertussis. The whole paroxysm has varied in duration, from half an hour to four hours; to which has succeeded a state of coma, that I have known continue, with little interruption, for two days. For three weeks these attacks of convulsive breathing recurred periodically, the intermission becoming more protracted as the general strength seemed to improve, their severity being reduced in frequency and degree: there nevertheless presented, at each recurrence, some new feature, indicative of the imitative powers of this singular affection; for scarcely a function in the whole body, whose interruption constitutes disease, has eluded the grasp of this mimic of diseases. I have observed its action on the brain, counterfeiting separately the various cerebral affections—as delirium, coma, mania, &c. I have noticed a spastic state of the muscles of one (generally the left) side of the body, including the extremities of the affected side. Here was a direct simulation of tetanus! The temporal and masseter muscles have been so rigidly contracted, constituting trismus, for the space of twelve hours or more, that all attempts to administer by the mouth were, even by the exercise of force, rendered perfectly impracticable.

Amaurosis of both eyes, to the effect of total blindness, forms the next item in this description. It has continued from twelve to twenty-four hours, the pupils remaining quite passive on exposure to a lighted candle. The most peculiar feature in this *mélange*, was a kind of hysterical somnambulism, under whose influence my patient has performed correctly on the pianoforte her favourite pieces; walked up stairs, undressed, and imperfectly fulfilled many accustomed domestic duties, unconscious of all around her; with no recollection, after the paroxysm, of what had transpired. Some portion of this detail may appear extravagant; I will, however, pledge myself to its accuracy. The irregularity in the heart's action was a general coexistent with almost every other symptom. The *globus hystericus* was altogether absent, and the secretion from the kidney considerably diminished; the convulsive efforts

made in respiration, have caused an augmentation in the capacity of the thorax to a very perceptible extent. Were I to give a more elaborate account of every symptom in such a train of morbid action as was exemplified here, I should be rather attempting a treatise on diseases generally, than the recital of an individual case.

I will now expose the plan of treatment pursued. My first care was to keep up a gentle and regular peristaltic action of the bowels, for which purpose I have used decoct. aloes comp. \mathfrak{ss} . pro dose. During the attack, when deglutition was practicable, I have exhibited combinations of aether, liquor opii sedativus, and camphor mixture; the stomach invariably rejected the preparations of *asafoetida*. I was induced, from the analogy existing between some symptoms in this case and the disordered respiration in pertussis, to make trial of the hydrocyanic acid, and must confess it afforded the temporary relief required. The tinct. lobel. inflat., in combination with valerian, was used with a view to obviate the dyspnoea, but failed in effect. I administered large quantities of the sulphate of quinine, thinking to check the periodic return of the paroxysms, with some advantage; but that medicine, from which the greatest benefit was derived, was the sesquioxide of iron, \mathfrak{ss} . bis terve quoti die, its administration being persisted in for some weeks. I recommended the use of the shower bath, but could not succeed in getting it employed; the cold bath was nevertheless substituted. It would be irksome for me to enumerate every remedy I have ventured upon: suffice it, that valerian, hyoseyamus, camphor, morphia, cubebs, arsenic, country residence on the coast of Kent, have all severally been had recourse to, with variable success; for, despite every measure ingenuity could suggest, the attacks, though mitigated, returned after a longer or shorter period of comparative convalescence. This detail comprehended a term of two years, at the end of which time circumstances transpired that opened a perspective of marriage to my patient. From maid she became wife, and a period not exceeding nine months made her mother. Sixteen months have now elapsed since she first became pregnant (which will be observed to have ensued immediately subsequent to marriage), during which

she has had no recurrence of any previous symptoms, and her general health has gradually improved to a natural standard. Her prolific powers are by no means inactive, she being at present five months advanced in her second pregnancy.

It appears from the examination of this, to me, unusual case, that distant local irritation was the cause of all the symptoms herein developed. The obstinate and long-continued constipation will appear ample grounds for remotely referring the whole derangement to the state of the alimentary canal; but admitting this as only a remote cause, and taking into consideration the contiguous relation of the uterus and its appendages with the lower bowels, the consequent continued pressure of a loaded intestine on the adjacent viscera, coupled with the constitutional irritation necessary to such a state, there is sufficient evidence to argue that the uterus, though secondarily affected, might itself become the source of the sympathetic disturbance indicated in distant organs. The facts of the disease being wholly arrested by marriage, the subsequent good health, and immunity from attacks, are sufficient to shew that disturbance in so important an organ as the uterus, partly dependent on the want of exercise of its natural function, is sufficient to induce a simulation of disease difficult to detect from actual disease by ordinary observation. I think that we are warranted in most, if not all, cases of hysteria, to consider it dependent on, or coexistent with, uterine disturbance, whether the local derangement be sufficient or not to attract our attention. We are all aware that disease may continue to exist for a length of time in an important viscus, without any considerable local disturbance resulting; it is therefore not unfair to conclude, that hysteria invariably, though not always evidently, depends on uterine derangement. An irritability of the nervous system peculiar to the female sex (without constituting the disease itself), may act as the medium through which the local irritation can develop itself with greater facility, in the same manner as the tubercular or strumous habit is more favourable to the development of phthisis than a robust constitution. I have met with ordinary cases of hysteria in public practice, in most of which I could de-

tect some deranged condition in the uterine function. In those few in whom I have failed to discover this, I have thought it right to imagine it to exist, though latent to my observation; I have therefore treated them in accordance with this view. We are too apt to think of alleviating the most conspicuous feature in a disease, without directing our attention to that which, though apparently insignificant, ultimately proves the actual source of all the mischief.

The foregoing remarks may appear redundant and intrusive, but the novelty of the above case will, I trust, exonerate me from a suspicion of impertinence.

CASE OF SUPPURATION IN THE VENTRICLES;

WITH

REMARKS BY SIR CHAS. SCUDAMORE.

To the Editor of the Medical Gazette.

SIR,

I FORWARD the enclosed case, thinking it to possess a sufficient degree of interest to merit publication.—I am, sir,

Your obedient servant,

JAMES PARRATT.

Mount Street, Grosvenor Square,
March 6, 1838.

Saturday, March 11, 1837. — Elizabeth Price, æt. 31, cook, suffering from severe pain in the head, referred more particularly to the forehead, which she describes as a constant throbbing and excruciating pain. Skin cool; pulse small and slow; tongue slightly furred; bowels regular; catamenia stated to have been always scanty; was in ordinary health until the evening of Wednesday last, November 8th, when, after much exertion in household work, she was seized with vomiting; at that instant came the severe headache, and it has continued to the present time.

States that for the last two years she has been subject to headache on exertion; is commonly very drowsy, and is accustomed to sleep for an hour after dinner. Has been in the habit of being bled twice in the year, in consequence of headache. Some years ago (possibly seven) she fell from a gate, and cut her head; but no particular notice was taken of it.

V. S. B. ad f. $\frac{3}{4}$ xx.; Hirudines, xvj. fronti et temporibus. Pil. Coloc. c. Calomel. iij. statim. Mist. Rosæ Aper. f. $\frac{3}{4}$ iv. sumet $\frac{3}{4}$ tiam partem horis duabus elapsis et repetat 4tis horis. donec alvus plene dejecerit.

12th.—Became very hot after V.S. and leeches; no relief from headache; did not sleep; bowels freely purged; motions dark; pulse 80; head hot.

Hirudines xvi. fronti et temporibus. Lotio Spirituosa, c. glacie capiti raso.

Evening.—Pain in the head as severe as before; has found no relief; eyes suffused; intolerance of light; pulse 88.

Cucurbitulæ Cruentæ Nuchæ ad f. $\frac{3}{4}$ xiv. Pil. Cal. gr. v. h. s. s. Haust. Sennæ crās, primo mane. Mist. Salin 4tis horis.

13th.—Throbbing pain relieved; complains now of intense pain over the whole head, as if it were being "riven asunder;" scalp hot; pupils natural; cannot bear the light; suffused state of eyes diminished; hearing morbidly acute; no sleep; pulse 88; tongue slightly white; urine scanty; bowels purged four times; motions dark.

R. Mist. Salin. 4tis addendo. Tinct. Opii $\frac{3}{4}$ ij. sing. dos.

Evening.—Has slept about half an hour since the morning. Headache intense. Other symptoms as before. Pain in the back; general soreness of the body and limbs.

Cucurbitulæ Cruentæ ad f. $\frac{3}{4}$ xij. temporibus; Empl. Cantharid. Nuchæ. Pil. Cal. c. Antim. 2 h. s. s. Haust. Sennæ primo mane. Perstet c. Lotion. Spirituosa et Mist. Salina.

14th.—Not relieved by cupping; continues to suffer same intense pain of head; groans a great deal; was slightly delirious in the night, for the first time; pulse soft, 100; bowels well purged; skin soft, but not apparently perspiring; much pain in the back, and general soreness.

charo.

Evening.—Perfectly insensible; pulse 108, regular and somewhat sharp; skin warm every where; bowels purged several times unconsciously; motions black; urine escapes as it is secreted; eyes glassy, pupils dilated, and scarcely affected by candle-light.

Perstet c. Mist. Iodin.

19th.—Mortua est.

Sectio Cadaveris.

On opening the head, the dura mater appeared every where exceedingly turgid. On its under surface it was in some places over both hemispheres firmly adherent near to the falx major, so as to require great care in detaching it, lest the substance of the brain be torn. The tunica arachnoidea covering both hemispheres was thickened, more on the left than on the right side. The substance of the brain was much injected, and exhibited innumerable bloody puncta on cutting into it: this was also greater in the left hemisphere. The left lateral ventricle contained from an ounce to an ounce and a half of serum; the right lateral ventricle contained from four to five drachms of pus, with flakes of coagulable lymph; gelatinous lymph was abundantly effused along the floor of that ventricle; on eleasing it, a patch the size of a shilling in the situation of the hippocampus major was altogether disorganized, presenting a brown-reddish colour, and exceedingly soft and pulpy. On opening the third ventricle, a small quantity of pus was seen, which is supposed to have escaped from the fourth ventricle at the time that the brain was being removed from the cranium; for, on opening the fourth ventricle, it was seen filled with pus, and the floor of it was disorganized as in the right lateral ventricle, but not

to the same extent; it was of the same reddish-brown colour, but not so soft, although much softer than natural.

The trunk not examined.

On Tuesday, the 14th, the advice of Sir Charles Scudamore was requested in consultation: he has favoured me with the following observations:—

"This case, unfortunate as it was in its result, affords much useful matter for reflection. It is unavoidable in the practice of physic that every now and then we are doomed to receive instruction from our failure instead of our success; so much is our art confined within certain limits. The pain of head which this patient suffered was remarkable for its severity, and she almost constantly exclaimed with agony as if she were undergoing a painful surgical operation. It appears singular that none of the bleedings yielded any relief from pain; the sense of beating was the only symptom alleviated; and hence it was, that on my first seeing the patient, and finding great evidence of exhaustion and debility, I did not recommend further depletion from the vessels, and thought it a safer course to employ medicines calculated to act consecutively on the liver, bowels, kidneys, skin, and nervous system; while, as auxiliary treatment, the sedative influence of cold was used to the head, and counter-irritation employed remotely. The cold failing, the relaxing power of heat was tried, as will be seen; but all the attentive treatment adopted in this case from first to last appeared to have scarcely the smallest useful result. The disease pursued its course with unrelenting severity. It was deep-seated *meningitis*; and it is highly probable that the sheath of the spinal cord was also affected, so remarkable was the pain down the back, the general soreness, the extreme restlessness, the inattention to a full state of the bladder, even before the 16th, when no urine had been passed for a considerable time, and three pints were drawn off by the catheter.

"Could any treatment have met with success in this case? None, I apprehend, unless at the very commencement a still freer abstraction of blood had been employed, carrying it each time *ad deliquium*, and with a view so to impress the heart and circulation that the vessels of the brain should have their morbidly increased action decidedly controlled; for, manifestly, it was purely inflam-

matory action terminating in *suppuration* which led to death. Such is our information derived from the post-mortem examination, but it must be at once admitted that Mr. Parratt's immediate treatment was active and quite appropriate. It is often difficult, perhaps impossible, to decide how far depletion from the blood-vessels shall be carried with propriety; for if our zeal with the lancet &c. be intemperate, we may rush from Scylla to Charybdis, and prove the immediate authors of destruction.

"But if there be one point of treatment more important than another in the most active inflammations, it is this—that our depletions from the vessels should be early as well as free, and quickly repeated, as far as may be necessary to control the heart and whole circulation in a very effectual manner. If such treatment be delayed till the disease has greatly advanced, it may not only prove ineffectual, but actually bring on the fatal termination.

"I have no doubt that the foundation of this disease had been laid very long. She had for a much longer time than usual omitted to be bled. It was remarked by her fellow-servants that for a considerable time past she had complained greatly of headache, and of oppressive sleepiness in the day-time. It was a chronic disease, all at once rendered perfectly acute."

DISEASE OF THE PLACENTA.

To the Editor of the Medical Gazette.

SIR,

HAVING read the case of inflammation and suppuration of the placenta, published in your last number, I am induced to forward a few particulars of a case of disease of that organ which occurred in my practice a few years since, in which the placenta contained a vast quantity of ossific matter nearly amounting to one-fourth of the whole substance. The symptoms were shortly these:—Considerable pain over the region of the uterus during the latter months of pregnancy, unattended by any other symptoms of inflammation. After the birth of the child, a fearful hæmorrhage supervened, rendering immediate manual interference necessary. The placenta was found firmly attached

almost throughout its entire surface to the fundus uteri, and could not be separated without very considerable force. When removed, it presented a very unusual appearance, being a firm, whitish, leathery-looking mass, interspersed with solid masses of bony matter. A preparation of this morbid placenta was made, and deposited in the King's College Museum, by the late lamented A. A. Cann, Esq., curator at that time. The patient did well, and has since been delivered under very similar circumstances; the placenta, however, this time did not contain so much ossific matter, owing, it was supposed, to the use of bleeding and purgatives in the latter months of pregnancy. If the foregoing brief account is thought worthy of a place in your journal, by publishing it you will oblige

Your obedient servant,

J. WETHERFIELD.

1, Henrietta Street, Covent Garden,

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tuarum; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

WHY IS QUACKERY SUCCESSFUL?

It has long been a moot point whether an unsparing enemy or an injudicious friend is most to be dreaded; for the support of the latter will too often ruin the best cause. We feel ourselves at present in this predicament, and are backed in this undesirable manner, by the writer of a pamphlet which is lying before us*. The writer tries to explain why quackery prospers, and how it should be put down, but we do not think he is very successful in either attempt; yet, as we agree with him in his object, it is with a natural reluctance that we shall endeavour to point out his omissions, and rectify his misstatements.

* Quackery: its Danger, Irrationality, and Injustice; the Causes of its Success; the best Means of its Suppression.

The causes of the success of quackery are very faintly and vaguely set forth by the Bath pamphleteer. He thinks that the success of charlatans may be explained by the "strong and absorbing feeling of the human mind—the love of life," to which their pretensions are addressed, and by the extravagant commendations of those who have derived benefit from quack medicines; moreover, patients "are ignorant of the structure and functions of their body, of the seat and nature of the great majority of the diseases to which it is liable, of the principles which should regulate their treatment, of whether they are capable of cure, *would get well of themselves*, or are inevitably fatal." With the exception of the few words we have underlined, these reasons seem to us singularly weak. The mere love of life, however strong it may be, however weak the person whom it afflicts, would never make him choose a quack, when he might have a Mead or a Heberden. Many people have a greater horror of shipwreck than of fever, yet this does not induce them, when they are about to undertake a voyage, to request the first schoolboy whom they see navigating a punt, to become the captain of their vessel. Quite the reverse; they make anxious inquiries whether the captain is experienced, the crew steady, and the ship A 1 in Lloyd's register.

Nor do we see why extravagant commendations are more likely to be lavished on a successful nostrum, than a successful remedy in regular practice; and as every sick man must have heard of fifty persons cured by educated practitioners, for one suffered to get well by a quack, the balance of commendation must be infinitely on the side of common sense and honesty.

The gist of the matter unquestionably lies in the few words we italicized in our quotation; the patient does not know whether or what diseases would get well of themselves, and, conse-

quently, if he recovers, ascribes all the merit to the Batavian Bolus, instead of the *vis medicatrix Naturæ*.

This, then, is the true reason why utter ignorance may long impose on the credulous public in physic rather than in other arts; most diseases have a natural tendency to get well. This tendency may be encouraged by judicious treatment, or thwarted by very bad; but the tendency is still there, and excepting, perhaps, in cases of malignant disease, this salutary effort is never absent. Hence we see why a painter turning physician, without any knowledge of physic, may make his 5,000*l.* a year by excoriating the chests of his employers; while if the converse were to happen, and a physician were to propose to live by painting, without knowing an atom of the art, he would be thought fit only for Bethlem. Hence, too, the analogy fails which the author institutes between a remedy absurdly extolled as curing every disease, and the supposed panacea of a *hygeian* watchmaker.

"What would be thought of the individual who advertised that he had discovered a something which, if put into a watch, would rectify all imaginary [imaginable] deficiencies; mend mainsprings, supply broken cogs, lost axles, renew worn-out wheels, and make the hands, on whatever cause their irregularity might depend, keep proper time?"

As in the former instance, the watchmaker has no help from any *vis medicatrix horologii*; and he who should attempt to make a watch go by poking something into it at random, would inevitably be set down by every customer as a fool or a madman. On the other hand, the watchmaker possesses the advantage of taking his machine to pieces, which the physician does not enjoy. Lastly, the watchmaker is the professor of a sort of exact science, while medicine is a conjectural art*.

* Est enim hæc ars conjecturalis. — *Celsus*, Lib. i. Præf.

A curious topic might be touched upon here, which is not even alluded to by the author of the pamphlet. Surgery has always been justly accounted the clearest part of the art of healing; its merits and effects are the most obvious*. The difference between a genuine surgeon, and an itinerant attempting to set bones by the light of nature, would be obvious, one might imagine, to the meanest capacity. Yet, even here, uneducated cataract-curers, rupture-doctors, and what not, have poached upon the medico-surgical preserves, and bagged some game.

Perhaps this may be attributed in part to the following reasons:—The entire domain of medicine and surgery is so vast in extent, that, until a very recent period, certain regions were hardly brought under regular culture, and lay like a kind of debateable land, between the limits of honest practice and charlatanism. Thus, not more than forty years ago, the first oculist in London used secret remedies; his prescriptions being drawn up in a way intelligible by one druggist only, in order to keep his lucrative mysteries as much as possible from rival eyes.

Now if the regulars did this, the public could not hope for better, nor experience much worse, at the hands of professional Cossacks and Lanzknechts. They would naturally say, if the tip-top oculist in London has no medicines but nostrums, why should we hesitate at taking them from our circumforaneous eye-doctors in Cornwall, or Cumberland?

This reason, however, will not apply to surgery proper, *quæ manu curat*; and here we are reduced to suppose either that those who employ the spurious surgeon are not within the reach of a genuine one, or that the genuine one

is a surgeon by diploma, not by skill, or that the patients have lost their wits.

This last supposition is the only method of explaining a curious advertisement for a quack, which appeared, not long since, in the *Leeds Mercury*. It seems that alarming accidents are of almost daily occurrence in the neighbourhood of Grassington, and therefore sundry benevolent persons, including three virtuallers, advertise—for what?—for a skilful surgeon? *Minimè gentium*—for a bone-setter! This is certainly not sustaining the character which the men of Yorkshire have acquired for acuteness in the common affairs of life. Even supposing (which we have no reason to do) that the neighbouring surgeons did not put up fractures with the most consummate skill, still this way will mend no broken bones.

It must be confessed, however, that as in surgery the superiority of the skilful over the pretender is boundless, and must be obvious to any one who is not utterly demented, so the mistakes of the half-educated will be painfully distinct to the patient, and will sometimes have the effect of throwing him within the grasp of the empiric. Thus, if we may be allowed to put a case by way of illustration, an Englishman sprains his ankle at Hamburgh, in the severest manner; in fact, it is a sub-luxation. He calls in an eminent surgeon, who uses the usual remedies, leeches and cold lotion, and bandages the suffering part with the dexterity of a practised hand, so that the patient is soon able to walk, the bandage not being disturbed by motion. He returns to England, and his foot still requires support; but living in a small market-town, he is no longer within reach of an eminent surgeon, but calls in his usual family attendant. A great mystery is now revealed to our astonished countryman: *it is not every one who understands all that he*

* Celsus, when speaking of the branch of medicine, *quæ manu curat*, says, "*estque ejus effectus inter omnes medicinarum partes evidentissimus.*" Lib. vij. Præf.

professes ; the foot bandaged by Dr. A , of Hamburgh, could walk up the Jungfernstieg without pain or stumbling ; the foot bandaged by Mr. B., of the small market-town, will not walk at all, for the bandage becomes loose in two minutes. Now the foot is the same foot ; it is therefore the surgeons that differ, and Mr. B. is no longer the cleverest man in Sussex. If a wandering professor of the art of bandaging should pass through Crowthorpe, we will not pledge ourselves that the disappointed patient will not employ him.

Again, as to the suppression of quackery, though we agree with the author of the pamphlet as to the end, we differ much as to the means.

One of his assertions concerning this branch of the subject is most startling ; he says :—

“ Quackery is suppressed in all the other countries of Europe. The French, German, Austrian, Prussian, and Italian systems of medical jurisprudence, all enforce the necessity of a comprehensive preliminary and medical education ; they protect the rights of medical practitioners, and prevent their *slightest infringement by illegal pretenders*.”

Assuredly, it is at least bold to say that quackery is suppressed in France. One has only to walk in the streets of Paris, and in spite of the regulation put up in letters a foot long, *il est défendu de déposer des ordures contre ce mur*, wherever there is a dead wall, it is covered with placards vaunting the *spécifique* of M. Un Tel, or the *Rob anti-syphilitique* of M. Chose. Those who have not seen Parisian dead walls may have read Parisian journals, which will bear witness to the same fact—to the flourishing state of quackery in the country where the pamphleteer supposes it to be suppressed. Thus, in the sitting of the Academy of Medicine on the 20th of February, the first article of the official correspondence consisted of a letter from the minister, sending a

secret remedy proposed by one Boyer ; and the fourth article was another letter from the same high source, with the receipt of a refreshing lemonade*. The Academy has the honourable office of investigating the merits of these nostrums, and reporting upon them to the government.

The same learned body, too, has been long occupied with attempts to suppress the sale of quack medicines ; they propose that patents shall not be given either for medicines or for cosmetics, and that the substances, whether simple or compound, which are employed under the name either of cosmetics or remedies, shall be subjected to the laws which relate to the compounding of medicine†.

These constant attempts to suppress quackery in France shew clearly that the previous ones have met with little success ; just as Hume says of the continual confirmations of Magna Charta, that they shew how little that great compact was observed. That the propositions of the Academy, if passed into a law, will be habitually eluded, no one can affect to doubt. At the sitting of the Academy where the article we have just quoted was confirmed, M. Desportes thought that the word *cosmétique* was not sufficiently clear, and wished to have it followed or preceded by an explanatory phrase ; on which a voice cried out—“ *C'est une affaire de dictionnaire*.” Like M. Desportes, however, we have our misgivings ; nay more, we go farther, for we fear that, in a free country, where thousands are willing to administer nostrums, and millions to swallow them, no definition, however logical, will prevent their sale. Nevertheless, we agree entirely with

* 1. Lettre ministérielle avec envoi d'un remède secret proposé par le sieur Boyer.

4. Lettre *idem* avec envoi de la recette d'une limonade rafraîchissante. — *Gaz. Méd.* Feb. 24, 1838.

† *Gaz. Méd.* March 3, 1838.

the Academy, and the author of the pamphlet before us, that it would be desirable to abolish the shameful practice of stamping quack medicines, and thus giving them a kind of royal sanction in the eyes of the ignorant.

DR. MARSHALL HALL AGAIN.

"*Ecce iterum!*"—We have received the following from Dr. Marshall Hall:—

To the Editor of the Medical Gazette.

SIR,

I am sorry I was not more explicit in my letter, and now send you a very brief note, which will supply this defect. The "misrepresentations" (the word is *borrowed**) in your two articles, are at least four:—

1. You represent my assistance as very insignificant. I have explained *what* it really was. I might have added that I had engaged also to supply the admission-fee and subscription, should the individual alluded to be elected an F.R.S.

2. You have represented me as trumpeting forth my assistance; whereas, in fact, I stated it in reply to a charge of "*suppression of facts*," this being the *only* fact which I had suppressed.

3. You have made a misrepresentation, arising out of the mystification which has been employed relative to the *subject* of discussion: that subject is the *third nervous column* in the articu-
lata, its discovery by Müller, in 1828, and that of its *motor* function by Professor Grant, as given in his lectures, in 1832.

4. You represent me as repeating the word *brutal*, in reference to the conduct of the Council of the Royal Society towards me. I did *not* repeat that word. But I *do* now repeat, that to refuse to witness my experiments, when I offered to give up five years of professional avocations and advantages, *was* brutal in the extreme.

To revert to the more recent subject of discussion, I beg your readers further to remember, that, in what I have

written, I was stimulated by unfounded accusations:—1. of "decided misrepresentations;" 2. of "suppression of facts;" 3. of "statements not in strict accordance with facts," &c., without one tittle of proof, by one whom I had befriended to the uttermost.—I am, sir,

Your obedient servant,

MARSHALL HALL.

14, Manchester Square,
March 12, 1873.

We are thus charged with four "misrepresentations;" and we shall answer them numerically, as set forth by our antagonist.

1. We did not represent the assistance as "very insignificant;" but we said, and we now reiterate the opinion, that the loan of 15*l.*, and recommending a pupil to Mr. Newport, did not warrant Dr. Marshall Hall in asserting that he had "fed, clothed, and housed," that gentleman.

2. We represented Dr. Hall as trumpeting forth his assistance, for this plain reason—that he did so; as every one must admit who took the trouble to read his letter published in a contemporary journal. As to his having been obliged to do this because he was charged with a "suppression of facts," the simple truth is, that the worthy Doctor was accused of suppressing certain facts regarding the nervous system; to which he replied by adducing certain facts relating to his account-current at Sir Claude Scott and Co.'s.

3. This relates to a matter of opinion, with regard to which we have made no "misrepresentation;" the most that can possibly be said is, that we are mistaken. We are perfectly satisfied, however, that the mistake lies with Dr. M. Hall.

4. The fourth paragraph shows the constitution of Dr. Marshall Hall's mind to be so utterly inaccurate and confused, as to render him incapable of conducting any discussion in which precision is requisite. We did *not* accuse him, as he erroneously states, of

* Possibly; but not from us.—ED. GAZ.

repeating the term "brutal," in reference to the Royal Society; our words were, "he does not *withdraw* the epithet of 'brutal' from the Council," &c.; and this assertion we made, and now reiterate, on the authority of Dr. M. Hall himself, in one of his published lectures. But farther, Dr. Marshall Hall, while indignantly accusing us of misrepresentation, in having said that he repeated the epithet brutal (which we never did say), makes use of these words:—"I do now repeat, that to refuse to witness my experiments, &c. *was* brutal in the extreme"!! It were a waste of words to argue with a man who seems to be so utterly regardless of all the courtesies of civilized life, and who thus contradicts himself at every turn.

Dr. M. Hall concludes by enumerating certain accusations brought against him by Mr. Newport; but he has omitted one rather important charge brought by that gentleman against him—namely, that of wilful falsehood. His words are, "the assertion is false, and Dr. Hall knows it to be so." When the Doctor next enumerates the charges which Mr. Newport has adduced, and which he has not found it convenient to notice, we advise him to add this to the list.

As we shall not be readily induced to recur to this subject, we may take the opportunity of stating, that Mr. Newport has addressed to us a letter, in which he assigns a reason for the pupil recommended by Dr. M. Hall having left him, which wholly exonerates Mr. Newport, and yet renders it impossible to give publicity to the circumstances without compromising a third party, towards whom the *exposé* would be an act of cruelty. This, however, we may state, that the separation of Mr. Newport and his pupil took place in May, 1834, and that in March, 1835(!), Dr. M. Hall penned the following certificate in favour of Mr. Newport:—

DR. HALL'S OPINION OF MR. NEWPORT.

"I have great satisfaction in bearing my testimony to the merits of Mr. Newport; his papers on Comparative Anatomy, published in the Philosophical Transactions, sufficiently attest his talent for this kind of investigation; but having known Mr. Newport during the course of his medical and surgical studies, I am enabled to say that he has been most assiduous in acquiring both the preliminary and the practical knowledge of our profession. On this ground I recommended, some time ago, a medical friend to place his son as a pupil with Mr. Newport; and I should think the young gentlemen who may in future have the advantage of Mr. Newport's assistance in their studies, will ever afterwards consider it as an important event in their lives.

"MARSHALL HALL, M.D.

F.R.S. Lond. and Edinb. &c. &c.

"14, Manchester Square,
March 20, 1835."

Now, if the pupil was removed in consequence of any disgraceful conduct on the part of Mr. Newport, as asserted by Dr. M. Hall, perhaps he will be good enough to explain how he came to grant that gentleman such a testimonial as the preceding, at a period subsequent to the perpetration of the alleged immorality? On comparing dates, we find that Dr. Hall's sense of Mr. Newport's delinquencies broke in upon him rather suddenly towards the end of 1836, when the Royal Society honoured that gentleman's paper with their medal; and, knowing that Dr. Hall has been a less successful candidate for similar distinction, the impression produced upon our minds we must confess to be, that the Doctor has subsequently viewed every thing connected with Mr. Newport through a medium which has perverted his feelings and blinded his judgment.

ON ANIMAL MAGNETISM,

No. III.

IN our last paper we considered the production of common sleep and of hysteri-

cal paroxysms, by the impressions made on the senses or the mind by the magnetic manipulations; we now propose to consider the several phenomena included under the name of magnetic somnambulism.

We showed that the production of common sleep depended on some common cause, as the *ennui* of a continued slight sensation, or imitation; and induced in this manner, in a person unacquainted with its real cause, but believing it to have been done by the will of the magnetiser, it will follow on each occasion with less difficulty, from the assistance which imagination, habit, and a kind of resigned expectation, will afford to its production. From the fact of its being more easily produced on each succeeding occasion, the magnetisers would deny the influence of imagination, which they say would act with less power each time, but it is evident (and we shall present in a future article several analogous cases proving it) that the reverse obtains; that the imagination once yielded to, acquires a stronger hold, and that its power over one whom it can once subdue is greatly increased by being exercised. We may see too the effect of habit in producing sleep rapidly every day. Most persons go to sleep on particular occasions without any regard to actual fatigue—as under the stimulus of a meal, or in the absence of stimuli on going to bed. It matters not how much or how little exertion of mind or body they may have previously undergone, the majority of persons in health go to sleep within five minutes of the application or removal of the usual stimuli.

Now the character of common sleep naturally produced varies infinitely in different persons—some never dream at all (at least as far as they know); some only occasionally; others have scenes, acts, and thoughts, presented before them with all the clearness of reality; some again seldom sleep without talking on the subjects of their dreams, on which, if another person can discover the clue, he may sometimes lead them into prolonged conversations: others, lastly (but these are far more rare), *walk*, as it is called, in their sleep, and are able during its continuance to perform all the acts of their ordinary occupation, or even others which they would not have dared to undertake, or would have been unable to effect, in their waking state. This

state (for the sake of distinction) we shall call natural somnambulism; its varieties are endless, and we regret that our space prevents us from offering to the reader some of the most remarkable cases which are recorded by authors on it; many, indeed, are, like those of magnetic somnambulism, far too marvellous, but in others, well authenticated, there have occurred phenomena which are of extreme interest.

Another state which we would request the reader to bear particularly in mind, is that of ecstasis, as first described by Sauvages, and of which a considerable number of cases may be found in different authors, under the names of Demonomania, Reverie, Cataphora, Catachus, Catoche, &c., appellations invented by nosologists in a vain endeavour to arrange the varied and anomalous symptoms which different cases have presented; some with lethargy, others with cataleptic rigidity, others with violent convulsions, others with raving delirium, &c. They are now, for the most part, merged into hysteria, for nearly all the subjects were girls, or women subject to that Protean disorder. We shall not attempt to lay down the most frequent characters of the cases we include under this head, but they will appear in the cases we shall allude to.

Other conditions which are occasionally met with, and which it will be well to remember in reading magnetic cases, are those of lethargy, trance, torpor, catalepsy, and day-sleep or day-mare, as described by Mr. Macnish in his *Philosophy of Sleep*. It is necessary to recollect the phenomena observed in cases related under these names, of which at least nine-tenths have occurred in hysterical patients, because we shall be able to show that there has never been a credible effect produced by animal magnetism which has not occurred in cases related under one or other of these names. And, if the exciting causes of these disorders are coincident with the supposed magnetic action, we repeat there is no reason for rejecting the former, whose influence is certain, for the latter, whose existence is altogether hypothetical.

The performance of the common acts of life during somnambulism is constantly observed, perhaps more commonly in this state when naturally than when artificially induced. We need quote no particular instances, for all our

readers must have met with such. It is to be observed, however, that if, before falling asleep, the somnambulist's mind has been much occupied by a plan which he is desirous of accomplishing, or if it have been much affected by some occurrence, then, like the imagination in common dreaming, the acts performed during sleep will take their direction from its previous train of thoughts. Hence in magnetic somnambulism, the patient's mind is filled with thoughts of the magnetiser and his manipulations, of her supposed or real disease, of her previous fits of convulsions, &c.; these will be the subjects of her conversation, and of all her acts. From this *direction* of the thoughts it is that, in natural somnambulism, the sleeper goes about the work that he has been anxiously engaged in or planning, and that in the magnetic state, the patient talks of pain in various parts of the body, imagines that she has obtained an insight into the seat of her own disease, and of those of others; in short, talks of and does all those things which she has heard or imagined to be the consequences of animal magnetism.

It is well known, too, that natural somnambulists have very often no perception of things which have not a reference to the subject of their dream. Thus, in the famous instance of the sleep-walker, Castelli, related by Soave, he heard nothing but what fell in with the train of his ideas, nor did he see any of the persons standing around him as he was reading, though if interrupted in his study he would answer and would carry on prolonged conversations on the subject of it. And so in the case quoted by Bertrand, as related by the Bishop of Bordeaux; in that of Negretti, as given by Muratori; in that told by Dr. Darwin, and in many others, the sight or hearing were awake to those impressions only which had some relation to the subject on which the somnambulist was actually engaged. In other cases one sense only seems to be awake; the somnambulists see every thing, but are insensible to impressions of hearing or common sensation. These phenomena of natural somnambulism are precisely similar to some of the most extraordinary of those stated to occur in the magnetic state—as the *rapport*, said to exist occasionally between the magnetiser and the patient, who will answer none but him, and perceives nothing but what is connected with

him, &c.; the magnetiser and magnetism are, of course, the subject of his dreams, and once dreaming, her thoughts may be led on in the same train. Hence, too, though sensible even to slight impressions which have reference to the magnetic condition, she is totally insensible to more powerful ones (though rarely to the most powerful) which have no such relation. If there be any credible cases of these phenomena, and in our belief there are a very few, they are thus explicable by their similarity with the above analogous ones, which are of more frequent and of natural occurrence.

Another occurrence said to be observed in magnetic somnambulism is that the patient remembers what occurred in the preceding fit, though it had been forgotten in the interval. This also is very generally the case in dreams and in common somnambulism. Such a case is quoted by Dr. Abercrombie, in his Treatise on the Intellectual Powers. The patient, a servant girl, used during the day to have somnambulant fits, in which she would continue her usual work with diligence and accuracy. She used to forget all the occurrences of each attack, but distinctly remembered in one of them the circumstance of having been taken to church during the preceding, which she had throughout the interval been quite unconscious of. The somnambulism ceased on the appearance of the *catamenia*, after six months. More remarkable cases still, perhaps, are those by Dr. Silliman, in the American Journal of Science, of three persons who were suddenly seized with delirium, from which, on their sudden recovery, after some time (in one case after two years), they recommenced the conversation that preceded the attack, or asked after the work in which they had been then engaged. One of them, who had several such paroxysms, used also to recommence at each attack of delirium the subject she had been talking on, and had suddenly broken off from, in the last—so that she appeared as a person might be supposed to do who had two souls, each occasionally dormant and occasionally active, and utterly ignorant of what the other was engaged in in the intermediate time. Hence Dr. Pritchard, who regards the cases as examples of reverie rather than any form of madness, proposes for them the name of *dipsychia*.

The same phenomenon was observed in cases related by Sauvages and Lorry, and is said by Andral to occur in epilepsy, so that in this again, which has been quoted as one of the most extraordinary circumstances in the magnetic somnambulism, we have nothing which does not occur, perhaps more frequently in that state, when produced without the apparent assistance of magnetism.

The insensibility to other impressions than those which have reference to the train of ideas forming the dream, may be carried to such an extent, that means which in the waking state would cause intense pain, may be employed without disturbing sleep. In the commoner cases of somnambulism, whether natural or magnetic, an impression of moderate violence is sufficient to arouse the patient, but in the severer cases of reverie, and still more in those of trance, the most powerful stimuli are insufficient. Thus in cases given by Dr. Darwin, in his *Zoonomia*, vols. 1 and 3: in one of these a girl was attacked by hysteria, in which the convulsions were followed by a reverie, in which she talked aloud with imaginary persons, sang, repeated poetry, and conversed sometimes sensibly on the subject of her dream, yet no notice was taken by her of even the strongest impressions on the ear which did not accord with that subject. So also in Lorry's well-known case of ecstasy, (in the *Comment. Acad. Paris, Mem. des Etrangers*, t. 3) the patient, though she conversed freely with those around her on the subject of her dream, could not be excited by severe pinching and pricking; and in that by Sauvages (*Acta Acad. Upsal.* 742) of Magdalena Valletta, the patient was even more vivacious than when awake in conversation, and in all the acts of her dream, singing, whistling, joking, and dancing, and yet she gave no sign whatever of sensation; a smart blow on the face, a finger moved rapidly towards her eyes, a lighted candle brought so near her open eyes as to burn her eye-lashes, striking hard on the bedstead with a stone, brandy and sal ammoniac placed under her eyes and put into her mouth, tickling the eye, snuff blown into the nostrils, pricking with pins, twisting the fingers,—all these, and many others of a like kind, were quite incapable of arousing her. A similar case is related in Blumenbach, *Bibl.* i. 376. We need only allude to those cases (now nume-

rous) of trance, in which persons have been buried alive, or awakened by the dissecting knife, or have suffered the excruciating pain of pulling off the nails, without awaking—these every one must know by tradition, if not by observation. They are, however, of great importance, for the insensibility, as evidenced by external signs, is perfect, although sometimes there is a consciousness of what is going on, without the power of resisting it. The immobility of the limbs alone seems to distinguish it from the cases above quoted, and from those of *complete* magnetic insensibility; a condition, by the way, far more rare than magnetisers would have us believe.

Such cases are fully sufficient, in our opinion, to counterbalance the most important, because the best authenticated, of all the magnetic wonders; but lest there should not be proof enough of the analogy of the two sets of cases, we will place one of each together. The magnetic one is, we need not say, that in which M. Jules Cloquet removed a scirrhous breast without any evidence of pain on the part of the patient, who had been put into a state of trance by a magnetizer. We need not detail the history of this oft-told case; suffice it to say, the patient was by habit easily put to sleep by manipulations, and was not aware of what was intended to be done. Our case is this; it occurred some few years since, and, for obvious reasons, the names are suppressed:—A young lady, subject to hysterical fits, fell down in one of them, and struck her forehead; she was taken up quite insensible, with her features fixed, her pulse regular, her respiration easy; in short, in a state of deep sleep—of trance. There was a puffy tumor over the situation of the blow, and under the idea that injury might have resulted to the brain or its membranes from the violence, she was trephined after having been insensible for two days. The whole of this painful operation elicited from her *no expression of sensibility*; every thing was found healthy, and the wound was closed again: she remained for two days more in the same state, and then awoke in her usual health. The wound did well, and, with the exception of one or two more similar fits, she experienced no further inconvenience than before the accident, her hysteria being soon after completely cured. On awaking, she detailed all the proceedings of the ope-

ration of which she had been *painlessly sensible*. In this particular alone did the case differ, as regarded sensibility, from M. Cloquet's, and from those before related of Sauvages, Lorry, &c., as well as from those of the fanatics of St. Medard, whose histories we shall take occasion again to refer to at length, who endured apparently without pain, and even called for, the most violent blows from heavy weapons on the most sensitive parts; and Bodin, in his *Demonomanæ*, p. 164, gives insensibility of parts of the body as one of the most frequent signs of *possession*.

Before proceeding to other phenomena, we must observe that if we have not hitherto exercised the privilege to which we have proved our right, of disbelieving very many of the statements made by so many magnetic authors, it has been simply that we have not yet had to deal with any that have not been reconcilable to common sense and probability. Not that we believe more than half the cases that have been told of the occurrence of the phenomena we have already considered, but finding fair evidence of their having been met with occasionally, and produced in appearance by magnetic influence, we are anxious to point out the causes to which they may be more properly referred; and this more particularly for the benefit of those who may hereafter witness or hear of similar cases. The statements we are now coming to, however, will need far more freedom of scepticism.

Among them are those of the occurrence of exalted sensibility. This is seldom noticed, but may have occurred; for it is a common occurrence in hysteria and other nervous disorders. It was present, in a very marked degree, in Sauvages' patient, Helena Renault, (*Observ. Med. Pract.* p. 248, and *Nosology*, vol. iii.) who could perceive the smell of weak ammonia ten feet off her, and went into her ecstatic fits when forced to smell it more strongly. This symptom we have often observed ourselves in hysterical girls, or in persons convalescent from acute diseases; and indeed most antipathies are founded on excessively acute sensibilities of particular organs, or towards particular stimuli. Exalted sensibility to some stimuli has also been observed in many cases of fanatic extasy, and both in them and in magnetic somnambles; and this is of some importance, as it may explain

what small portion is true of the tales about transferred senses.

Increased intellectual powers are said to have been exhibited during magnetic somnambulism, especially in M. Puysegur's cases. We are not disposed to think that much of this was dependent on any thing but the disproportion between the magnetizer's own intellect and his imagination; but there are analogous non-magnetic cases related on as good authority. Two of the fanatic convulsionnaires of Loudun (of whom more hereafter) were known during their fits of ecstasis to converse in Latin with fluency—a language of which, in the intervals, they knew scarcely more than the rudiments. This resulted, however, from the perfection which the memory sometimes acquires in cerebral affections; no new language was ever acquired. The fanatics of Cevennes, for example, are said to have talked polite French in their fits, and *Patois* in the intervals, but they never talked German; the new languages they spoke were like the unknown tongues of our own day, unintelligible—a mere babbling, which the hearers supposed it was their misfortune not to understand. The most remarkable case of perfection of memory by cerebral disorder, occurred some years since at St. Thomas's Hospital. A man fell on his head, and remained for some time insensible; on recovering, he spoke a language unknown to all around him, and could not in any way make himself understood, till a Welch milkwoman, coming into the ward, recognized her own dialect. It appeared now that he had left Wales, where he was born, at three years old, and had totally forgotten the language till he met with the accident; the blow which had knocked out all his English, restored him his Welch. When he recovered, however, he again lost the latter, and regained the former. Now had this man been magnetised, one might indeed have said "*Quel prodige!*" Similar though less remarkable cases of improved memory are sometimes met with in common delirium. And in dreams, during the absence of every thing that might distract the attention, not only are forms and ideas recalled to the mind with unusual accuracy, but the imagination is exalted so as to attain extraordinary power. We need only allude to the composition of the well-known sonata by Tartini, to which he imagined himself in his dream to be

instigated by the devil, and to the many instances in which thoughts of peculiar beauty have suggested themselves to imaginative minds during sleep. Had they occurred in magnetic somnambules they would have been deemed peculiar to it.

Other extraordinary intellectual powers, shewn by somnambules, have been, an insight into the diseases of others, and a discovery of their remedies; these were especially enjoyed by the patients of the philanthropic Puysegur. As he lived, however, during the popular prevalence of humoral doctrines, they saw every thing, as it were, through humoral spectacles; and they diagnosed actions, acrid matters, and other things, whose existence is about as evident as that of the magnetic principle itself. The remedies, too, which they ordered, were of the simple and efficacious character generally known in the class in which the patient lived, as vegetable purges, &c., on which the patients of course sometimes recovered. When Broussais was in the ascendant, nothing but gastro-enterite was seen—the intestines of every patient were red or ulcerated, and leeches and gum-water were the only prescriptions. We would venture privately to predict what will be the discoveries and remedies of the first physician-somnambule that is met with in London. This medical power, however, is but an imitation of that long ago enjoyed by the *possessed*, and various fanatics; and it is singular that the words in which Corré de Montgeron describes it in the *convulsionnaire* of St. Medard are almost identical with those in which it was first announced as enjoyed by somnambules. It needs no explanation.

ROYAL COLLEGE OF PHYSICIANS.

Monday, March 5, 1835.

THIS was the second meeting of the season, and was numerously attended. A paper, containing many interesting facts on the subject of Heat, by Sir Charles Scudamore, was read. We regret that we have not room for it this week, but we shall, if possible, give it in our next number.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

March 12, 1838.

THE PRESIDENT IN THE CHAIR.

READ: a paper by Dr. Travers Cox, of Yarmouth, descriptive of

A Cyst found at the under Surface of the Liver,

on dissection of a patient of whose case the following history is given:—

The patient, a muscular man, of 32 years of age, came under the observation of the author, in 1832, while suffering from ascites, for which he was tapped, when twenty one pints of fluid, resembling ordinary bile in consistence and colour, were drawn off. The patient afterwards took iodine and diuretics, and no fresh accumulation took place. He continued at work, as a coal heaver, from this time till April 1836, when pulmonary disease manifested itself, and he died of hæmoptysis in November last. On examination of the body after death, a large distended cyst was discovered at the under surface of the liver, attached by a small portion of its surface to the right of the gall-bladder, and in front of the transverse fissure. The cyst a preparation of which was exhibited, was about four times the size of the gall-bladder, contracted in its centre, where it was cartilaginous, and was found to contain a gelatinous mass composed of concentric layers capable of being unrolled from each other. The outermost of these were nearly transparent, those in the centre being opaque. Between these fibrous layers lay here and there small pieces of a substance resembling wax and vermillion, prepared for injecting arteries in the dissecting-room, both in consistence and colour.

Read also,

Observations on the Dislocation of Phalanges of the Fingers and Toes. By JOHN P. VINCENT, Esq. Surgeon to St. Bartholomew's Hospital.

The object of the author, in this paper, is two-fold: first, to point out the principle upon which the reduction of the phalanges of the fingers and toes should be conducted; and secondly, to call the attention of surgeons to the manner in which the force of that portion of the muscles which remain uninjured may be made to co-operate with their efforts in the reduction of dislocations in general. With reference to the former point, the author

insists strongly on the propriety of extending the dislocated phalanx, in a direction at right angles to the bone from which it has been dislocated, instead of employing the force in the axis of the bone. These observations are illustrated by a diagram, in which it is shown that the lateral ligaments, supposing them to remain entire, oppose an insurmountable obstacle to the reduction in the latter direction.

With regard to the second part of the inquiry, the author adduces reasons for believing that, in the reduction of other dislocations, the operator can do no more than bring the head of the bone down to the acetabulum or glenoid cavity; after which, its replacement is effected by the agency of the muscles which are commonly employed in moving the bone upon its axis. The paper concludes with some observations on the effect of position of the body in keeping fractured bones in apposition, and relates an instance of recent occurrence, in St. Bartholomew's Hospital, of fracture of both clavicles, where no bandage at all was employed in the treatment, and the patient was discharged in a month with the bones well united.

Read also, a paper on

The Perforation of the Third Lobe of the Prostate Gland. By R. A. STAFFORD, Esq. Surgeon to the St. Marylebone Infirmary.

The author recommends this practice to be adopted in cases of enlarged third lobe of the prostate, considering it quite free from danger. He relates an instance in which he had performed the operation in a man of 82 years of age, in whom it appeared to him to produce no bad effect. The patient died shortly afterwards of apoplexy, when the author had an opportunity of examining the bladder; a preparation of which was exhibited.

PERFORATION OF THE ACETABULUM, CAUSED BY A FALL ON THE TROCHANTER.

M. GAMA has given a case of the above-mentioned accident. It occurred to a man æt. 30, who had fallen from a height of eighteen feet, and who had suffered a severe contusion in the region of the right trochanter. There was neither shortening nor deformity, but there was very severe pain at every movement of the limb. Some days afterwards the patient walked in the garden on crutches, and said that he felt very little pain. On the fourth day symptoms of violent peritonitis, with inflammatory swelling of the entire limb, came

on. On the dissection, infiltration of pus was found in the immensely distended subcuticular cellular tissue, from the hip to the calf of the leg. In the right iliac fossa a conical swelling arose, and extended nearly to the kidney; this was an abscess containing pus and torn pieces of the psoas muscle, and at the bottom of it the head of the femur was to be seen where it had burst through the acetabulum. The acetabulum was broken in three pieces; the smallest of these was placed with the round ligament upon it, and unbroken on the head of the bone; the second was the horizontal ramus of the pubis which was separated from the symphysis pubis and ischium; and the third, the ischium, which was no longer connected with the ilium.—*Gazette Medicale, and Dublin Journal.*

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, March 15, 1838.

Thomas Birt, Stroudwater.—Loraine Weaver, Liverpool.—George Ebenezer Ely, Rochester.—Thomas Cam, Bath.—Charles John Robert Cook.

Mr. W. R. Rogers passed his examination on the 1st of this month. The name was, by some accident, omitted in the printed list.

LECTURES ON TUMORS,

Delivered at St. George's Hospital,

BY CESAR HAWKINS, ESQ.

LECTURE V.

III. SARCOMATOUS TUMORS (*continued.*)

On the Nature and Properties of Malignant Diseases.

9. *Verrucous Tumors of Cicatrices.*

10. *Carcinomatous Tumors.*

Definition.—Various Forms of Carcinoma. Period of Life,—Hereditary?—Exciting Causes.

History of a Cancerous Tumor.—Treatment, General and Local.—Operation for.

WE have now discussed eight different genera of the third order of the class of tumors; namely, the adipose, fibrous, neuromatous, conglomerate, conglobate, scrofulous, cystic, and tuberculous cystic tumors, and we have found that they are all innocent, *i.e.* nonmalignant; not possessed of any contaminating influence, even of the lowest kind, so that they are all local diseases in this respect; unless it be that the conglobate and the tuberculated conglobate tumors are malignant; but I am rather inclined to call even those tumors incurable affections of the absorbent glands, than really malignant diseases. I do not think there is sufficient evidence that either of these tumors, nor the cystic, nor tuberculous cystic tumors, possess the power of causing the same structure as their own to be formed by their influence in the surrounding tissues, nor in the absorbent glands, nor in the whole system. But, at the same time, we have found that they are not innocent in their effects on the patient; on the contrary, they may be

fatal to life itself, by irritation, by ulceration, sloughing, and bleeding, unless they are removed by operation, which may be done with safety with all of these tumors, except sometimes the tubercular conglobate tumor, if the operation is done early, and the tumor is accessible to the knife.

But you must not forget that all tumors may become malignant, although they are not so originally; and perhaps they are in themselves a source of malignancy; that is to say, if the constitution of an individual is disposed to malignant action, and happen to have a tumor in any part of his body, that part will be selected for the development of the constitutional taint; just as, if a patient deranges his system so as to dispose it to form ulceration somewhere, the new structure of a cicatrix will be the first, in all probability, to give way. Thus a mole, or a fatty tumor, may become malignant, and go through all the changes of a malignant tumor: a man was admitted into the hospital, for instance, under Mr. Babington's care, with a fungous tumor of the size of the fist, which, for forty years, had been a small mole unchanged in size and nature. A new action is suddenly developed, and a new character assumed by the part, and it now gains the property of contaminating the structures around, and making them like themselves in appearance, and of contaminating also the glands, and of poisoning the whole body. I need hardly say, then, that this observation is a sufficient reason for your taking away even innocent tumors, if the patient can be induced to submit to their removal, lest they should become a cause for the development of malignant action, which the patient might have escaped if no morbid structure existed.

I have used the expression malignant condition of the whole system; now, what are you to understand by this? You will recollect what was formerly told you as to

the different degrees in which malignant action is exhibited; first, it may be apparently entirely local, so that forty years may leave a patient with only one part affected. Secondly, the glands to which the absorbents come from a malignant tumor may be enlarged in consequence of their connexion with that tumor, and yet the general health may still remain pretty good; but, thirdly, the health may give way nearly simultaneously with, or even before there is any evidence of local disease at all, shewing, in the latter case, that the constitution must have been tainted before the formation of the tumor. But now comes the important question, whether any malignant disease whatever is really local, or whether the constitution is always affected first, as it unquestionably is sometimes?

It was said, I believe, first by Mr. Wardrop, with regard to fungus hæmatodes, and the opinion is elaborately supported by that zealous pathologist Dr. Carswell, as to all malignant tumors, that the actual matter of the disease circulates in the blood, and the arguments in favour of the opinion are threefold:—first, because the new substance is deposited by the capillary vessels, nutrition and interstitial absorption going on together, so that the malignant matter simply occupies the place, and assumes the form of the original materials of the body; an argument that goes for very little, as it would apply equally to cartilage or urine, though nobody goes further with regard to such substances than to affirm that their elements are contained in the blood, and separated by the capillaries in a new form from that fluid.

Secondly, because the matter of malignant disease is found in the blood-vessels; you will see in these preparations the trunk of the *vena portæ*, and all its branches in the liver, completely filled with solid substance, so that the circulation must wholly have been interrupted through the vessels. But this also is no proof that the blood has contained the peculiar substance in that shape. *a.* In the vessels, as well as elsewhere, the malignant structure is deposited, in all probability, by the capillary branches of those vessels, as in ordinary nutrition, and it is therefore generally organised and adherent to the sides of the vessels, by means of organised communication. *b.* It gets into the vessels by ulceration through their coats, and then spreads rapidly, from its being subjected to less pressure: you may see here a little portion of tumor just ulcerating into, and hanging loose in the *vena cava superior*; another portion is ulcerating through the pericardium, and the gentleman from whom I took the preparation, who was a

patient of Dr. Scymour's, died suddenly while at the closet-stool, by hæmorrhage into the pericardium. *c.* Sometimes, again, malignant matter gets into the vessels by absorption; I have seen it, in the absorbent vessels, coming from a tumor, in its passage to the glands, and I believe it is found in the same way in the small veins; but this is *after* it has been secreted by the capillaries, just as pus is found in the same vessels, and thus you have one mode of contamination of the system.

Thirdly, the only probable proof that the malignant matter exists in the first instance in the blood, without having been previously formed, like every other part, by the vital action of the capillary vessels, is the circumstance of an effusion being observed in a soft condition, in some places consisting of a mixture of blood and malignant matter. But I have not seen this satisfactorily made out. I have often, indeed, seen a mixture of fluid malignant matter mixed with blood, but only when it appeared likely to have been formed previously to the rupture, either in the cellular substance or on the surface of a membrane,—in the same way as you may often see a mixture of purulent matter and blood, without adopting the supposition that the pus had been mixed with the blood, so closely combined as to be dropped from one another, as it were. The pus and the malignant materials are, surely, alike formed out of the elements of the blood, by the capillaries in some part of the body, before these respective substances become mixed, as such, with the blood in the circulation.

See, now, what an important question this is in practice: if the whole system be so poisoned, as actually to contain perfect malignant matter in the circulation, before it is deposited anywhere, either in the molecular structure, or as a secretion, there can be no such thing as a local malignant disease; no operation can consequently be performed before the whole system is tainted; the blood always circulates the poison. I trust, however, that there is often a predisposition only, or tendency, to malignant disease, just as there often is to scrofulous action, before any serofulous matter is formed; I trust, therefore, that a tumor composed of malignant substance may sometimes be local, aye, and for several years, during which time the blood does not contain any formed malignant matter; but, at last, if a further influence is exerted on the system, or if the matter already deposited is absorbed and mixed with the blood, so as to deteriorate that fluid, the patient has now passed the boundary within which an operation affords any security against a return of the malady. Sometimes, on the

other hand, there is not only a slight predisposition, but the blood has so strong a tendency to separate those elements which, when united, constitute malignant structure, that the whole system may be said to be in a malignant condition, before the vessels have yet formed any local tumor; or, if a tumor has been formed, although no malignant matter has yet been absorbed, so as to be mixed with the blood, yet an operation is useless, or worse than useless, and may hasten the formation of the same structure elsewhere in the body.

Now, there are several forms of malignant disease which are, for a greater or less period of time, merely local, especially in the skin; one such form I shall hereafter speak of, with the other diseases of the face. There is also another, which is so peculiar in several respects, that I shall speak of it, a little out of its place perhaps, as another genus of sarcomatous tumors, under the name of

III. 9. *The Verrucous Tumor of Cicatrices.*

I think it deserves separate consideration, because it has not been well described in surgical works, a circumstance which induced me to publish a series of cases which I had seen of the disease in the 19th vol. of the *Med.-Chir. Transactions*, to which I may refer you for a more minute account of it than our time will at present allow.

It belongs to those cases which are called, sometimes, semimalignant; but, for my own part, as I think it is essentially carcinomatous in its nature, I prefer the term locally malignant, by which I mean that it is a kind of cancer which contaminates only the neighbouring textures, and does not affect the glands; at least, I have not yet seen it do so. I have never seen it, except in the cicatrices of old injuries, and I think it probable, therefore, that the peculiar texture of the new skin may influence its growth, making it occur where the constitutional tendency is less than would be sufficient to develop malignant disease in sound parts, and causing it also, when formed, to differ from the malignant tumors of original and sound skin. The injured parts may remain quite well for many years, or may frequently thicken with common inflammation, or ulcerate from the usual causes, and with the common appearances, before the peculiar changes in question evince themselves.

The warty tumor of cicatrices presents three successive stages to your notice:—1. Here is a tumor which formed in the scar left by a flogging, and was removed by Sir Benjamin Brodie, from a man who had been sentenced, eleven years before, to

receive 1,000 lashes. It was vascular, warty in appearance on the surface, scarcely ulcerated, but discharging an offensive watery secretion; in this particular case there was very little pain, but the pain is sometimes considerable. You may see, also, little elevations of the same character around the larger portion of the tumor. The section of any portion of the tumor in this condition shews you a firm hard structure, of a dense white colour, rising in a fibrous manner, perpendicularly, from the substance of the cutis.

In the second stage, the tumor becomes less warty in appearance, and is composed of a mass of rounded fungous elevations, still very solid, but less fibrous, when cut into, than before. You may see it in this preparation, which was removed from a man's back by Mr. Jeffreys, and which also followed a flogging received 27 years previously. Or you can see the nature of the disease still better, in this plate and preparation, from a young woman of 28 years of age, who was under my care. This is the earliest age at which I have seen it, and it followed a burn received when she was a child, which had healed, and left a scar from the toes to the knee. It had broken out into an ulcer, six months before her admission into the hospital, which had generated a luxuriant mass of fungous warts, accompanied with the most intolerable pain, and a very offensive discharge, under which her health seemed rapidly sinking. She refused the amputation which I had proposed to her: but one day, on coming to the hospital, I found, from the house surgeon, that she had told him if I would perform the operation directly she would submit to it, but that she would not have it done on any future occasion. You see a large mass of fungous growth, two inches in thickness, and nine in diameter, and the section still shews, in some parts, very well the fibrous warty nature of the disease; you may also perceive that although of this large size, and attached to the periosteum, the morbid growth had produced no alteration, except a little inflammation in the bone below. This woman remained quite well two years afterwards, and had no return of disease in a part of the cicatrix, which I had left, in order to amputate the limb below the knee.

In the third stage, the fungous growth ulcerates, and leaves a foul ulcer on the level of the skin, and spreads by the edge around, when the skin goes on forming warty elevations of the same character. Here is a very beautiful preparation of the disease in this state, which I took from a man whose limb was removed by Mr. Gunning, when I was house surgeon, and

in whom it formed in consequence of a gun shot wound. A patient was under my care for a very extensive ulcer in the back, following a burn, which had been healed eleven years; it was too late for operation, being ten or twelve inches in diameter, and the man fell a victim to the intolerable pain it produced. Even then, however, it had not extended below the fascia, and there was no sign of morbid structure in any part of the body.

I have seen various methods tried to destroy the morbid growth, many of them on the supposition of the disease being only an unhealthy ulcer, but without avail. Looking upon it as a malignant disease, it is evident that we ought not to expect any measure to succeed which does not insure the entire destruction of the new growth, which can, of course, only be effected by strong caustics, or by the knife. Of the caustics, the best is the chloride of zinc, but I much prefer the excision of the tumor, if that is practicable, by the knife, or the amputation of the limb, when the disease is too extensive for excision. The patient remains, I believe, free from a return of the disease, as he ought to do if the disease is only locally malignant, and as he has done, as far as I know, where I have seen the removal of the disease practised.

Separating, then, for convenience sake, the verrucous tumor of cicatrices from cancer, of which it is probably only a variety, the two remaining genera of tumors are malignant in the highest degree, affecting not only the surrounding textures, but the absorbent glands also, and poisoning the whole system; and most of the remarks I have to make upon them, apply equally to the disease, whether there be, strictly speaking a tumor, or whether the new structure be only an interstitial deposit, as in the cancelli of the bones, or the textures of the internal organs, without increase of their bulk.

III. 10. *Carcinomatous, or Cancerous Tumors.*

Surgical writers have often divided this disease into two stages:—1st, Scirrhus; 2d, Cancer; terms which are synonymous with the expressions, occult and open (or ulcerated) cancer. Scirrhus is a bad name, however, to retain, since it is used by the older authors to designate any hardness which is the result of inflammation or disease. I should rather say the older English authors, for it is still very often used by foreign writers, without any definite idea of the disease as an affection of the system; some of the French, for instance, often speak of scirrhus and cancer from syphilis, a sequel of the latter disease purely imaginary. Unfortunately, these efforts of the

imagination are not confined to the mind, but are carried into surgical practice, and nothing is more common than to hear of a great number of operations for cancer of the rectum, in which that gut (sphincter and all), has been cut out for simple ulceration, or of a great number of cases of excision of the cervix uteri, in young women of eighteen, for supposed cancer of that part. Some, indeed, instead of dying of cancer, have survived the operation, and have borne children afterwards, grateful, doubtless, to their operative friends for the preservation of their lives! such cases, no doubt, having been instances of hardening and enlargement of the os uteri from simple inflammation, for which some persons might prescribe caustic, and some matrimony; and either remedy, I dare say, would be pleasanter than excision, and quite as efficacious.

By *carcinoma*, then, I mean the generic name applicable to all forms and stages of the disease, whether there be a distinct tumor or not, and whether the part be recently formed, or extensively ulcerated. Almost every structure in the body is liable to carcinoma, but some textures are more disposed than others to the disease; it is very common in glandular organs, such as the breast and liver, which you may here see; and, where mucous follicles abound, as in these preparations of the cervix uteri, the cardia of the stomach, the œsophagus, the colon, the rectum: you may see it here in the lungs; here in the skin, and at the junction of the mucous membranes with the skin, as in the penis and labia; in this preparation you perceive it in the serous membrane, the pleura: and in this in the bones. And, in whatever tissue it originates, the morbid structure affects, by degrees, all the contiguous textures: you see in this plate, for instance, and in this preparation, that it implicates distinctly all the coats of the stomach, after having begun, as it would appear, in the mucous membrane.

Cancerous structure affects several different forms, and varies much in its appearance. *a.* The most usual form of an external tumor is that of a tolerably circumscribed tumor, which is generally firm and hard in texture, something like cartilage, sounding under the knife when cut: running through this you can distinguish a number of bands, or rays, of a white or brownish white colour, from which the disease derives its name of cancer; these bands extend to the neighbouring structures, however, from the tumor, and are the result of carcinomatous deposit in the cellular tissue, which is much disposed to the disease, so that you will occasionally see the skin connected to the tumor by these cancerous bands, while the interme-

diate fat remains healthy. It seldom, therefore, happens that a tumor is really as circumscribed as it appears to be; it is not confined by a cyst, but these bands are sufficient to propagate the disease after the tumor itself has been removed. In the interstices of these membranous bands a cancerous tumor is less compact, and you can squeeze out a milky fluid, or a transparent liquid like glue. *b.* At another time the tumor is less solid and has few bands, and resembles what was called, by Mr. Abernethy, the udder-like or mammary tumor. *c.* Sometimes the tumor has a number of cysts within it of small size, and containing mucus, or a bloody fluid, or a liquid like chocolate in appearance, and in a large cell fungous excreescences of cancerous structure are sometimes found. *d.* In another instance, especially in the hollow viscera, as in these instances, it is soft and transparent, constituting gelatiniform cancer, or cancer areolaire, as it is called by Cruveilhier, or the *matiere colloide* of Laennec. *e.* In other cases, the cellular bands are almost entirely wanting, and there is a larger quantity of unorganized greasy secretion in the interstices of the cellular membrane, making the lardaceous tumor, such as you here see in the lung and liver. *f.* In other cases, any of these structures will affect a distinct tubercular form, with a surrounding cyst more completely insulating the diseased substance than usual, as here in the liver or lung, or in the form of a number of little tubercles around the original tumor, without any apparent connexion with it. *g.* Or, lastly, you will find millions of little hard rounded or flattened tubercles in the serous membranes, especially the pleura, as in this instance, projecting into the serous cavity. But there is no essential distinction in the disease from these variations of character, and you will meet with all these forms of structure in the same person in different organs or tissues, and several of them at once, in separate parts of even the same tumor.

A characteristic distinction of cancer from other malignant tumors, is, that it is a disease of the middle period of life, from about 35 to 55; it is very seldom met with under 30 years of age: I have only once seen it in a young woman under that period; but no rule is without exception, and Sir Everard Home met with an instance of a girl who, when 15 years old, received a blow on the breast, which left a hardness in the injured part, and at 20 this lump began to enlarge, with the usual signs of cancer, and was subsequently removed by operation. So also cancer sometimes shews itself after 60 or 70 years of age, but seldom, except in the skin, at such an advanced age.

Cancer appears much more frequently in females than in men; it is said, in the proportion of ten to one; and in females (in whom it takes place chiefly in the uterus and mamma), the disease occurs very often about the time that menstruation begins to cease, and when these organs are no longer useful. It is said, too, by many persons, that cancer of these parts occurs more frequently in unmarried females than in those who have borne children; as if these organs, when their natural functions are not called into action, are like children, who cannot remain idle, and are therefore always getting into mischief, if not properly employed. I am, myself, however, very doubtful if this observation be well founded, or whether even the reverse may not really be the case.

It seems not improbable that cancer is, to a certain extent, hereditary, so that you will often find the parents and children in a family, successively, have the disease, or several sisters will each die, at a certain age, of the disease. Of course, from what I have before said, you are not to understand that cancer is born with them, or that cancerous materials exist in their blood from birth, but only that a certain peculiarity of constitution is hereditary, so that when any exciting cause is applied, cancer is more likely to shew itself in them than in persons who have not this peculiarity: just as persons with an hereditary predisposition to scrofula cannot expose themselves to cold with impunity; though no one imagines that scrofulous matter is circulating in the vessels.

The cause of the development of a cancerous tumor is, then, the existence of such a state of system as that just described; but the situation chosen is frequently attributable to some external injury, or other exciting cause. It frequently takes place in the hardness left by inflammation, as by a blow on the breast; it often arises from the local irritation of soot upon the scrotum, or of a tobacco-pipe upon the lip. Sir Everard Home met with this remarkable case: a sailor contrived to get his penis squeezed by a piece of wood, and flattened like a half-crown, an accident which, as you may imagine, made the man faint from pain, and produced inflammation of the penis and testes; he recovered, however, except having a small pimple, which, six months afterwards, ulcerated in the form of cancer of the penis; this was followed by a tumor in each groin, which ulcerated also, and in four years he died in this hospital, from frequent bleeding from the ulcerated parts; and, after death, a number of glands were affected in the lumbar region in the abdomen, and in the mesentery, liver, and other parts. Sir Everard Home went

so far as to believe that cancer never was developed unless in a part which had been injured, or diseased in some manner or other, previously, in which case, the morbid alteration of a simple kind, the pimple or wart, or whatever it might be, became afterwards cancerous; but he was, no doubt, wrong in thus supposing that it did not occur in healthy parts, and you will find cases, not unfrequently, in which, with all their fondness for finding local causes, your patients can assign no reason why any particular locality is attacked.

Cancer, as it is modified by texture and situation, will be more particularly described to you hereafter, with the diseases of the breast, the scrotum, the lip, the eye, and so on, and in your medical lectures; but let us now trace the progress of a cancerous tumor, in any part of the body, in its common form below the skin.

A cancerous tumor, in its early stage, feels like a firm, hard mass, circumscribed and distinct from the organ in which it is situated, but yet generally giving you the sensation of its being intimately attached to other textures; sometimes moving freely below the skin, and upon the deeper parts; but this circumstance also is doubtful even in the early progress of the tumor: the tumor is generally irregular on the surface, with somewhat angular projections, but in many cases where the interstitial fluid is in considerable quantity, so as to make the tumor softer, its exterior feels quite smooth and uniform. It has grown to a certain size without being observed, and without pain, but as it increases further, it is attended with a good deal of pain, which is described as acute, lancinating, stabbing, darting, and so on, expressing its irregularity in degree and kind; the tumor is not very tender in general, but the pain is much increased afterwards by handling; sometimes the pain is most at one part, and this occasionally from a nerve stretched over the tumor.

The pain is considerably aggravated as the second or ulcerative stage comes on. The tumor now becomes attached to the skin, which is generally puckered and contracted at the point; then it becomes red and ulcerates; or a part of the tumor grows more rapidly than the rest and projects, and becomes of a dark colour; it gets thin, and gives way by being stretched as it were; it does not suppurate, but simply ulcerates and wastes away. The discharge is thin and watery, or an imperfect pus mixed with mucus, or it is ichorous, and has a peculiar foetid odour. The ulcer is flat, and the edges thin and superficial, and increases gradually, as represented in this cast; or it has sloughs formed upon it of a dark colour, with fre-

quent hæmorrhage, as in this cast, and the edges are sometimes thick, raised, and everted, as is shewn in this cast. Sometimes ulceration is established in the interior of the tumor, instead of on its surface, and suppurates imperfectly. I attended a patient, with Mr. Peregrine, in whom a considerable sized cavity was thus formed, with such an extent of hæmorrhage from the inner surface that the cavity was obliged to be freely laid open to control the bleeding; then the disease became quiet and nearly dormant for above a year, but it has since been fatal.

Now commences the third stage perhaps. Hitherto the general health may have been not much affected, but after the ulceration the patient begins to droop, looks thin, emaciated, haggard, with a dulness of eye, and relaxation of muscle, and has a peculiar sallow, or leaden hue in her countenance, which is well depicted in this plate of Alibert's, or in this cast, and which communicates an expression which the experienced eye of the surgeon recognizes as indicative of a malignant condition of the system, perhaps before much complaint is made by the patient herself. If seen there is now no hope of cure from surgical operation, and the unfortunate sufferer is condemned to drag on a miserable existence, sensible, too, of the disgust created in the feelings of her attendants, by the appearance and smell of this horrible complaint. The condition and state of mind in a cancer ward is well depicted by Milton:—

“Despair

’Tended the sick, busiest from couch to couch,
And over them triumphant Death his dart
Shook, but delayed to strike, tho’ oft invoked.”

The time which elapses before a fatal result varies very much; it is influenced by the texture in which it arises—by the organ in which it is situated; it depends on the kind of carcinomatous formation in each case, and various modifications of the disease will be described to you by and by, which will influence your practice, especially in the breast. For the most part, about three or four years will be occupied from the first discovery of the tumor. The last scene is sometimes very rapid: a woman, for instance, came under my care with a tumor, which she discovered a year before, and which was just beginning to ulcerate, and in three months from this time she died with most extensive disease in both breasts, and in the skin and glands, and in the internal viscera: and sometimes your patient will die in a few months from the appearance of a tumor, when there is no evidence of internal disease to hasten the event. On the other hand, cancer sometimes proceeds very slowly: a woman was

three weeks under my care for some other affection, suffering so little, that she allowed this time to pass before she even mentioned to me that she had had a cancerous tumor in one breast, which had been ulcerated eleven years, and had existed twenty; she had also a tumor of the same kind in the other breast, of four or five years' standing, and had a little cough, that appeared, perhaps, to be connected with disease in the chest.

Cancer runs its course, I think, quicker in young persons than in old; I knew a lady who had had a tumor forty years, ulcerated several years before she finally died of hydrothorax, at an advanced period of life. It is more rapid, perhaps, in fat and bloated individuals, than in those of less ample dimensions. In short, there are great varieties in different cases of cancer.

I need hardly say, after this account of cancer, that we possess no cure for it; the removal of the diseased part, before the system has become affected by it, affords us the only chance of safety from the complaint. But even when the operation has been considered improper, or has been ineffectually performed, we can still do much, both locally and constitutionally, to alleviate the patient's sufferings, and to retard its final result.

Unquestionably, whatever debilitates the body, or irritates the mind, accelerates the appearance of the complaint, and hastens its progress. Anxiety of mind, such as that induced by poverty, or the loss of children, or other dear relations, is often the immediate exciting cause; and it runs its course quicker in persons of irritable constitutions, and occasions much more suffering.

Mr. Pearson, who is a high authority on some medical subjects, recommends a starving diet, and depletion by purging, and so on, to retard the progress of cancer. More modern experience, however, has fully established the reverse, and I advise you to recommend a moderately nourishing diet. Whatever stimulates does harm, such as wine and bark, if any heat or fever are caused by them, but, on the other hand, whatever lowers the tone of the system accelerates the rapidity of the disease. A young woman, 29 years of age, was under my care, as an out-patient of this hospital, with a cancerous tumor of the breast, and enlarged glands of the axilla, and the state of the parts altogether induced me to advise her not to have an operation performed: after some time she changed her residence, so as to make it more convenient to her to attend at another hospital, where she was kept on low diet, and had a great number of leeches applied during

six weeks, at the end of which time the pain was intensely increased, and she was emaciated, and apparently dying. I immediately put her again on a more generous diet, and gave her a course of sarsaparilla, and in a short time she had regained her flesh and strength, and nearly lost the pain in the tumor. Subsequently, of course, the tumor ulcerated, and she fell a victim to the disorder, but her life was certainly prolonged considerably, and her condition rendered much more supportable.

The medicine I have just mentioned is, on the whole, the best, I think, given in considerable quantity—a pint of the comp. decoction, with a dram of the extract daily, if the patient bears it, and continued for several weeks, whenever the health appears to be sinking, before the irritative fever of the last stage comes on. If the countenance is assuming the peculiar aspect I have alluded to, about $\frac{3}{4}$ of a grain of the oxymuriate of mercury, or five grains of Plummer's pill, or $1\frac{1}{2}$ grains of calomel and a grain of opium, is of service with the sarsaparilla. Sometimes other tonics are of more service, such as gentian, or calumba, which may be joined with soda, or potassa and rhubarb, where the appetite is beginning to fail. Sometimes small quantities of carbonate of iron, or the comp. steel pill, will agree, but not so often as the less heating and stimulant tonics. I have seen the malignant state of the system repeatedly disappear, for a time, under this plan; I have even seen the tumor become much smaller, so as to excite delusive hopes in the patient's mind of final recovery.

Such a method of treatment as I have now recommended is of service to the patient under several different circumstances, though it will not cure the disease: it is useful before an operation, enabling the patient to bear it better; it is of service after an operation, by delaying, at least, the recurrence of the disease in some other situation; and when an operation is altogether improper, the case I narrated to you shews what benefit it may confer upon the sufferer, by retarding the progress of the complaint. Almost the only thing you can do besides, is to soothe the patient's sufferings as much as possible by opium and conium, and other narcotics, with a little coloeynth, or other purgative, to prevent the constipation and diminution of the secretions, which attends their use when employed singly.

Locally, also, you can do much good. When slightly inflamed and hot, a weak spirituous and gently stimulating lotion, used cold, or tepid under an oiled silk, according to circumstances, will agree much better than poultices and fomenta-

tions; warmth generally increasing the pain. Occasionally, a few leeches are of service applied around the tumor, not upon it, especially when the skin is thin and inflamed, otherwise the ulcerative process is hastened by the leech-bites; and you must take care, at the same time, that they are not applied so often, or in such numbers, as to weaken the patient by loss of blood.

In the early stage of the tumor, when not inflamed, a warm plaster spread on leather, and placed over and around the whole tumor, gives frequently great relief; it may be the mercurial, or opium, or soap, or ammoniacum plaster; or, when the pain is severe, a plaster consisting of one-third part of extract of belladonna, with two-thirds of soap plaster. The opium and belladonna are both, however, offensive to some patients, and induce headache; and the latter, in large quantity, will dilate the pupil and cause headache and other symptoms of its narcotic influence. I have seen the pain, when of three years' duration in a tumor in this stage, kept quietly within moderate bounds, merely by these applications.

Pressure has been recommended as a means of cure, by the late Mr. Young, but I believe it only lessens the tumor by rendering it more solid, when it would otherwise have had fluid within it, and by causing the absorption, not of the morbid structure, but only of the ordinary effects of inflammation.

When the tumor is ulcerated, the fœtor is subdued and the sore made more healthy by the chlorides of lime or soda in solution, and they check the sloughing process; a charcoal poultice, or the yeast poultice, will do the same. The pain of the sore is much relieved by a poultice of fresh hemlock leaves, if you can procure them, or by a solution of the extract: $\frac{1}{2}$ a drachm to $\frac{1}{2}$ a pint of water, may be used as a lotion, or in a poultice. The woman from whom this cast was taken derived more relief from the following liniment, than from any other application, which you may rub down and spread on lint:—

R. Liq. Plumbi Subacet. ʒiss; Tr. Opii, ʒiss; Conserva Rosæ Gall. ʒj. M. fiat Linimentum.

In another case, most relief from pain is given by prussic acid.

R. Acid Hydrocyanici, ʒss.; Aquæ distill. ʒviij. M. fiat Lotio.

When the sloughing ulcer bleeds much, as it often does, apply one of these applications:—the muriated tincture of iron, Ruspini's styptic, the decoction of tormentilla, or of galls, or the subcarbonate of iron in powder or mixed with honey, so as to spread on lint.

Sometimes, under some plan or other of these kinds, with judicious constitutional treatment, the sore will become more healthy; it does not granulate indeed, but is healthy enough to cicatrise completely though not soundly, a thin shining dark-coloured skin only being formed; or perhaps just as it is completed ulceration is again established, and goes on to its fatal termination.

The great point, however, with all cancerous complaints, is to get rid of the local disease, whenever this is practicable and desirable. One method, which is often resorted to by quacks, is to destroy the disease by caustics, of which the most common is arsenic. If used to an ulcer, it may be employed in three ways:—as a paste, by mixing up equal parts, or a third of white arsenic and two-thirds of sulphur, which destroys the whole at once; or in a solution on lint, from five to ten grains in an ounce of lime water, the effect of which is more gradual and less painful and severe; or, as recommended by Dupuytren, in powder, with calomel, but this is the least useful of all the forms. Be very much on your guard, however, whenever you use arsenic, and never employ it at all with a large sore; for many a patient has probably been destroyed by it, as it is easily absorbed. A better caustic, from its not being attended with this risk, is the chloride of zinc, mixed with two-thirds of sulphate of lime in paste, and with a small diseased part, and a superficial ulcer, it may be used with advantage sometimes, but not if the tumor is large or thick. And caustics are always to be considered inferior to the knife, if the patient is willing to have it used, and the situation of the disease renders it easily accessible.

The removal of a cancerous tumor by the knife forms a very important subject for consideration. It is not, indeed, very often that any operation will effect permanent good; the disease, in a large majority of instances, will return again, and often in a very short time after the removal, where circumstances appear at the time not very unfavourable; but still some few persons escape without any return, and their lives are doubtless preserved by the operation. It is right, too, to perform it sometimes in cases in which a complete cure is perfectly hopeless, in order to afford a respite to the patient's fate, and remove a source of local suffering. A man, 75 years of age, had a cancer of the penis; it was removed because his health was good, and the disease very painful, although a gland was enlarged in the groin. A woman was under my care with a large cancerous tumor of the breast, with enlarged glands in the axilla, the tumor being full six inches high, and sloughing, and irritating

her so much that she could scarcely have lived three weeks. I removed the tumor, with a great part of the pectoral and intercostal muscles, in which a number of little cancerous tubercles existed, and the woman said she would gladly have gone through the operation for less than a week's freedom from her previous sufferings; she got well in health, and enjoyed life for eight months afterwards, when she finally fell a victim to the disease. Your patient may again, even in an advanced stage, get rid of a loathsome malady, which she exchanges sometimes for one of equal bodily suffering perhaps, but in an internal viscus, the lungs, or the liver, it may be, but removed from sight, and causing therefore less mental agony.

But in other cases the operation may only hasten your patient's death; sometimes it returns with greater activity in the part itself; sometimes the operation affects the constitution so as to hasten the development of disease elsewhere; and sometimes there are dangerous and even fatal results from the operation itself.

The question of an operation depends a good deal on the kind of cancer in each case, or the organ in which it is situated, and some circumstances of this sort will be explained to you, with the separate diseases of the breast and other parts; much however depends also on the state of the parts affected, and the state of system wherever the disease is found, and I will briefly allude to some particulars which are to guide you.

We have seen that the disease is propagated in several ways; let us examine how each of these affects the chance of removing the whole disease:—first, cancer spreads to the neighbouring parts, where these are even so little affected as to be apparently healthy, yet when cut into, the disease may quickly return in the cicatrix, or the wound never heals entirely. You may see the skin sometimes altered, firmer and thicker when you pinch it up, presenting a number of spots and black specks, from enlarged sebaceous glands, when compared to the skin around; and I have alluded to the curious fact, that the skin may be thus contaminated, while the fat between the skin and the tumor remains healthy. Sometimes you find, perhaps unexpectedly, in the operation, a number of little cancerous tubercles in the muscles and in the fat around, perfectly distinct from the chief tumor, varying in size from a pin's head to a pea; or you may distinguish them with the finger moving below the skin; or little flat or roundish tubercles are found and seen, as well as felt, in the skin itself. I have seen such a disposition to this tuberculation that all the marks left by the cupping,

scarificator, and by leeches, have become cancerous tubercles. Now, whenever the skin is thus diseased, or tubercles exist anywhere around the tumor, you have no chance of removing the whole disease, and the operation will generally do harm by its effect on the system. For the same reason, when the skin is ulcerated, an operation is seldom admissible, but I do not think a state of ulceration so bad as the thickening and tuberculation of the skin.—Secondly, cancer is propagated by the poison being conveyed by the absorbent vessels; the evidence of which is a hardness in their course, or an enlargement in the next series of absorbent glands—in the neck, the axilla, the groin, the loins, and so on. Now, whenever glands are thus enlarged, the operation becomes either altogether improper, or affords you very little chance of permanent good, even if you can remove, at the same time with the tumor, all the glands that appear diseased. Sometimes, indeed, especially with cancer of the skin, the glands are irritated and swelled, as they might be from any disease not of a malignant nature, and in such case the glands may subside after the removal of the irritating cause. You endeavour to distinguish whether this be the case by the hardness or softness—the inflammatory redness and throbbing pain, or lancinating pain, of the two cases. But, except to remove a cause of great suffering, as in the instance of my own, before described to you, you should seldom operate if the glands are altered in structure by cancer.—Thirdly, the whole system becomes affected, either previous to the appearance of, or by absorption of morbid matter from the local tumor, according to the circumstances of the case. You are to look carefully, therefore, for evidence of this state, in the sallowness, emaciation, dulness, and languor of the patient. Sometimes, cough, hæmoptysis, or hydrothorax, will show you that the lungs or pleura are affected; sometimes an examination will show you the uterus affected, when there is also an external tumor; and the whole body must thus be investigated before determining on an operation on any part.

Something depends on the age of your patient. A comparatively young person may encounter more risk than an old one, from the greater number of years that may be gained if the operation be successful; at least she may do so if the tumor is insulated, and unattached, and not growing rapidly: otherwise, the very fact of cancer appearing in a young person is an argument in favour of the system being probably already poisoned, or at least very strongly predisposed to the disease. In very old persons all operations are formidable, and you will probably accelerate their

dissolution by performing one, for the disease is slower in its progress than it is in earlier life. You may be guided by the natural constitution of your patient, whether she is fat and bloated, or has a more healthy constitution; and much also by the temper of your patient: you should seldom, indeed, press the operation very strongly on a reluctant person, for this very state of mind may cause a fatal result, in a case where a person of a calm cheerful disposition would recover, and have no return.

LECTURE VI.

III. SARCOMATOUS TUMORS, *concluded*.

II. *Fungus Tumors.*

- a. *Fungus Hæmatodes.*
- b. *Encephaloid or Medullary Tumor.*
- c. *Melanosis.*

II. *Fungus Tum vs.*

THE last genus into which I have divided the solid tumors, is, like the carcinomatous, of a malignant character; and it may be divided into three species; viz. (a.) *The Fungus Hæmatodes Tumors*; (b.) *The Medullary Tumors*, and, (c.) *The Melanotic Tumors*. The most striking peculiarities attending these tumors, besides a more rapid increase than the last genus, are, the growth of an irregularly-shaped fungus when the tumor is not subjected to pressure, or when it is exposed by ulceration, and generally a disposition to erosion of the vessels of the tumor, occasioning hæmorrhage, sometimes in considerable quantity, from the exposed substance, or into its interior, and we will call it the genus *Fungus Tumors*.

These tumors have received, however, a variety of different names, derived from their different appearances, sometimes only at different stages of the same structure, which occasion modifications of colour, and various alterations in their course, without materially affecting their essential characteristics. They used formerly, and not very improperly, to be called soft cancer, to distinguish them from the last genus of carcinomatous tumors. Sir Everard Home imagined that the disease was cancer in muscular structure; but, in reality, cancer is as distinct in the muscles as it is in other textures. They began to be described nearly at the same time, in this country, by Mr. Hey, under the name of *Fungus Hæmatodes*—by Mr. Abernethy, under that of *Medullary Sarcoma*—by Mr. Burns the term *Spongoid Inflammation* was used (a very bad term, however, since inflammation is not essential to their formation)—by Dr. Baillie the appellation of *Pulpy Testicle* was used to describe the appearance of the

fungous tumor in that organ, and Dr. Monro adopted the name of *Milk-like Tumor*, for another form of the same complaint. Soon afterwards great attention was paid by Laennec, and other French pathologists, to the same form of the disease which Abernethy called *Medullary Sarcoma*, and they used the corresponding terms, *Encephaloid*, or *Cerebriform Tumor*, to describe its appearance. It is singular, however, that while they have much improved our knowledge of the subject, and have discovered another form, the *Melanotic Tumor*, they should, many of them, have remained ignorant of the real nature of the disease so well described by English authors, and should still class together the vascular nævus and the real fungus hæmatodes. Sir Astley Cooper, again, has used the term *fungoid disease* for all varieties of the complaint; but as the peculiarity alluded to is not like a fungus, but is actually a fungous growth, I prefer the name placed in the table behind me, *Fungous Tumors*.

One of the latest and best of our authorities upon the subject of malignant diseases, Dr. Carswell, has placed them all under one head, with the title of *Carcinoma*, which is subdivided into heads:—

1. *Scirrhus*, under which name he includes scirrhus, or cancer, in its ordinary form, and in that of a lardaceous, and a gelatiniform mass, and also the pancreatic tumor, or conglomerate tumor, of our division.

2. *Cephaloma*, placing in this division the medullary or encephaloid, and the hæmatoid varieties of fungous diseases, and also the mammary, or mastoid, tumor of Mr. Abernethy, which I mentioned as a variety of cancer (which is not the mammary tumor of Sir A. Cooper, you will recollect), and also what Mr. Abernethy called common vascular sarcoma; but what that is I do not profess to understand.

Now we shall find, presently, that there can be no doubt whatever that cancer and fungous diseases are very much allied. For instance, here is a preparation of cancer of the breast removed by Sir Benjamin Brodie, which was followed by fungus hæmatodes of the rib; but I am not quite pleased with the generic name of carcinoma, as including both these forms of disease, since it is almost universally, in medical and surgical writings, confined to one of them, viz. the true cancer; and it seems very doubtful to me, whether some of the diseases included by him, especially the conglomerate tumors, have any title to be placed among the malignant diseases. And then, again, fungus hæmatodes is not like brain, as the term cephaloma implies; and exactly the same reasoning which connects together the carcinomatous and

medullary, and hæmatodes tumors, will join to them also melanosis, which Dr. Carswell excludes from the class; because just as cancer is often joined with a fungous structure in the same tumor, or they mutually succeed each other in the same part, or in different organs of the same individual, so also does a melanotic tumor join itself to each of the others. All of them are allied, while each possesses some peculiarities, and melanosis is, perhaps, most allied to the fungus hæmatodes in the rapidity of its growth and the extent to which it affects the system.

They may then all, I think, be included in one great division of malignant diseases, of which we noticed the carcinomatous or cancerous variety in the last lecture, and we now have the encephaloid, hæmatoid, and melanoid varieties, to take into our consideration. The origin of all these is often the same exciting cause, and the external characters are so much alike, that we can often not tell what tumor our patient has till it has undergone some farther changes, and sometimes even when removed we cannot, in the present state of our knowledge, decide of what character the tumor is.

Still the division between them is real, in many respects, and it is useful, because our reasoning upon the proper treatment to be adopted, especially with regard to the important subject of operation, very often depends, not upon the general characters in which they all agree, but upon those specific differences, or upon the changes undergone by the tumor at different stages, in which its characters are sometimes, to a certain degree, merged in those of another variety.

The Fungous Tumors, in their more ordinary form, the encephaloid and hæmatoid varieties, are, on the whole, softer than carcinomatous tumors during all their growth, and often feel quite of a pulpy consistence: a quantity of soft substance may be washed out of them, leaving a flocculent membranous structure pervaded by numerous vessels. In colour they vary much; sometimes there is a soft white matter, exactly like brain; sometimes a yellowish or brownish hue predominates, and there is a mixture of effused blood in some parts, as in this example, in minute specks, or in larger masses; sometimes there are a number of cells filled with different fluids, and mixed with solid fungous matter in the intervals between the cells, and these cells are often half broken down, or more or less filled with coagulated blood, as in these preparations; which fact is probably explained by supposing that the soft coats of the blood-vessels have been ruptured by un-

equal pressure. The consistence of fungous tumors varies, however, considerably, from a milky semi-fluid substance, which will not retain its form, when you cut across it, to a solid firm structure, almost like scirrhus: even the hardest, however, want the peculiar radiated and fibrous appearance of cancer, and the peculiar stony hardness, like cartilage, of that kind of morbid structure.

Contrast the two genera in these internal viscera. In the lung there are, in this case, the solid, hard, round, well-defined tubercles of scirrhus; here are the large, soft, yellowish white (not insulated) masses of cerebriiform disease, and here the soft, red, brittle, vascular tubercles of the hæmatoid fungous tumors: the former seated on the surface under the pleura, and projecting into the cavity of that membrane; the latter intimately, and almost inseparably, united with the parenchyma of every part of the organ. Look again at this portion of a liver containing large diffused tubera of fungous disease, with all the branches of the vena porta filled with the same substance (as I explained in the last lecture, or as you may see in this plate of Cruveilhier), and compare it with this mass of carcinomatous substance, with the centre harder and depressed, puckered in, as it were, while the rest of the morbid growth expands around—exactly, in fact, as the nipple is drawn in and retracted in cancer of the breast, with prominent enlargement of the substance around it. Such, then, is the kind of structure you will ordinarily find in this genus of tumors in its two species of medullary and hæmatoid materials, which I have for the present blended together, as they run insensibly into each other; and the peculiarities I have described are sometimes as distinctly marked in a tumor not larger than a pea as they are in one of twenty pounds weight, and differ materially from the forms of cancer.

I told you in the last lecture, that scirrhus affected particular organs more than others, especially the female breast and uterus; so also does a fungous tumor; but it is frequent in parts which are not usually the seat of scirrhus. Fungus hæmatodes is very common in the testis, while cancer of that gland is almost unknown. Fungus hæmatodes is frequent in the globe of the eye, and in the orbit, while cancer is rare in those parts; but cancer is, on the other hand, often found in the eyelids or lachrymal gland. So indisposed, in fact, is the globe of the eye to cancerous ulceration, although so readily affected by the other forms of malignant disease, that you may see it quite surrounded and insulated, and hanging loose in a large and

deep cancerous sore, without being itself tainted. Fungus hæmatodes is rare in the coats of the alimentary canal, which are frequently the seat of gelatiniform cancer. Still no structure, probably, is exempt from either of the diseases, though, perhaps, the contamination of fungous disease is less resisted by most structures than scirrhus may be.

Fungous tumors, like cancer, frequently arise from local causes. Here is a preparation, which was removed, when I was house-surgeon, from the breast of a groom, thirty years of age, five months after he ruptured some fibres of the pectoral muscle, in catching a run-away horse; the tumor began a fortnight after the accident, and was of the size of an egg in five weeks; then it grew more rapidly, and in four months from the accident it ulcerated, and a fungus as large as an orange, of which this is a section, grew from it, and the whole mass of the tumor was seven or eight pounds weight. A tight shoe has been known to occasion fungous disease of the foot. A gentleman, a pupil of this hospital, three or four years since, pricked his finger with a needle, and fungus hæmatodes arose from the injury, which was speedily fatal.

But certainly fungous tumors are less frequently local in their effects than cancerous tumors. Either the system is more affected before any local disease is formed, or the secretions of the part are more easily absorbed, so as to contaminate the system, and the poison is less frequently arrested by the absorbent glands. This fact involves the important consequence, that you have much less chance of a successful operation than for some forms of cancer, and the disease generally reappears in a greater number of places. For instance, Mr. Keate removed a fungous tumor of the breast, in January, from a woman whose general health was so little disturbed that the disease was at first opened as for an abscess. Before she died in the following April, that is, in three months, twenty or thirty external tumors had formed in different parts of the body, besides extensive morbid deposits in several viscera; and these tumors seemed to present every variety of form, both of cancerous and fungous structures.

There is, doubtless, an original difference of constitution, which has something to do with the kind of malignant structure which is developed when a malignant diathesis is engendered. The patients, both with cancer and fungous complaints, become emaciated and unhealthy as the disease proceeds; but cancer chiefly appears in persons whose countenance is pale and bloodless when the system is affected, with sunken eyes, and a leaden com-

plexion. Fungus hæmatodes, on the contrary, frequently appears, and grows to the size of a person's head, perhaps, in young people, stout, and with a fair skin and florid complexion, and apparently healthy constitution, for a considerable time. Mr. Travers expresses this circumstance by giving it as his opinion, that fungus hæmatodes is cancer in a scrofulous system; the delicacy of the skin and full development of the cutaneous circulation being, in such cases, like what may be observed in scrofulous individuals not immediately labouring under that complaint. At last, however, in all the forms of malignant disease, whether cancerous or fungous, there occurs that half-jaundiced complexion, and peculiar aspect, which the experienced eye detects without much difficulty.

Another circumstance which strongly demonstrates the different condition of the system, is the age at which the two genera of tumors respectively occur. Cancer, as we have seen, is a disease of the middle and latter periods of life, very seldom taking place under thirty years of age. Fungous disease, on the contrary, may appear at any age, but it is most frequent in young persons, and is seldom met with in mature years. Here is a plate of fungus hæmatodes of the eye in a child of eight months, and I have seen it in much younger infants even than this. Still fungus hæmatodes may take place at any age, and you are not to regard the two genera of tumors as the same disease modified by different ages; for if an encephaloid or fungus hæmatodes tumor take place late in life, the disease is just as characteristic as in young persons; except, indeed, as we might expect from the greater activity of their circulation, that the fungous disease is generally more rapid in its progress in younger persons than in adults.

Another circumstance in which the cancerous and fungous tumors are contrasted with one another, is, that the fungous tumor may be handled in general without its causing much pain, while the examination of the scirrhus tumor is sure to be followed by increased pain, even when you do so gently. During the progress of the fungous tumor, it is, in its first stage, much less attached than scirrhus to the surrounding parts, and it is insulated and confined by a cyst of cellular membrane, more or less condensed, allowing it to be freely moved, and more easily removed. The skin also is seldom fixed to the tumor till ulceration begins, and is seldom affected by this genus of morbid growths, while it is easily contaminated by scirrhus. These tumors have also large tortuous veins on their surface more frequently than other kinds of tumors, although this

appearance is not to be looked upon as necessarily implying the malignancy of a tumor.

A striking difference between cancer and fungous tumors is afforded by the comparative rapidity of their growth. Scirrhus generally increases steadily for several years, and seldom attains any great magnitude, nor are the fungous growths from its ulcer very large and vascular. Fungus hæmatodes, on the contrary, may, in a few weeks or months, become as large as a person's head; or, having grown slowly for a certain time, will suddenly increase with frightful rapidity from some internal change in the tumor, or from the removal of pressure by ulceration, or other circumstances. A girl was, not long since, in the hospital, under Mr. Cutler's care, with a fungous tumor, of a mixed medullary and hæmatoid character, below the hip, a part of which by degrees protruded upwards under Poupert's ligament, and immediately, from the little pressure it was subjected to in the abdomen, increased with additional rapidity, and in about three weeks, I think, from its first being perceived, this part, which had only a narrow connexion by vessels to the mass of the tumor below the pelvis, grew to the size of more than a foot in diameter. If the pressure is taken off by ulceration, an immense fungous mass is sometimes exposed, which bleeds most profusely from erosion of the vessels.

One reason of the rapidity of the growth of fungous tumors is the cells which are often intermixed with the solid part of the tumor, the fluid contents of which are more readily secreted to distend them, than the solid matter can be deposited and organised. Look, for instance, at these two testes which I amputated. In a tumor of the breast, of encephaloid character, I emptied some of the cysts occasionally, from one of which, at a time, as much as six or eight ounces of fluid sometimes flowed. In a patient of Dr. Seymour's, lately, I gave great relief, for a time, by evacuating about four ounces from a cyst in a fungous growth in the abdomen, I know not of what organ.

Recollect, then, in examining tumors, the existence of cysts in those of a fungous character, and endeavour to ascertain the nature of the solid portions of the tumor, if there be any at the same time. But further, there is a frequent source of error in diagnosis, from the cyst-like division of a fungous tumor, when there is really no fluid; the semi-organized deposits in these separate portions feel pulpy, especially in the medullary kind, and are very often mistaken for abscesses. The distinction is chiefly this: the tumor feels firm and elastic, like fluid, when you press upon it,

but does not fluctuate if you tap it on one side, and press your finger on the other; and there is a difference in degree of solidity in the several parts of the tumor, one part feeling just as if there was fluid below, while another part is more solid and resisting. The testis affected with the disease will look and feel at first like a hydrocele, but a careful examination will show that it is somewhat irregular and tuberculated in its shape and consistence. If you are in doubt as to the nature of a tumor, you may puncture it, and then, if it be fungous, you will see nothing but a little blood, or serum, or gelatinous fluid, escape, and the resistance will be that of a body more or less solid. If you do puncture the tumor, and I know no harm from doing it, it should be with a grooved exploring needle, not with a lancet; the wound made by the latter instrument is liable to ulcerate, and the tumor inflames, and a fungus rapidly arises, which is not the case when the needle is used.

Another peculiarity in fungous tumors is of great consequence; they are sometimes, especially in the hæmatoid variety, very vascular, and very large vessels circulate within them. This is an important circumstance in the diagnosis, for the tumor may then pulsate exactly like an aneurism. There is in the museum, I believe, but I could not find it for you, a preparation of a tumor which was situated in the thigh of a woman, which pulsed everywhere like an aneurism, the pulsation being controlled by pressure on the common femoral artery. The surgeon whose patient she was, however, felt doubts upon the subject, and punctured it, on which a stream of arterial blood jetted out to some height; still he had doubts, and on other occasions punctured it again, with the same result. I was present when the artery was tied, as for aneurism; and on the patient dying a few days afterwards, it was found to have been a large hæmatoid tumor of the thigh.

A very instructive and interesting case has been published by Mr. Guthrie, in the fourteenth volume of the *MEDICAL GAZETTE*, in which he tied the common iliac artery; and it is one of the few instances in which the operation has been performed with success. A lady had a tumor of the size of the head on the buttock, which was seen by several distinguished surgeons, of whom Mr. Keate was the only one who expressed any doubts of its being an aneurism of the gluteal artery. The operation having been done in August, the tumor diminished considerably, and the patient was supposed to have been cured of her aneurism. The tumor, however, returned, and she died in the following April, with an immense tumor of the me-

dullary and fungus hamatodes species mixed, which originated in the os innominatum.

It is fortunate when surgeons of distinguished reputation have the candour to publish their mistakes; and all must make mistakes. Such cases, indeed, are not intended to justify carelessness on the part of those who are of less eminence, but they should teach caution to all in the exercise of their judgment, in practice as well as prognosis, especially to the young, who are prone to think that they know every thing; they should inculcate a lesson of charity, also, when mistakes are committed by others.

But this is not all, for you may be led into exactly the opposite error. Here is an enormous aneurism of the thigh, which looked like a malignant tumor, as it had no pulsation, except where the femoral and popliteal artery passed, not through it, but over its surface. I did not myself examine it very narrowly before it was amputated by Mr. Keate, for as mortification was beginning in the toes from its pressure on the blood-vessels, the operation was called for, whatever the nature of the tumor might be. A man had a tumor in the thigh, where the femoral artery enters the sheath of the triceps, into which an opening was made with the intention of dissecting out the fungous tumor that it was supposed to be; but a coagulum was found, through which the arterial blood of an aneurism made its appearance, on the discovery of which I made pressure over the wound, while the artery was tied above. The patient afterwards got well. I believe I was the only one who suspected that the tumor was aneurismal; and I mention the circumstance, that I may tell you why I formed the opinion, in order to guide you in similar cases. I believe that a fungous tumor pulsates like an aneurism, and you can alter its size by pressure; but the diminution never seems to be in one part only, and on the removal of your pressure the blood never comes into the tumor again with the peculiar thrill of an aneurism: in this case, on the contrary, I distinctly felt a kind of central softer depression after I had pressed some blood out of the cavity, and there was a thrill on its regaining its former size, which thrill you may distinguish with the stethoscope, or the ear, when you cannot by the hand. Almost all aneurisms, in fact, even when most solid, have some fluid within them, which you can thus press out, unless the aneurism is under the process of natural cure. Even this, however, is not an universal rule, for Mr. Lawrence has published a case in which he amputated the thigh, as for a solid tumor, but which proved to have been an aneurism, which

had completely lost all pulsation, and could not be made to vary its size at all.

Thus, then, it appears that, in its first stage, a fungous tumor may occasion some doubts in your minds regarding its nature; not so, however, when it reaches its second stage, that of local ulceration. When this begins, your patient will complain of more pain than he had hitherto experienced; the skin becomes dark-coloured and more vascular, and then purple, and ulcerates and discharges a thin watery fluid; then there arises a fungous projection, at first of the surface of the cyst inclosing the tumor; then a slough forms, a dark yellow slough, perhaps, as in this preparation, or of a brown colour. The edges of the skin, perhaps, look thick, and welted, and everted, as is well seen here, but are still distinct from and unattached to the surface of the tumor; while, on the contrary, no division can be perceived when cancer is thus ulcerated; and although the discharging surface is fetid, the factor is rather that of a gangrenous ulcer than the peculiar sickening odour which emanates from cancer.

A third stage commences as these sloughs separate, by which process the large vessels of the tumor are opened, and bleed considerably, and irritative fever comes on. You see here the large tumor I have alluded to in the breast, in its second sloughy and fungous state; in this preparation you see a tumor in the same situation in its third stage, which illustrates the mode in which a patient frequently dies of the disease. The wound had nearly healed, when a little tumor formed by the side of the cicatrix about three months after the operation, and in three months more it had formed a large bleeding and sloughing tumor, with prominent florid masses of granulations alternating with the sloughs, and he died worn out with irritation, and pain, and loss of blood, and cough, and hectic fever. You may see all that had not sloughed away adherent to and implicating the upper ribs, and projecting into the cavity of the chest, with a portion of lung adherent to it; and the pleura was also full of serum, which compressed the lung. Hydrothorax is, in fact, not an unfrequent result of either cancerous or fungous tumors, and its existence must be well investigated before an operation is performed on any tumor on the chest. I have repeatedly seen a fungous tumor commencing in the rib itself, and care must be taken lest an operation be undertaken on the supposition of the case being only a tumor external to, and only attached to the rib, when it really, perhaps, projects almost as far within the chest as it does externally. I recollect a case in which a large soft swelling existed

on the side of the chest, in a state of incipient suppuration, and with an impulse communicated to it by coughing, as in a case of empyema. When Mr. Keate punctured the tumor, a quantity of broken and dead pieces of bone, mixed with some pus, were felt by the finger, and the case proved to be really an instance of fungus hæmatodes of the ribs.

It is not only by hectic and irritative fever, or serous effusion in the chest or abdomen, that a fungous tumor causes death; witness many of the preparations on the table. In this case a man was admitted into the hospital under Mr. Keate, and you may see that the fracture is across a tubercle of medullary substance in the bone; indeed, it is not unfrequent in the osseous texture. A few days afterwards he died suddenly of vomiting of blood, and you may perceive extensive disease of the same kind in the lungs and œsophagus, with a large ulcerated opening in the latter tube, from which the fatal hæmorrhage had taken place.

Here is a case of fungus hæmatodes in the bladder and prostate gland, for the hæmorrhage of which disease the high operation has more than once been performed, though unnecessarily as I conceive, since the blood can be dissolved and washed away.—Hæmorrhage again took place in this instance into the pericardium; and I have seen the same thing in the other internal cavities.—This medullary tumor was removed by Mr. Ewbank from the head of a young man, while I was house-surgeon; but the disease returned, and proved fatal by stupor and other symptoms of pressure on the brain.—The same thing, or apoplexy, or watery effusion, will be the termination of such a tumor as this within the brain itself; and it is singular that the gentleman from whom I removed this hæmatoid disease had lost two others of his family with a similar disease, nearly in the same situation in the cerebellum.

When an external fungous tumor is situated on the thigh or trunk of the body, where it can easily gain skin from the neighbouring surface, it seldom ulcerates till it has attained a great size, and thus it frequently happens that the patient is carried off by some co-existing internal disease of the same kind, where its pressure occasions fatal results, or where it ulcerates more readily than the external tumor; a happy circumstance, very often, for the patient, who is perhaps spared the dread of hourly impending death from a bleeding surface, together with the annoyance and pain and suffering of a sloughing fœtid fungus.

The hæmorrhage, by which so many are exhausted in the progress of fungous

tumors, is not merely the result of their great vascularity, especially in the hæmatoid variety, but is the consequence, as it would seem, of some peculiarity in the texture of the coats of the vessels, so that in an operation your patient may almost die of hæmorrhage under your hands, if you cut across a part of the tumor, while he will hardly lose any blood if the incisions are made just beyond the limits of the tumor, through the same vessels, of course, which transmitted the blood in the former case, but which have a contractile property, which those in the tumors are destitute of; the vessels in this respect resemble those of the vascular naevi.

And this peculiarity of the texture of the vessels influences also the hæmorrhage frequently observed in the interior of the tumor; the vessels, when congested, are easily ruptured, so as to cause effusion into the cells and cellular texture of the tumor. At the same time, I do not wish you to understand that the effusion of blood in the texture of a tumor is a complete proof of its malignancy; the same circumstance may doubtless occur in other tumors, if there is a similar brittleness of texture in their interior. So, also, the strangulation of a portion of the tumor during its irregular growth, and the consequent mortification of that portion, may occur in several kinds of tumors, perhaps, in the manner suggested by Dr. Hodgkin, which I explained to you formerly. But, whenever you see in a tumor of doubtful nature much disposition to internal effusion of blood, and to partial sloughing of portions of the interior, you should strongly suspect that it possesses a malignant character.

There is yet one other circumstance in the history of fungous tumors to be mentioned to you. The sloughing process occasionally pervades the whole tumor, and it dies. The patient is, perhaps, near dying too, but recovers from the dangerous constitutional symptoms he has laboured under, and the disease is cured, at least in that part. A man was under my care with a fungous tumor in the ham, originating in the femur; this ulcerated and then sloughed, after he had refused amputation, and was almost dying with the jaundiced appearance of malignant diseases, and he left the hospital, expecting to die each hour; but having as great horror of being examined after death, as he had of the knife while living, and when it might have saved him. I saw him, afterwards, however, and continued the small doses of calomel and opium, with sarsaparilla, which I was giving him, and in six weeks the cavity in which both hands might have been put, filled up with granulations. He became stout and well enough

to resume his occupation of a groom. Only half the tumor, however, had thus sloughed, the other part of the bone was affected, and six months afterwards he was again looking thin and haggard, and I dare say he did not long survive.

The history I have thus given you of the progress of a fungous tumor, applies chiefly to those in which the vascular hæmatoid species predominates; the well-marked *cerebriform* species is less vascular in its texture, and hence, perhaps, is less seen in very young persons than the hæmatoid; and its lesser vascularity influences its progress to a certain extent, so that it is, on the whole, rather less rapid in its growth; there is less hæmorrhage and sloughing in its interior, a less disposition to form cells of various fluids, and less bleeding from its surface when ulcerated, and from its structure when cut or torn in operation. It has been sometimes said, from its great resemblance to brain in appearance, that this form of fungous tumor originated in the nervous matter; but the opinion is quite erroneous, and the medullary tumor really originates in every texture that the other forms affect, and the difference must arise from something in its growth which is not yet understood.

Fungus hæmatodes, and medullary tumors, are, however, often mixed in different parts of the same tumor, and a medullary tumor often changes its character as it proceeds, and a part of it becomes redder and more organized, and like the hæmatoid species. Here is a large tumor connected with the ligamentum patellæ chiefly, the surface of which became fungated, and bled enormously. I amputated the limb, and the patient died in a few days afterwards with hæmorrhage from the bowels and by the mouth. You may see that the base of the tumor is exactly like brain, while the projecting fungus alone is like fungus hæmatodes.

Still the medullary and hæmatoid species are not, as some have imagined, merely the first and second stages of the same tumor; each is often distinct and well marked at its commencement, and preserves its specific difference to its termination. The medullary form is not unfrequent in the glands; and I recollect examining a patient of Mr. Merriman's, at Kensington, with an immense lobulated tumor, composed of a great number of glands, reaching from the upper part of the head into the mediastinum, which had destroyed a large portion of the parietal, temporal, and maxillary bones, with which it was in contact, by suppurating under their periosteum; and yet, when of this extent, every lobule was perfectly white

and brainlike, and no portion had in the least assumed the characters of fungous hæmatodes.

The cerebriform species of fungous tumor is no less fatal and no less deeply rooted in the constitution, and no less universal in its appearance, than the fungus hæmatodes species; and I may observe, that if the tuberculated conglobate tumor is really a form of fungous tumors, rather than a separate species, it is to the medullary tumor of the glands, such as the case I have just now alluded to, that it is most allied.

Melanosis is a species of fungous disease which derives its name from the peculiar dark colour of its masses, which are black, or purple, or dark brown; and it was first described, I believe, by Laennec, as a separate affection from the encephaloid and hæmatoid species. This colour arises from the secretion of the peculiar coloured matter into the cells or cellular texture of the tumor or organ affected, and it varies in solidity from a semifluid consistence to a completely solid substance. *Melanosis* generally consists of a number of globular portions united together, as in these preparations from the eye. The first case which I ever saw was a tumor of considerable size on the dorsum of the foot, which, from this form, and from its colour, looked exactly like a bunch of dark purple grapes, besides several other single tubercles which she had elsewhere. I well recollect the case, as I accompanied Mr. Ewbank, whose patient this woman had been, twenty miles into the country, on an exceedingly wet night, and having our ardour in the pursuit of science rewarded with a positive retraction of the promise which had been given for us to examine the body.

Sometimes the whole surface of the body, as in this plate of Alibert's, or as in a patient who was a year ago in the hospital, under my care, whom some of you may remember, is studded with an immense number of little blue tubercles, like seeds in size. You may see the same appearance in this portion of the liver: sometimes it is in larger masses, as in this plate of Cruveilhier's; at another time, though not so frequently, it is seen in the form of a number of distinct round tubercles, as in this beautiful preparation of the liver, from a patient of Mr. Keate's. Here is the eye of the same patient, which was removed some time before her death, where the melanotic matter is mixed with other morbid structures of a different appearance. The disease in the liver showed itself not long after the operation.

Melanosis is very frequent in the eye,

and it has been imagined that the pigment of the choroid coat might influence the colour and growth of the tumor, while the retina was supposed by the same persons to determine the medullary form of tumor. In reality, however, melanotic tumors are found in as many structures as the other varieties of fungous disease, and cannot be attributed to any peculiarity in the tissue affected. The disease has been observed not unfrequently in white horses; and Dr. Carswell has supposed that this circumstance may arise from the absence of coloured matter in the skin and its other proper tissues; but then, why should we see the disease in every colour of the human species, and not in albinos only?—and why is it not confined to the lungs, or to the eye, or rete mucosum? In fact, however, the nature of the colouring materials of melanotic tumors has not been well ascertained. Chemical examination shows us in them carbon, with some phosphate of lime and iron, but affords us no reason for the peculiar deposit, nor for the constitutional condition on which the formation of melanosis, as well as of the malignant growths, depends.

The structure of melanotic tumors is most like that of the cystic and other kinds of fungus hæmatodes; so that it seldom feels very firm, but I have sometimes seen the tumors very hard and solid when examined through the skin. Melanotic tumors have not the same high degree of organization that the hæmatoid tumors exhibit, there being a good deal of the secretion in the tumor, but the cellular texture is tolerably vascular.

Melanosis is equally fatal with either of the other species of fungous tumors; but perhaps its less organised condition is one reason why the tumors less frequently ulcerate and generate a bleeding and sloughing fungus than the others: another reason, however, appears to me to be the fact of the still more uniform malignant condition of the system, so that, pervading more structures at the same time, the constitution sinks under it at an earlier stage of any one tumor than even in the other forms of fungous disease. Melanosis is, on the whole, a disease of later life than the hæmatoid variety, in which respect it resembles the cerebriform tumor and cancer. It ultimately occasions the same emaciation and gradual sinking as other malignant diseases, with a fatal result from the affection of some internal organ,—sudden peritonitis or pleurisy, or ascites, or hydrothorax, or universal anasarca, as is beautifully shewn in this picture of the disease in Alibert's work. A melanotic tumor is sometimes observed a longer time than a hæmatoid tumor before

the final result, but is in general quite as rapid as that disease.

All the malignant diseases, however, are often mixed up together—melanosis with cancer—and both with the encephaloid and hæmatoid tumors. The last patient I myself had in the hospital came under my care for a tumor in each axilla, which tumors were of the joint characters of fungus hæmatodes and medullary tumor; and in a short time melanosis made its appearance most extensively, both in the integuments and in various internal organs.

The term melanosis is sometimes very improperly applied, even by pathologists as distinguished as Andral and Cruveilhier, to the collection of carbon often found in the glands of the bronchi, and to the change of colour produced in the blood by chemical agents. Of the latter kind is the blackness of the stagnant blood in the vessels of the intestines and peritoneum, from the contact of their contents, either before or after death; such, also, is the black vomit from effused blood, from cancer, or other ulcers, which erode the vessels of the stomach. Dr. Carswell attributes this to the action of the gastric juice and other acid secretions of the alimentary canal, whence the change is only observed in those situations, and proposes the use of the designation "spurious melanosis" for such appearances. You will recollect, however, when you see the appellation, that these forms of black appearance have nothing whatever to do with the disease melanosis, as a fungous disease, to which, therefore, to avoid confusion, the term ought to be restricted.

Such, then, is an account of these curious malignant affections, as ample as our time will allow, in their several forms—fungus hæmatodes, eucephaloid tumor, and melanosis. There are also some other trifling differences in the appearance of some tumors, which, at present at least, are not sufficiently distinguished to require notice as separate species. They are all, we find, allied, and, like carcinomia, are all incurable; and an operation for their removal alone offers any chance of permanent success. They may temporarily diminish under pressure, and iodine will also sometimes considerably lessen their size. Here, for instance, is a case of fungus hæmatodes of the rib, which appeared like a tumor of the breast, from its pushing that gland forwards; this was seen by Sir B. Brodie three or four years before the patient's death, and for a time its size was materially diminished. Relief is sometimes obtained by evacuating the fluid of the larger cells, by a grooved needle, as I have before mentioned.

Caustics afford the same means of destroying these tumors that they do in cancer; they imitate, in fact, the natural cure by sloughing. They are dangerous, however, and have even less power than in cancer of destroying the whole tumor, their greater activity of circulation giving them, perhaps, more power to resist the action of caustic: hence the knife alone is a safe means of extirpation.

You may adopt the same remedies to retard the growth of the disease, and make the operation more successful, which I before recommended for cancer. Sarsaparilla and other tonics, sometimes with small quantities of bichloride of mercury, or, if the countenance is yellow and sunk, small doses of calomel and opium, a half or quarter of a grain of the former to half a grain of opium, night and morning; and I have mentioned one case, in which, under this plan with sarsaparilla, a patient of mine rallied from the sloughing process, and got stout and well in health. Narcotics and gentle evacuants are also called for, as in all malignant affections.

Neither shall I detain you with speaking of local remedies, which are also to be of similar qualities with those which I spoke of in the last lecture as useful in cancer; but you can do much less towards stopping the hæmorrhage and sloughing of fungous tumors than you can do in cancer.

In the last place, with regard to the propriety of operations for the removal of fungous tumors, somewhat similar rules are to guide your determination, since the disease is propagated nearly in the same way; but still there are some modifications of your practice to be adopted.

1st. There is less contamination of the surrounding textures than there is in cancer; there is often a complete cyst around the morbid structure; and the textures of the skin are seldom adherent and diseased: consequently, there is much greater facility in removing the whole tumor. Fewer circumstances have to be inquired into with regard to the local condition of the disease, and the morbid structure seldom returns in the cicatrix, as it is so prone to do after operations for cancer; unless, indeed, the ulceration is extensive, as in this tumor of the breast, in which, however, there is probably some admixture of cancer with fungus hæmatodes.

2d. The disease is propagated, as in cancer, by the absorbent vessels. Here, for instance, is a fungous disease of the testis, which I removed by operation, and I found distinctly the same white medullary fluid in some of the absorbent vessels of the spermatic cord, which existed in parts of the testis, and which was perceived still more remarkably in a large mass of fungous

cerebriform tumor in the lumbar glands, from the effects of which the patient died soon after the operation. In one case, indeed, Sir Astley Cooper informs us that he found the receptaculum chyli and thoracic duct completely filled with the same morbid matter that the testis of the patient contained, so that there was no more passage for chyle through it than there is in this preparation for blood to flow through the vena portæ; the respective fluids must in each case have got into the circulation by some circuitous route. I have also seen the absorbent vessels filled in the same manner by morbid matter from malignant disease of the bowel. But although the disease is propagated in this way, and the abdominal glands are very often affected by disease of the testis, still I think there is considerably less affection of the glands by fungous tumors in other situations, than there is in the cancerous tumors of the same parts; and you will often find the next absorbents unaffected by a tumor, while the malignant state of the system is shewn by the occurrence of other tumors of the same or analogous character elsewhere. If they are enlarged, even when you have no evidence of disease in other situations, the operation is generally useless; but remember, moreover, that when the glands are perfectly safe, the chances are still great that you will find malignant disease in the viscera.

3d. You should, therefore, devote more especial attention to the state of the general system, in order to detect, if possible, the simultaneous morbid condition of the lungs or liver, or some other part. Certainly, I think, considering the whole history of the disease, that an operation is less frequently successful than one for cancer, bad, indeed, as is the prospect even there. Mr. Wardrop, in his observations on fungus hæmatodes, which well deserve your perusal, has collected a great number of cases, in not one of which was the patient exempt from a return of the disease a year after an operation; but then these cases are almost entirely instances of fungous disease in the eye, on which organ the operations are notoriously unfavourable. Certainly in other parts of the body, even when the tumor has been growing a longer time, it would appear that the life of the patient is occasionally prolonged. I have notes of a case which I well recollect, where the testis was removed by Sir Benjamin Brodie, and the section of the disease was considered by every one, at the time, to be a remarkably fine specimen of fungus hæmatodes; yet I know that this man was alive and well nearly five years afterwards. I know not how long he has subsequently lived.

A few such cases are a sufficient en-

couragement to us to operate, where there are no forbidding circumstances, though with but a feeble hope of ultimate success. Even when the disease already exists in more than one part, yet if one tumor is ulcerated, or affects the system much by the irritation it excites, it may be right sometimes to get rid of this part of the malady. We thus retard that fatal result which we cannot wholly prevent. A gentleman, of whom I formerly knew something, had a tumor on the thigh, which was so malignant in appearance that amputation was refused by several surgeons, although he was greatly emaciated, and dying of this tumor, while there were several others in other parts of the body not in so advanced a state. Sir William Blizard, however, performed the operation; and twelve years afterwards, when I last heard of him, he was still alive, even although two or three of the other tumors subsequently enlarged so much as to require removal at different times. These latter operations were performed by Mr. Lawrence, who has published the case as an encouragement to operate in cases of the tuberculated sarcoma of Mr. Abernethy, of which disease Mr. Lawrence considered the case an example, though it appears to me, from all I have heard of it, to have been more probably a modified case of fungous tumor.

It appears to me, however, as well from this case as from other facts in particular instances of fungous tumors, that there is probably some variety in the degree in which different cases are malignant, as there undoubtedly is in cancer, as it affects particular localities, and is modified by texture. Future investigations therefore, I hope, may determine more precisely the several species and varieties of these malignant affections than our present knowledge enables us to do; and by greater accuracy in laying down the appearances of the tumors, and the states of system attending each variety, to guide us in resolving in what cases an operation is proper to be performed, as affording a tolerable chance of success; and under what circumstances, on the contrary, it is to be avoided, as likely to aggravate the morbid condition of the system. In the skin especially, I have seen a few tumors in the skin, (in which texture cancer is less virulent than in most other textures,) of the nature of which I could not feel certain, but which I have suspected to have been some rarer forms of fungous tumor of this texture. Here, for instance, is one like a mushroom in shape, which was attached to the skin of the thigh by a narrow pedicle, the surface of which having ulcerated, bled repeatedly, to the ex-

tent of above half a pint at a time, though the vessels which I divided in dissecting it off were not remarkably large; but its texture is not distinct.

ON THE INTRODUCTION OF AIR INTO THE VEINS.

By M. VELPEAU.

[Concluded from p. 959.]

Estimation of the Cases which have occurred in Human Life.

EXCLUDING the cases which occurred in animals, I may divide those belonging to man into four classes: the first containing the unimportant cases; the second, those in which death did not supervene; the third, containing fatal cases, in which there was no examination; and the fourth, those where there was an examination.

FIRST CLASS. Cases to be rejected.—These are the cases which are built upon mere hearsay. They are four in number, being those attributed to MM. Gräfe, Lodge, Duportail, and Sir Astley Cooper. It seems certain, indeed, that these are not real facts, and that they have been referred to merely through some mistake.

SECOND CLASS. Cases not followed by death.—Fifteen of the cases above analysed, in which it is mentioned that the patients came to themselves again, seem, at any rate, to prove that they did not die under the influence of the first symptoms. One of these cases belongs to Mr. Mott, two to M. Clemot, one to Mr. Barlow, one to Mr. Warren, one to M. Roux, one to Mr. Mirault, one to M. Rigaud, one to M. Delaporte, one to M. Dubourg, one to M. Malgaigne, one to M. Begin, one to M. Toulmouche, one to M. Amussat, and one to myself.

These fifteen cases are of very different values. Those of M. Rigaud, of M. Malgaigne, and Mr. Mott, only indicate a wound of the external jugular vein. Those of MM. Amussat and Toulmouche merely relate to the mammary veins. In Mr. Barlow's case, and in one of M. Clemot's, it also seems that neither the axillary nor the internal jugular vein was wounded. There remain, then, only those of MM. Roux, Warren, Begin, Delaporte, Dubourg, and my own, with one of M. Clemot's, which allow us to regard the fact as possible, considering the region, and the vein wounded. The case taken by M. Guérétin, from M. Mirault's practice, leaves us in doubt as to the vein opened.

THIRD CLASS. Cases followed by death, but without post-mortem examination.—These

are six in number, and are attested by the name of Warren, Clemot, Barlow, Goulard, Klein, and Maugeis.

In M. Clemot's case the vein opened is not well determined; in M. Barlow's it was probably the internal jugular; in Klein's, it was the thyroid plexus; and a subscapular branch in Mr. Warren's. M. Duplat asserts, positively, that it was the axillary in the case which he attributes to M. Goulard. The median vein at the bend of the arm was the only one opened in M. Maugeis' case. This simple abstract sufficiently shows how vague must be our ideas, when such facts are presented to us.

FOURTH CLASS. *Cases followed by death, where there was a post-mortem examination.*—These are seven in number, and belong to MM. Piedagnel, Dupuytren, Delpech, Castara, Ulrich, Roux, and Putegnat. M. Putegnat's case being given without any particulars, and on the word of a third person, must, I think, be put aside. M. Piedagnel says it was the external jugular vein which was wounded in Bauchène's patient. He has also informed me, that in Dupuytren's case the tumor was on the right posterior and lateral region of the neck; consequently it is not possible that the internal jugular vein, or the subclavian, could have been wounded. In M. Roux's and M. Delpech's cases, the operation was amputation at the shoulder-joint, and the only veins wounded when the bad symptoms came on, were unconnected with the axillary. M. Saucerotte says, that in M. Castara's patient it was a subscapular vein which had been opened to the extent of less than a line, which was also the case in Mr. Warren's. Hence M. Ulrich's case is the only one which affects the region where, according to our experiments, the introduction of air into the veins appears possible and dangerous.

If we now take up the question again at a higher point, we are in some sort compelled to admit the following conclusion—Either the experiments hitherto performed on living animals are incomplete and deceptive, or else these cases concerning the introduction of air into the veins of man are not conclusive.

Looking upon the question, I see, in fact—First, by direct experiment, that it requires a large quantity of air to kill a dog; that air does not enter the heart spontaneously, excepting by very large apertures in the jugular, subclavian, or axillary vein; and that the right cavities are then always distended by a red frothy matter, evidently formed by the intimate mixture of blood and air. Secondly, in many of the cases in which human beings were concerned, the only veins wounded were the external jugular, or the veins of the

breast, shoulder, or face. In the others the aperture in the vein was small, and but little air could enter; and, lastly, cadaveric examination never showed, in any case, the appearances which have been established by direct experiment.

It is not necessary here to refute the language of those who, no doubt through inadvertence, have always kept beyond the points at issue, both in the course of our experiments, and in the discussions at the Academy; and who have always reasoned as if I and others had denied the possibility and the dangers of the entrance of air into the veins. Without seeking for the motives which may have induced some of my colleagues to fall so continually into this unfortunate error, it is sufficient to refer to the bulletin of the Academy, to show the falseness of the supposition. A point which I must take up, as it might otherwise lead to error, relates to the manner in which some have thought to refute the interpretation which I had put upon certain cases. M. Roux, for example, who, in relating several cases, which, though otherwise interesting, were completely foreign to the subject, thought it very strange that I endeavoured to conclude from animals to man; that I accused observers of not having given all the requisite details of their cases; and that while rejecting one explanation, I gave no other; M. Roux, I say, whose discourse seemed to make an impression on the assembly, yet appears to me, I must confess, not to have thrown light upon any point of the question.

To assert that, at the instant of accidents like these, the surgeon has not sufficient presence of mind, and is too disquieted and too grieved, to think of any thing but the danger which threatens his patient, and that he cannot give an exact and circumstantial account of what has happened, and that in the midst of such occurrences it would be unjust to reproach operators with having published cases destitute of sufficient details, or badly drawn up, is, indeed, a sufficient justification of those who have been placed in these unfortunate circumstances; but does it, in the eye of science, improve the facts, or make them more conclusive? Is it not, on the contrary, confessing at the outset that these facts are necessarily incomplete, and that in so arduous a question it is impossible to bestow our complete confidence upon them?

M. Roux, while allowing that the phenomena observed in animals are far from resembling those which have occurred in human beings, exclaims that this proves nothing; for since symptoms offer numerous varieties, even in different individuals

of the same species, or of different species, in direct experiments, we may well believe, he says, that matters will not be the same in men as in dogs. I might answer, that I myself mentioned this supposition to the Academy, and proposed to take it into account long before M. Roux had uttered it. But he must allow, in his turn, that it is only a supposition; and that the differences between what has been said of human beings and what has been seen in animals, are so striking, that until the contrary has been proved it is impossible not to retain some doubts upon the subject. Besides, M. Roux seems to have forgotten that reasoning of this kind would authorise us, at the outside, to presume the fact in question, to regard it as probable, or as very probable, but that it cannot be demonstrated in this manner. But what is the question between us? Not to know if it is *possible*, *presumable*, or even *very probable*; but whether it is *demonstrated*, irresistibly, that in the cases referred to, death took place from the introduction of air into the veins. Thus we remain in doubt, which, in my opinion, is the real state of the question.

As to reproaching us with not explaining why the patients died, if we do not allow that they died from the introduction of air into the veins, I think that M. Roux must have done this through inadvertence; for if we must always consider those facts as demonstrated or incontestable of which we cannot give any other explanation, or must admit them, because in denying the explanation of a phenomenon we cannot give any other more satisfactory one, it would certainly not be long before science was overwhelmed with an infinity of dangerous errors. Nevertheless, I must say, that all the cases which have occurred in the human species have something strange, and altogether unusual, about them. Though it is true that patients may die of syncope, hemorrhage, alarm, or exhaustion, during great operations, it is also true that in such cases life is extinguished with a different train of symptoms from those which have been related. If we erase from the list the cases of Klein, Dupontail, Lodge, Dubourg, Mauzeis, and Sir Astley Cooper, which are either quite unimportant, or which may be easily explained without the supposition of air having entered the veins, it is difficult not to return to this way of explaining the others. If we suppose that in the cases related by MM. Rigaud, Clemot, Begin, Malgaigne, and myself, the gush of a small artery against some organic layers, or the entrance of air into the sinuities of a *cul-de-sac*, may have produced the hissing, the bubbling, or the sound of emptying a bottle, mentioned by authors,

it is almost impossible not to admit something more in the cases of MM. Pielagnal, Dupuytren, Castara, Delpech, Ulrich, Barlow, Warren, and Goulard.

In this state of uncertainty, might one not ask whether, at the moment of the operation in human beings, veins *enlarged* by the nature of the tumor itself, or by the handling to which they are exposed, may not be (for the moment) in the state which is the natural one of the veins at the apex of the chest in living animals. With the help of this explanation, however, the only cases which can be brought into the class of *very probable* ones are those of MM. Goulard, Predagael, Dupuytren, Castara, Delpech, Warren, and Mirault. It appears to me clear that nothing had caused this transformation in the cases of MM. Rigaud, Amussat, Toulmonche, Mott, and Malgaigne.

Can we attribute it, then, to the previous debility of the patients? Every thing tends to show (although our direct experiments still allow some doubts upon this point) that a great loss of blood must make the entrance of air more dangerous. But on analysing the cases, we see that the patients were still strong, with the exception of those belonging to M. Piedagnel, M. Roux, and Klein; that most of them were in perfect health; and that they had not lost more than a few ounces of blood when the symptoms came on.

If practitioners are unwilling to abandon this comparison, our last resource is to admit, that either physically, or physiologically, or pathologically, the conditions accompanying the entrance of air into the veins are remarkably different in the human species and in animals. These differences may be regarded as possible, when we reflect that air in the veins kills a horse sooner than a dog—that death is more speedy when the animal is held in one position than in another—that by blowing in air from the mouth, we kill with the rapidity of lightning, while it requires a pretty long time to produce the same effect if a syringe is employed.

I am ready to allow, however, that no one of these reasons is conclusive; and nothing of what I have said is sufficient, at present, to place beyond the limits of doubt what has been advanced in favour of the introduction of air into the veins of man.

The most reasonable thing to rely upon, to aid us against all these difficulties, is the want of care with which the cases have been drawn up. There is no doubt, that if writers had had a more accurate knowledge of what had been already done, they would have entered into minute particulars as to what concerns human beings. There is no doubt, too, but that a number

of important circumstances have been either omitted, or inaccurately related, or wrongly explained, by those who have published these cases. I say this without blaming observers for it, because in phenomena which rapidly pass away, and are at the same time complex, and difficult to apprehend, persons do not take every thing into account, unless the question implicated in the phenomena has already engaged their attention, and unless they are well acquainted, beforehand, with all the details which it is possible to collect.

Summary.—Meanwhile, to give my candid opinion, I consider the introduction of air into the veins as *probable* in the cases of MM. Bégis, Malgaigne, Mirault, Warren, Barlow, Delaporte, one of M. Clemot's, the first pointed out by M. Roux, and my own. There is no proof that this accident took place in the cases of MM. Pottinmouche, Mott, M. Clemot's second and third cases, or in those of MM. Rigaud, Dubourg, Maugeis, and Amussat. It appears to me *extremely probable* in those of Delpech and Ulrich, and *almost certain* in the cases of Dupuytren, Castara, and Goulard. But after all, this can only be given as my personal belief; for I allow that no one of these facts can be exactly compared with the results of direct experiment, and that, in a scientific point of view, there is not one that carries absolute conviction with it.

Thus my readers will see, that at the end of this discussion I find myself brought back, by force, to repeat what I said on the introduction of air into the veins, in 1832 (*Méd. Opér.* t. ii. p. 194)—“Without denying the possibility of this phenomenon, when the veins form open canals extending to the thorax, I think that new experiments are required to decide the question.”

I will add, as I said in 1833 (*Anat. Chir.* t. ii. pp. 104, 457, 471, 2nd edit.) “That if the fact is really so in human beings, we must look for a different physical explanation from the one given by MM. Poiseuille and Bérard; for it is clear that phenomena resembling those which seem to denote the introduction of air into veins, have been observed in other parts besides the neck and the axilla.”

The reader will see, at a glance, how much the question has been cleared up by late experiments, if he compares its present state with what I said of it at the first sitting of the Academy. I then summed up in the following manner:—

“The introduction of air into the veins raises several important questions. There are already about twenty instances (I ought to have said thirty, at least), where serious symptoms, which have supervened during surgical operations, have been attributed to it. Of this number there are

several, certainly, which are not conclusive. Bichat thought that it was enough to inject a few air-bubbles into the veins of an animal to kill it, and that death then took place through the brain. Nysten showed, on the contrary, that it required a great quantity of air to kill a dog, and that death then took place by stoppage of the circulation. Nysten's experiments have been since repeated by a host of persons, among others every year by Magendie, and have always been followed by the same results.

“By showing that the large veins of the root of the neck are always in a state of tension, M. Bérard has proved that air may pass through them when they are open; while M. Poiseuille maintains that this is not possible at more than a few centimetres from the first rib. But in most of the cases several of these conditions are wanting. Thus, Dupuytren's patient had a tumor on the shoulder, and twenty-four hours afterwards only a few air-bubbles were found in his heart. In others so little air seems to have entered, that, to judge of what we see in animals, they could not have died of it. Lastly, in others the operation was performed upon the face, chest, &c.; and physiological experiments do not allow us to grant, that death can occur by the introduction of air into those parts. Hence the question is still open for examination.”

Therapeutic Means.

Treatment.—In scientific questions there is a rock which we ought to make every effort to avoid; I mean the error of forming an opinion too soon, and wishing to pronounce a positive decision, in spite of the absence of proofs. Although the facts quoted in favour of the introduction of air into the veins are as yet incomplete, it would be wrong to conclude that this accident has never taken place. For my own part, I repeat that, in my opinion, it has happened several times; only I feel that, until more conclusive proofs are alleged, this can only be a personal belief, and that there is nothing at present in science that can change this belief into a general conviction. With this phenomenon before us, we are like magistrates in whose presence there stands a criminal against whom there are no witnesses.

Holding these opinions, I have reflected, like many others, on the means of warding off the dangers attributed to the introduction of air into the veins. These means must be divided into two kinds, the preventive and the curative.

Preventive means.—There is a difficulty at the outset which will long throw doubt upon the efficacy of the attempts which may be made to prevent air entering the

veins during operations. The difficulty is, that no one can tell beforehand if the phenomenon will take place or not, supposing that such or such a vein is opened. Thus, suppose some particular precaution is taken in the case of three, six, ten, or fifteen patients, in whom tumors are extirpated near the apex of the chest, and that the air does not enter the veins in any one of them. Those who put their trust in the given precaution will not fail to conclude, that if nothing had been done, some of the patients would have sunk. Yet this conclusion, which would seem very natural, might be altogether erroneous; for the cases quoted of the introduction of air into the veins are very rare, compared with the number of operations of a kind which would seem to favour it. I have myself more than fifty times extirpated submaxillary, parotid, axillary, supraclavicular, or supra-sternal tumors, obliging me to go very near the great veins of those regions, and often even to open them; yet the case which I related above, and one of a young boy, are the only ones which alarmed me, even for an instant, as to the introduction of air into the veins. I will add, that when assisting M. Roux, I saw him make a large incision in the upper part of the subclavian vein in one case, in the upper part of the axillary vein in another, and in the lower part of the internal jugular in a third; and yet nothing which could be referred to the introduction of air ever resulted. When we reflect on the number of amputations which have been performed at the shoulder-joint—on the frequency of operations in the axilla for cancerous or lymphatic tumors—on the numerous instances in which arteries have been tied above the clavicle, and in the carotid regions, without any results comparable to what takes place when air enters the heart—we are forced to admit, at least, that the accident in question is hard to happen. How, then, can we be certain that, if it does not take place in a given instance, we are to attribute this to our precautions, rather than to the natural resistance of the frame? Hence we see that, to settle the question of preventive means, requires, like the rest of the subject, numerous experiments. Let us, however, examine those which seem to have attracted attention up to the present time.

Compression of the thorax during the whole of the operation seems to me to be suitable neither in theory, nor according to the experiments already tried. If the compression were sufficiently strong to prevent any raising of the ribs, the patient would obviously suffer a constraint so considerable as to be insupportable. Moreover, the

chest would be equally extended in its vertical diameter by the depression of the diaphragm; nor has it yet been shewn that the dilatation of the heart has no share in the absorption of the air.

M. Poiseuille, reasoning as if inspiration alone could draw air into the heart (*Gaz. Méd.* 1837, p. 671), thought that it would be sufficient to prevent this accident, if we could make the patient carefully avoid deep inspiration. This recommendation seems to me to be connected with the same error which suggested compression to M. Gerdy. In fact, experience has long shewn surgeons that, during serious operations, the chest of the patient is generally contracted spasmodically—that respiration becomes slow, and is performed by small movement—and that one has rather to excite patient's to breathe deeply, than to prevent them from doing so, if we wish the venous circulation not to be too much clogged.

Compression of the veins between the heart and the incision.—When the idea of the introduction of air into the heart first arose among practitioners, the first remedy which necessarily presented itself was this kind of compression; it seems so natural and so certain. Thus Larrey says that, when bleeding in the neck, we ought to compress the vein below the incision until the bandage has been put on, if we wish to prevent air from reaching the heart (*Clin. Chir.* t. i. p. 357.) Dupuytren does not omit to point out the same means when narrating his case (*Arch. Gén. de Méd.* t. v. p. 438), which he had previously communicated to the Academy. A similar recommendation is to be found in Mr. Barlow's memoir (*Gaz. Méd.* 1831, p. 355.) M. Putegnat likewise gives it in his thesis. Mr. Warren states, at page 266 of his treatise on Tumors, that the surgeon who operates in the vicinity of the jugular, subclavian, axillary, or iliac veins, or even of the saphena, when it is dilated, ought to leave to the last the separation of the pedicle of the tumors on that side, in order to be better able to compress the veins before opening them. He adds that, if possible, one ought to compress the veins between the incisions and the heart. I have myself thought it necessary to insist upon this recommendation, and to follow it in some cases of extirpation of parotid and submaxillary tumors; but it must be confessed that the remedy is a weak one. If, like the first observers, we admitted the possibility of air being inspired at a very great distance from the heart, the remedy would deserve our serious consideration. In case of the internal saphena, or femoral veins, the iliacs, the veins of the arm, the face, and the external jugular, nothing

would be so easy as to put it into practice; but if it is true that the introduction of air is impossible in all these regions, compression is useless as a preventive. On the other hand, who does not see that, in the region above the clavicle, the upper part of the axilla, and the upper hyoidian region, where it would be useful, it is inapplicable? The subclavian vein, concealed under the clavicle or the sternum, and separated from the ribs by the root of the scapula, lies in such a manner that its calibre cannot be obliterated through the skin. It is the same with the internal jugular vein below the larynx. To which we must add, that compressing this vein, when we are operating near the parotid region, puffs up the face, and increases the size of all the veins, which we are in danger of wounding.

For these various reasons we must admit that compression of the venous trunk between the wound and the heart is a resource of small importance, and rarely applicable.

Hence it follows that, in practice, we cannot count upon the efficacy of any of the preventive means which have been hitherto mentioned, and that all which is in the surgeon's power may be reduced to these three points:—

1st. To avoid with the utmost care wounding the internal jugular or subclavian veins in operations.

2ly. In cases where he is obliged to go near these vessels, he is not to separate the pedicle of the tumor without previously compressing it between his fingers on the side of the heart, or passing a strong ligature around it.

3ly. He must avoid as much as possible all stretching, pulling, and separating the parts, lifting the arm, or throwing back the shoulder or the neck, when the bistoury is near the great veins at the apex of the chest.

Curative means.—If the art of healing possesses nothing capable of preventing the air from entering an open vein, we must confess with sorrow that it is still poorer in any method of expelling air from the heart. I greatly doubt that it can be of much use to place the patient on his side, as recommended by M. Forget (*Trans. Méd. t. x. p. 75*).

Compression of the thorax—the jerking compression by which Nysten thought he could expel the air from the auricle through the incision in the vein—is evidently useless, at any rate in human beings. Even in dogs, the air contained in the right ventricle cannot be thus driven out, and the right auricle gives up but very little of it. Who does not see that, in human beings, the thorax, which is far

less flexible than in dogs, can never be flattened to such a degree as to react efficaciously upon the heart?

The most obvious method of all, that is to say, closing the incision in the vein, which has been already frequently adopted, offers, perhaps, as much danger on one hand as advantage on the other. While it puts a stop to the introduction of air into the wounded vessel, unfortunately it also obstructs the exit of the air which the contractions of the heart tend to expel; so that it cannot succeed unless, at the moment when it is applied, the air is not sufficient in quantity to cause death.

Drawing out the air by applying the mouth to the aperture of the vein can hardly ever be applicable. The least reflexion, too, would suffice to shew that it could not be of advantage.

Artificial respiration, either by means of tracheotomy, or by introducing a tube into the natural passage, were means tried by Mr. Warren, but seem to me to have no object.

The introduction of a saline fluid into another vein, which he also recommends, would only be adding to the danger of the patient.

There remains the plan of drawing out the air by a tube or syringe, introduced as far as the heart. But this suggestion, which arose from experiments on animals, should be rigorously proscribed in human beings, if I am not mistaken. It is plain that it could be adopted only when the internal jugular was wounded; and it is equally clear that, in order to introduce the tube, the vessel must be placed in the precise condition most favourable to the introduction of air. Moreover, during a serious operation, it would be requisite first to inquire whether the symptoms which had supervened really depended on the phenomenon in question; then to look for the aperture in the vein; then to ask the assistants for the tube prepared for this purpose; then to introduce it, and apply the syringe or the mouth to it. Now all this would necessarily require more time than intervenes before the death of the patient, if the accounts of these cases are correct. In short, we have really nothing to oppose to this occurrence.

This is a painful avowal, no doubt, but it is the truth. We are reduced, therefore, to the general remedies against syncope, unless there is any efficacy in bleeding, which was formerly proposed, and is still extolled, by MM. Boulay, Leblanc, &c. To avoid extending the veins in the neighbourhood of the chest during operations; to apply the finger to the wound, and to suspend the operation for a short time, when the supposed characteristic sound is

heard; to keep the patient in the horizontal position, and stimulate him with the vapours of ammonia, alcohol, or vinegar; to use friction to his body, and to throw water upon his face—such are, at present, the only means which reason and experience allow us to use without apprehension.—*Gazette Médicale*, Feb. 24, 1838.

STRICTURES
UPON
DOCTOR ARNOTT'S TREATISE
UPON
WARMING AND VENTILATING.

By JULIUS JEFFREYS, Esq.

[Continued from page 967.]

I TAKE the liberty of mentioning a case, remarkably illustrative of the fact, that freshness of air in a house lessens, instead of increases, the liability of the inmates to take cold; although I am aware, while apparently necessary, it was a bold experiment which could not always be followed, inasmuch as it was unmitigated air which was so freely admitted.

In her father's house a lady had been accustomed to rooms in which the ventilation was greatly lessened by close fittings and felt. Yet, since open fires were used, there could not fail, as will be shown hereafter, to be more air admitted than by the use of Dr. Arnett's stove in the common way. In her own house, accordingly, she followed up this plan. The house was made very secure, and the children, though allowed plenty of exercise, were kept as snugly as possible from every draught; nevertheless they were always catching colds, and the more she checked draughts the more they ailed, catching also every epidemic that prevailed. Living in the country, she was led to contrast with her own the healthy children of the farmers around; and, observing their ill-fitted casements and doors, and open fires, with large mouthed chimneys, resolved boldly to copy what she saw. Having removed to an old-fashioned house, with doors and windows fitting as badly as she could desire, she allowed them to remain as they were, and the children to run constantly, even in cold weather, in and out of the parlour door, which opened into the garden. Such has been her course for some years. Her children now know not what it is to take cold;

and although one has a constitutional tendency to an affection in the head, which grew alarming under a system of ventilation, more liberal even than the thermometer stove alone can ensure, they are now the pictures of health.

I trust I shall be excused for having occupied my reader's time with this case, since it appears to me an instructive one; not because with a profusion of fresh air the family grew so healthy, for there are farm-houses in every part of the country presenting the same aspect, but because this, which was the extreme of what Doctor Arnett pronounces to be the catarrh and pleurisy-exciting system, did actually deliver them from the catarrhs, which, under a different system, they were constantly suffering from. Once more I would repeat, that this extreme course is not held up for general imitation; that it would not answer in the case of delicate constitutions; and that for these the air should be rendered mild, but its salutary copiousness should, if possible, be retained.

Having brought himself and his reader gradually over from the advocacy (if strong language and illustrations mean any thing) of a system of more copious ventilation than is usual, to one of much more confined ventilation, it seems necessary, lest there should be any misgivings in the reader's mind—any wonted longings after fresher air—that his thoughts should be familiarized with a Russian state of things, where almost no ventilation exists, and in such a manner, that penny-a-day ventilation may be associated together, in his mind, with long life and rubicundity. The author, therefore, continues, "To these persons," namely, all the people who are advocates for open fires, "it must appear wonderful, that in Russia where, all through the winter, there are only close stoves, and double windows carefully closed, and no provision made for ventilation, beyond accidental crevices, the people are very healthy; and more individuals attain a very advanced age than in almost any other country in Europe." On reading this Russian argument, one is led to exclaim—What has become of the ease of the poor Buckinghamshire lace makers, and where is now its contrast, the delicious trout stream of the author's imagination? Alas, he has left it far off upon the opposite side, and has taken up his

abode in a land of suffocation! As this argument, however, is not without plausibility, and as it may have weight with many readers in favour of what, I believe, would be a dangerous revolution in popular feeling, it is necessary to request of my reader an attentive examination of it.

The squalid appearance of the inhabitants of very northern regions, after their six-months' inhumation, travellers have often noticed. I had supposed the appearance of the Russian poor, who were much at home, must have partaken to some extent of such effects of close confinement; and that although, as in most simpler states of society, individual cases of longevity might be more common there than in England, England had greatly the advantage over Russia as to the chances, or average duration, of human life. The case, however, with which we have to deal is not at all affected by the author's argument. The Russian might be able to live for ever without air, like a toad in a stone, and it would be no proof that the system would answer in England, where all our experience, as formerly shown by the author himself, is against it. The Buckinghamshire lace-makers, for instance, have been trying the experiment for years, even in a more moderate degree, for they *have the opening of the chimney*, and it has miserably failed, disease and early death being the effects of a stifling system, practised in a greater degree with impunity, if not with vigour, by the Russian poor. The reason of this there will be no difficulty in seeing.

The quantity of ventilation necessary for man decreases in some very high degree with the temperature of the climate. It may not be easy to explain upon what physical causes this depends—how the animal system is so modified by climate, as to require the presence of so disproportionate quantities of air in different climates; but the fact is an unquestionable one in regard to the several climates with which Englishmen are most familiar, and our author's very argument establishes it in Russia. In tropical countries—in India, for instance—we find it necessary to build houses with gigantic doors and windows, to the English eye, at first, out of all proportion large and numerous. This is not done for the sake of coolness only; for the mean temperature, during

the hot seasons, is much lower in houses which have massive walls, and few and small doors and windows. It is chiefly for the sake of fresh air. And although these large and numerous doors and windows, ill-fitted as they are, allow of a leakage, when closed, manifold greater than our similar ventilation in England, it is still necessary to throw them all open for several hours every night, even when the outer air, as is oftentimes the case, is much hotter than the inner. In the western provinces of India especially, from the month of March to the middle of July, during the whole twenty-four hours, the air out of doors is hotter than that within. Nevertheless, although air passes freely through the house all the day, not by crevices only, but through doorways, before which are wetted surfaces, which, while they cool the air, give free passage to it, so that it might be supposed more ventilation could not possibly be needed, it does still prove necessary to throw aside, some time after sunset, every window and door for several hours. Any family neglecting this practice, soon declines in health. Here is a case, where, in an oppressively hot climate, a great sacrifice of coolness has to be made to freshness. It will not be said that all this air is wanted merely to carry off the increased perspiration in a tropical climate, for the quantity is ten thousand times more than would be abundant for that purpose. Compared with this ventilation, any in England is as nothing. Is it not plain, then, that, as a ventilation to be tolerable in India must be a hundred fold what will suffice in England, so a ventilation to be tolerable in England must be manifold greater than what may do in Russia? Hence, the Buckinghamshire women failed deplorably when they experimented with Russian ventilation, or rather non-ventilation, here, just as would any family in India which should try English ventilation in that country. The author's Russian argument, therefore, though a dangerous one, must, if rightly understood, go for nothing. The closing sentence of the paragraph remains to be noticed:—"In a room of twelve feet in all its dimensions, and containing, therefore, 1728 cubical feet of air, there is, without any ventilation whatever, an allowance of two feet a minute for one person for fourteen hours." The author, though not mean-

ing it, of course, speaks, in this place, as if the air could be used in distinct parcels until the whole was consumed, each parcel being put aside as it was done with, like a heap of waste paper, so as not to contaminate the rest. Whereas (as he has himself said elsewhere) every breath mixes with all the rest: the whole air is soon a little tainted, and ought then, without delay, to be renewed.

The time has now come for us to notice a grand omission of the author. He has, throughout all his arguments, spoken only of the demand of the lungs for oxygen, and of the presence of the carbonic acid they give off. He has said nothing of the animal impurities, of a much more pernicious kind, thrown off profusely both by the lungs and by the skin. The air of an assembly, of which so little has been used by the lungs that the chemist cannot detect any diminution in its oxygen, nor any of the carbonic acid they have added to it, may in the meantime have become very oppressive on account of animal impurities of the other kind so freely discharged into it; and, if he were to lock up the assembly, until he could discover, with all his skill, the presence of any considerable quantity of carbonic acid, he would have sealed the fate of most of them, by forcing them to imbibe their own poison—matter, though less offensive, perhaps, yet as truly animal off-scourings—as thoroughly excrementitious—as any that goes forth into the draught. I make no apology for using expressions which, under other circumstances, would be unpardonably coarse. It would be a mistaken affectation which should hesitate to do so upon the present, a question of vital importance. The above is a fact, which no physiologist will venture to deny. It is one which cannot be too generally known by the public. Moreover, the confined habit of body of a large portion of our city population, especially of the sedentary classes, is such, that the skin and the lungs, in addition to these their natural duties, have to throw off, in vaporous discharges, much that ought to pass off in another way. So deleterious are all these matters to the health, that, as the author himself has shown in his Introduction, pestilential diseases have decreased in our land, in proportion as our streets and our houses have be-

come wider and more airy. What now must be thought of objecting to the bare ventilation which our houses, with their open fires, commonly afford us; nay, to the indulgence in any quantity of air which we can severally afford to warm?

Such is the beneficial influence of fresh air over the body, that, as experience proves, with all the trying vicissitudes of weather opposing him, the more nearly a person can live in the open air the better, for the most part, will his health be. The ploughman enjoys more vigorous health than the equally hard-working mechanic; and the coachman seated on his box, than the accountant at his desk. It cannot be said that exercise is the chief agent in effecting this difference, for a joiner in his workshop, even with much more air flowing into it than the quantity the author has set as a maximum, does not in general present the hearty aspect of a coachman or a guard, although the work of the former throws all his muscles into the most useful exercise, and the occupation of the latter has the defect of being sedentary; showing that exercise, even confessedly beneficial as it is, cannot make up the difference between the effect, not of a very confined, but of a fairly ventilated place and the open air. With regard to exercise, it is of importance to remark how subservient is its influence to that of the open air. It loses greatly of its beneficial powers, nay, often proves injurious, when deprived of fresh air to give effect to it. It is very common to hear warehousemen and mechanics complaining that the work is too much for their health; work less laborious, in general, than that with which the hedger-and-ditcher, or the lighterman, is familiar. The effect of the exercise of the former persons appears often to fall unequally upon the system, and therefore too heavily upon some one part; while upon those who work abroad, it would seem to be more equally diffused. Determinations to the head, the heart, the lungs, &c. being, I believe, much more common effects of labour within doors than of labour without.

If the presence of the air of heaven around the body, *without measure*, is unquestionably beneficial—the benefit increasing, if the weather is mild, with the speed with which it passes over the

body, a windy being more invigorating than a calm day, and a seat outside of a coach than one even with the windows open inside—are there any properties in brick and mortar which empower them to subvert this order of things within doors? It is true that the body at rest cannot endure cold or draughts. These, of course, must be afforded the fullest consideration; and it will then be obvious that the only limit to that quantity of fresh air which is desirable—that quantity which is to exercise the most salutary influence on the human frame—is to be found at the point where the current excited in the air commences to be too strong, or the expense of warming it too considerable. What limit is there, then, to the quantity of fresh air a person should be allowed within his house, if he can introduce it without draughts, and if he can afford to warm it? Nay, if such a person should be philosophical, and should have ascertained that one-sixth of a cubic foot of air per minute will do for the breath, and should prudently have allowed two cubic feet, on account of the constant mixing of the damaged with the fresh air, and should liberally, as he thought, have apportioned to himself two or three cubic feet of air per minute, and should be satisfying himself that the air of his apartment ought, therefore, to be warmed for less than a penny a-day; would it not be the duty of any friend, upon whose mind the previous and a multitude of other evidence which might be cited to the same effect, were exercising their proper influence, to contend against economy such as this, as of a very erroneous kind? Might he not say—I will not dispute your philosophy, whether I can admit your measurements or not; but I affirm, that, unless miserably poor, you ought to be seeking fresh air in quantities compared with which all that is indispensable for mere existence is but an indefinitely small fraction. You have before you irrefragable, irresistible proof, that, to air flowing over them in boundless quantities, myriads of your fellow men do chiefly owe their hale and vigorous health. It is but a small part of this which, sedentary, and within doors, you can command; but do not reduce this quantity, limited as it must be, five hundred-fold more. Inquire not upon how trifling a sum you can manage to warm air for your rooms, care-

fully meted out in cubic feet; but, of the two, rather inquire what is the utmost sum you can afford towards warming and introducing it in unmeasured quantities into your house. If you will alter your supply, increase its quantity by all means, but on no account think of diminishing it. Behold the hale looks of your neighbour, whose occupation keeps him always abroad, and ask yourself, if any, or if all of your luxuries together, are capable of doing for your health what boundless fresh air is doing for his, and be guided by your own reply. You will then give your luxuries up, one and all, rather than part with any of the little air compared with his, which you already have.

To the poor man this argument may with great, if lessened, force be applied. To him it may be said, that no person ever yet could prove the *habitual* use of any quantity of beer, or spirits, to be necessary, nay even to be beneficial, to the health; that they may be a luxury, but not certainly a necessary; whereas, no one can deny the very beneficial effects of abundant fresh air. Give up, then, your useless beer and pernicious spirits, and devote a part of the saving to the warming of more air for your family. Let him be offered every assistance towards employing his fuel more economically, but never by any plan which does not insure to him his former supply of fresh air, at the least. Any plan which involves with it a yielding up of a portion of fresh air, should be considered as applicable only to the cases of the destitute, who have no lesser necessities to part with, rather than to sacrifice any portion of so great an one.

Defective as the open cottage fire is in some respects, the ventilation, which it not only permits but vigilantly insures, is a redeeming quality of far greater importance. If the chimney draught were put an end to by the use of close stoves, in the manner recommended by the author, impure and infectious effluvia would not, as now, be hurried away up the chimney ere they had time to excite disease, but they would circulate for hours about the rooms of the poor before they were completely removed through the crevices; and it is too probable that, when an epidemic was lighted up, it would not, as now, commonly attack a few of the inmates only, but would, as in some

countries, waste itself upon the whole family with aggravated force. I will not here anticipate matter belonging to my third division—warming and ventilating by the aid of combustion. Under that head it will be shown, that the favourable comparison the author has drawn regarding the ventilating powers of the thermometer stove will not stand the trial either of careful reasoning or of experiment.

In concluding this portion of my subject, I have to express a hope, that my humble endeavour to defend the general opinions of Englishmen in favour of the free ventilation ensured by open chimneys, against the arguments opposed to them by the author in the treatise before us, especially in Art. 82, upon which I have commented at some length, will not appear to my reader either as uncalled for or unsuccessful. It has been rendered especially necessary, by the promising manner in which the author commences his work as the advocate of ventilation, so copious, that any reader must understand by it a larger, instead of a less, supply than is usual in our dwellings, and may thereby be placed off his guard, and be in all the greater danger of lapsing into the subsequent bias of the author's mind. The vast importance of the questions to the well-being of the community on the one hand, and the weight of the author's authority on the other, do also add to the necessity of a commentary, such as I desire to conduct with right reasoning and candour.

YELLOW FEVER—QUESTION OF CONTAGION.

To the Editor of the Medical Gazette.

SIR,

HAVING seen in a late number of the MEDICAL GAZETTE a letter from my friend, Sir Andrew Halliday, covering another from Dr. William Fraser, of Demerara, setting forth that a highly contagious yellow fever had been devastating British Guiana, I feel it incumbent upon me, from having officially visited those regions, to take this early opportunity of giving as explicit and direct a contradiction to the assumption of that disease being, under ordi-

nary circumstances, either infectious or contagious, as it is possible for me to give.

No question has been so frequently and satisfactorily decided in the affirmative, by the concurrent testimony of experienced medical men, as the non-contagion of yellow fever; yet it has always, after a time, been revived, and the alarm rung again; and this will ever be the case as long as quarantine establishments and boards of health are paid to discover imported contagion, in justification of their own appointments. Men have ever possessed a wondrous facility in bringing themselves to believe what it is their interest to believe; and we might as well look to find the expectant subalterns advocating the reduction of the army, as a quarantine officer failing to discover imported contagion whenever an epidemic disease pervaded the country. They are, in fact, enlisted in the cause. It is their trade to discover it; and to suppose that they would not act up to the principles and motives of that trade, is to suppose what rarely occurs in the affairs of men. But to the point in question.

As in every epidemic where multitudes are in the course of being affected, and every degree of necessary communication must be constantly taking place amongst all classes of the community, no one can possibly discriminate, in the first instance, between the epidemic and contagious current of disease; so Dr. Fraser has taken advantage of this state of things to relate various instances where the disease appeared to have been communicated from direct intercourse, which being the natural law of society every where, he could have no difficulty in doing, for the living or the dead were equally at his disposal to choose the infection from. I acknowledge, then, that his cases would be good enough in the way of proof, if we had not others equally good, which will shew contagion to have been impossible, of which I shall now state some from the official records of the Army Medical Department, when I was last in the West Indies; merely premising, that these are not got up for the occasion, but taken from documents of long standing, that have stood unimpeached and unimpugned for nearly a quarter of a century. It would be an unwarrantable abuse of your valuable

pages to cumber them with a mass of formal documents, I shall therefore adopt the form of narrative abstract, leaving the authenticated writings, which, being public property, may be examined, by all who choose to take the trouble, at the office of the Army Medical Board.

In the summer of 1815, the *Regalia* transport arrived at Barbadoes from the coast of Africa, with liberated negroes, in a very sickly condition from scurvy and dysentery. She was a fine vessel, and on that account had been selected to convey invalided white soldiers to England. I went on board to inspect her, accompanied by Deputy-Inspector Forbes and Dr. Mortimer, then Chief of the Navy Medical Department in the West Indies, now of Haslar Hospital, when, to our astonishment, we found that she had been under what may be called a course of aggravated yellow fever ever since quitting the coast of Africa, every man having been ill with it, and five having died with all the worst symptoms during the passage; that she had been at Barbadoes for four days a few weeks previously, when the captain's wife sickened and died, and the captain himself underwent the same fate on the second day after sailing for the Saints, an appendage of Guadeloupe*; that before returning to Barbadoes she went to Antigua, still unquestioned and unsuspected. The fresh men that had been shipped in room of those that had been lost, regularly sickening and dying themselves in the same proportion; and when inspected by us, the mate, who nine days before had been taken on board from a healthy Newfoundland ship, was lying ill of concentrated yellow fever. Here was the disease and free communication with a vengeance, for there had been no report of bad health, consequently no restraint in any way, nor communication of disease at any of the places where she had been; and it was only by chance, I may say, that we discovered the mate in the above condition, and then all the foregoing was brought to light from unwilling witnesses, who, by dint of cross-questioning, were obliged to confess, that immediately before leaving the coast of Africa a large quantity of greenwood had been cut

and laid in for fuel on the same day, and that as many tons of it then remained as would serve for the voyage to England; that on the second day after sailing the fever broke out amongst the crew, until then perfectly healthy, and two presently died; and that they did all they could by fumigations to stop its course, but these were of no avail. We then ascertained that the ballast was shingle ballast, greatly fouled with mud, and that the ship was comparatively a leaky ship, keeping the ballast, that had not been changed for years, in a state of moisture, and, with the help of the greenwood, almost in a state of fermentation. Fumigations were then attempted by the Agent of Transports; but it would not do, for the cook, an old well-seasoned subject of fifty years of age, who alone had resisted the fever, presently sickened and died with black vomit in our hospital ashore*, and it was not until I got the ballast altogether changed, and the hold subjected to the concentrated heat of many stoves, that the fever was stopped. She was then employed as a transport in the expedition against Guadeloupe, and I saw her three months afterwards, filled I may say to the brim, with rebel French prisoners from the gaols—one of whom having been put on board indisposed, was then dying of yellow fever with black vomit on her decks—proceed the next day to France, without further accident or sickness worthy of notice during the voyage. No yellow fever whatever existed at this time amongst the inhabitants of Barbadoes, the shipping in the bay, or the troops in garrison; and it was not until the beginning of the following year that the first case of yellow fever appeared in Bridgetown, in the person of a youthful stranger recently arrived from Europe; and further, for more than twelve months after the arrival of the *Regalia*, none but rare insulated sporadic cases amongst the new comers were known in Barbadoes.

On the 26th of August, 1816, the Childers brig of war came into Carlisle Bay in a state of the greatest distress with yellow fever; the captain, all the

* It was then the rendezvous of our squadron watching Guadeloupe.

* He was received into the largest and fullest fever ward of our general hospital, where I saw him tenderly nursed, and carefully dissected after he was dead, the report of which last, by Deputy-Inspector Forbes, was recorded at the time, and is now extant.

medical officers, one midshipman, two petty officers, and seventeen seamen, lying ill at the time—four midshipmen, two pursers, and fifteen of the men, having died of the disease during a ten days' passage from Trinidad, and the people continued to fall ill for some time, in numbers varying from three to four daily, until more than five-eighths had passed through the disease. All the sick were promptly removed to our hospitals, where they were received literally with open arms, and in my report dated 8th September I find the following:—"It is most gratifying to report that no sickness of any kind has been communicated to any medical officer or other attendant of whatever description employed about the sick, although the devotion of the medical officers to their duty on this important has been unbounded. The hospital assistants have scarcely ever quitted the hospital yard since the seamen were brought on shore, and two of them are young men recently arrived, for whom I had the most serious apprehension—not that they would be exposed to contagion, which in these climates I have ever found to be impossible under circumstances of due ventilation, discipline, and accommodation, but that fatigue, watching, and exertion, would predispose them to be attacked with the epidemic yellow fever of the country;" yet true it is, that soon after fatal yellow fever began to infest our hospitals, not, however, amongst the attendants on the sick seamen, but chiefly amongst the newly-arrived soldiers of the Queen's regiment. It had existed sporadically * in the town at the distance of little more than a mile, with which there was at all times the freest communication from the beginning of the year, and the garrison, from occupying the better and quarter of St. Ann's, were enabled till then to resist the epidemic influence; but here again we obtained the most decided proofs of its non-contagious nature; all the attendants on the sick (and those of the Queen's were unseasoned) being infinitely less liable to be attacked with the disease than the inhabitants of the barracks who never approached them †.

* The ratio of invasions was about one every ten or twelve days, and then for a long time only amongst newly-arrived Europeans.

† As in the case of the Regalia, the Childers underwent a thorough purification at the dockyard at Antigua, when the ballast was found to be actually in a state of fermenting sludge, and a candle could scarcely be made to burn in the hold. After the purification she became perfectly healthy.

This was satisfactorily proved from official returns, and these proofs are still on record.

The year 1816 was one of the sickly seasons of the West Indies. Towards the close of the year the endemic fever pervaded the whole island of Antigua and even the coloured population began to suffer like those described by Dr. Fraser, in Guiana, from intermittent and remittent fevers. To a white regiment in Monk's Hill Barracks were assigned the dock-yard guards of English Harbour, the most pestiferous probably in the West Indies, where the men, after standing sentry at night, would be seized shortly after with the fever, and expire in all the horrors of black vomit when carried back to Monk's Hill*. This occurred to numbers, but in all that time not a single case of the disease originated in, or was communicated to, the quarters—that is to say, the families of the garrison, the staff, and non-combatants of every kind; all, in fact, who never slept out of it, remained free and untouched. Need I go on with similar narrative, every word of which is taken from official reports and returns prepared in the face of day, and in presence of the army who were its subjects?

I shall now go further back to a period of twenty antecedent years, when our army served in the St. Domingo war, and I was then surgeon of the 67th regiment during the years 1796, 7, and 8. I presume it will not be denied that where so many thousands perished from yellow fever†, the black vomit, Dr. Fraser's own diagnostic must have reigned triumphant. I can take it upon me to assert that in all these three years not a single day passed when it might not have been seen in some quarter or other of the army, and the regiment to which I belonged may be said to have died three times over from the disease; for three times were we filled up and renewed by recruits from England, and drafts from other regiments, yet not a single individual who had been in the country for a twelve-month, whether medical, military, or civilian, ever supposed that contagion could have any thing to do with it. The constant daily experience of their

* It is a small insulated hill, 600 feet high, immediately overhanging the marshes of English Harbour.

† Yellow fever is an absurd name; the best designation being that of the French Creoles, who style it *la fièvre Européenne*.

lives satisfied that it was impossible; and had any learned *newly-arrived* doctor (for I must confess that all were contagionists on first arrival) preached to them such an absurdity as contagion, the very women and drum-boys of the army would have laughed him to scorn, for they all knew, because they had uniformly found that there was no danger whatever to be apprehended from approaching and tendering the kindest offices to their dying comrades; that these offices were, in fact, the safest they could perform, the causes of the disease being exposure to the heat of the sun, to the chill and dews of the night, to fatigue, to anxiety and fear, to intemperance, and, above all, to being unseasoned*: and after all this, is it to be borne that such men as Jackson, and Baneroff, and Burnett, who in various colonies, and with different armies, while living both by sea and land under the direst scourge of the disease, should be branded with the imputation of infidel principles, and classed with Tom Paine, Hume, and Voltaire, because they had honesty and courage first to renounce their own prejudices in regard to contagion, and afterwards sought to disabuse the minds of their fellow-countrymen? Out upon such abominable cant, which can only bring disgrace upon the man who forces it into an investigation of medical truths. I would recommend to Doctor Fraser a more suitable vent for his religious feelings in the example of the celebrated Doctor Rush, of Philadelphia, who, like many others, deceived by the first visitation that he had witnessed of yellow fever, stood forth a strenuous contagionist; but when convinced of his error, on seeing it return during successive sickly seasons, and being on his deathbed, devoutly implored pardon of his God, of his country, and of every friend of science and humanity, for having been instrumental in propagating so pernicious a delusion!

But further. The yellow fever has, at times, fearfully devastated the seaboard of North America during the autumn; but at no other time of such sickly seasons as assimilated its towns to the climate of the tropics, and pains were taken to ascertain the opinion of those medical men who had seen and treated the disease

in regard to its contagious nature, of whom 26 were in the affirmative, and more than 150 dissented; and when we consider that the quarantine staff must, in all probability, have fully comprehended twenty-six officials, we need not wonder at the number stated. When I was last in the West Indies, I in like manner addressed the same query to every individual under my orders, throughout the whole of the colonies; and although the yellow fever was then raging before their eyes, the muster of contagionists was only two. I further proved, from incontestible returns, that the immediate attendants on the sick, whether on sea or land, were less liable to be attacked with the disease than those who never approached them; and if this be not the criterion and touchstone of the existence of contagion, the very *experimentum crucis*, I know not what is. Staff-surgeon Dunkin, Doctor Fraser's respected predecessor in Demerara, stated to me officially at George Town, that during the many years he had been in Demerara, and witnessing various invasions of yellow fever, he never perceived any thing that at all resembled contagion, except once or twice amongst sailors in the foul ill-ventilated holds of merchant ships, under which circumstances it is very well known that all febrile diseases will more or less assume a contagious character,—in fact, generate a contagious atmosphere, which will prevail until ventilation and purity be restored, but no longer. And here I will state an occurrence as related to me by Doctor Dunkin, that took place shortly before my arrival in Demerara, which will prove, I think, to Doctor Fraser, that the worst yellow fever with black vomit may arise without the possibility of its having been imported. Two youthful Europeans arrived in Demerara at a time when the colony was healthy, nothing like yellow fever having been seen for a long while previously. They were welcomed with all the hospitality so characteristic of the West Indies, and at a convivial dinner party in the country, a sportive challenge passed between them, when heated with wine, to run a race. The race was run, but both sickened on the following day, and both speedily perished in all the horrors of the black vomit. Dr. Dunkin declared he never saw two worse cases. They were surrounded by their friends and tenderly

* The Inspectors-General, Bowland, Warren, and Theodore Gordon, are yet alive, and I know will fully bear me out in all the above.

nursed; and I can vouch that no infection proceeded from them, for the colony continued to be healthy; no more than it ever did from the hundreds I am sure I have seen where the matter of black vomit was received upon the hands or upon the clothes, or its exhalations freely breathed by the attendants of the sick*. Doctor Fraser attempts to prove that the late visitation in Guiana was imported from Barbadoes, and differing from any thing in the shape of yellow fever he had ever seen before; but he surely must know, that the mildest form of scarlatina, subjecting the patient every where to no greater annoyance than the *nimia diligentia medicorum*, will, without any cause that we can possibly comprehend, suddenly assume the features of an exterminating plague; or has he never heard of malignant measles, or typhoid pneumonia, without any thing in the seasons or ostensible circumstances that could account for such change in the diseases? and would any one be justified in proclaiming these to be new imported plagues? for such must have been the case with the late yellow fever of Guiana, where the poison ever lurks in one of the deepest swamps of the world, and according to laws of its own, which we can neither understand nor control (for there are more things in heaven and earth than are dreamt of in our philosophy), invadeth where it listeth, there being seasons, and even courses of seasons, in no way differing from others in regard to heat and moisture, when this poison will lie dormant, and then, seemingly without a cause, burst forth amongst the white inhabitants, to the terror and desolation of whole districts. But I have not yet done with contagion. I freely acknowledge that there exist true contagions, and terrible ones too; and, as I have said before, that it may be made possible for temporary contingent contagion to be generated any where; but the yellow fever is none of the first; and when Dr. Fraser attempts

to raise the wild alarm of imported pestilence, he does what in him lies to loosen every social bond—to sever every domestic tie—to cause the sick to be deserted at their utmost need—and to convert men, otherwise humane and kind, into selfish barbarians; for while possessed by the insanity of panic, all reason will be extinguished in the paramount instinct of self-preservation, and its appeals given to the winds. When the Asiatic cholera invaded the British Isles, which is just as much a contagion as the yellow fever of Guiana, shipwrecked sailors were stowed upon the beach, under suspicion that they came from infected places; and wayfaring women, seized with the pains of labour, were, under the same suspicion, thrust from the out-houses where they had sought shelter, and committed to the chances of the public highways. Panic fear ever steels the heart, and, when the cholera prevailed, caused scenes to be enacted through every nation of Christian Europe, that bring disgrace upon human nature; and if now told of the New Zealanders, would scarcely be believed. Happily for Dr. Fraser, and the colony where he resides, the inhabitants of Demerara will not believe him; they will appeal to their own observation and common sense—to the records of past epidemics—and to the testimony of other trustworthy medical men, and then the ban of pestilence will no longer be pronounced against the dying man, nor will the faithful coloured people desert his couch; but were it possible for him to prevail, he would go far to disorganize society, annihilate its commerce, and cause the desertion of its towns, almost as effectually as the cry of mad dog in their streets*.

I may now call myself an old man, for nearly half a century has passed away since I first entered the Medical

* To shew how the American faculty appreciated the vaunted contagion of black vomit, I will here relate an incident I recollect reading in a periodical of the time:—A party of them had procured a chamber-vessel full of the liquid from a dying patient; this they tasted, smelled too, stuffed up their nostrils, into their ears, and in-oculated themselves in every variety of way, until one of them casting his eyes upon a large clyster syringe that chanced to be in the room, filled the instrument with it, and administered to himself a full enema!

* I think it is Dr. O'Halloran (I may mistake the name, for I have mislaid the book, but I am sure of the fact) who relates, that when he entered a town in Spain where the yellow fever was raging, he beheld a soldier dragging a man, evidently far advanced in disease, at the extremity of a long rope. He followed this strange spectacle through deserted streets—no inhabitant daring to appear—until he saw him deposited in a large remote wooden shed, which he then discovered to be the receptacle for the outlawed victims of the disease: and this is the tender nursing Dr. Fraser would establish for his friends in Demerara; for whether he means it or not, such would infallibly be the result, should he once succeed in convincing the people of the reality of imported pestilence.

Department of the Army; but while I have power to raise my voice, or to hold my pen, I never will permit so false and pernicious a doctrine as the contagion of yellow fever to pass unimpaired. This letter is a long one, I fear too long; but I trust, Mr. Editor, you will give it publicity, for it is a letter of defence and retaliation against a gross attack, and on every principle of fairness the reply ought to appear in the same pages from which the provocation issued.—I am, sir,

Your obedient servant,

WM. FERGUSSON, M.D.

Inspector-General of Hospitals.

Windsor, Feb. 24, 1838.

SUGGESTIONS
FOR THE
BETTER REGULATION
OF THE
IRISH MEDICAL CHARITIES,
AND
REMARKS UPON THE BILLS OF LATE INTRO-
DUCED INTO PARLIAMENT FOR
THAT PURPOSE.

To the Editor of the Medical Gazette.

SIR,

To improve the present system of public medical aid in Ireland, and to make it adequate to the effectual relief of the sick poor, it is necessary to amend the law in several very important respects, as well as to supply the defects of former legislation.

A fundamental means for this end is the providing by law for a vigilant inspection of the medical charities, combined with an efficient control. The only security under the existing law for their proper management is to be found in the association of gentlemen who subscribe, and certain *ex officio* governors. But such persons seldom visit the institution to which they belong, or take any part in the administration of its affairs. Even the committee they appoint is, in general, merely nominal; no minutes being kept of its proceedings, or no meetings held, but every thing left to the medical attendant, or the treasurer, who is probably his friend; and it is not to be expected under such circumstances, without the corrective influence of an active and intelligent superintendence on the one side, and a sense of

responsibility on the other, that the medical charities should fulfil their legitimate ends. Moreover, the very materials furnished to the sick poor at these institutions, the proper mode of purchasing, preparing, and preserving these materials, the very accounting for their expenditure, can be understood by professional men alone; while it is easy for the medical or other officer to make such returns in writing to a series of set questions when proposed, and to furnish such a statement and account of the application of the funds, and exaggeration in the number of persons relieved, to be laid before the grand juries at each Assizes, as shall be sufficient to cover abuse. Hence there is an obvious necessity for appointing duly qualified persons to visit and inspect the medical charities, and to report upon their actual state. This necessity has been acknowledged of late: the bills introduced into parliament have all been framed with such a view.

But the medical inspectors to be entrusted with this charge must themselves be subject to control, in order to insure the proper performance of their duties. To make them report to a medical charities' office in Dublin, as was proposed in the last session of parliament, is clearly of no avail. Again, to establish a board of superintendence from among medical practitioners, if they are to act without any remuneration, as is provided by the bill now before parliament, is not likely to have the effect desired. For, supposing such a board to be established, the next thing, in all probability, would be an application to the government for paid medical commissioners as well as paid inspectors, upon the plea of the great sacrifice of time they would be compelled to make in discharge of the duties assigned to them by the bill. But a main objection to the establishment of such a board is, that it would not possess sufficient authority over the inspectors, while it would itself be quite independent of the Poor-law Commissioners, and might thus give rise to conflicting regulations for the management of the sick poor, and the poor in general, which it is intended to obviate.

Another proposition is, to put the medical inspectors upon the staff of the poor-law commission; but this, I conceive, would not be a popular act. Much obloquy, it is to be feared, might attach to such a plan, as it would not fail to be

insinuated that the attempt would thenceforth be made to dole out medical relief upon the contract-scheme, and by the institution of medical clubs, instead of administering it liberally as heretofore; and if public opinion were to set in against the Poor-law Commissioners through this means, it might be directed against the measure itself in the execution of which they were employed, and thus an unnecessary risk would be incurred. But, independently of any consideration of this kind, it should be borne in mind that the medical charities are capable of so much usefulness in Ireland, owing to the prevalence of sickness, and its liability to spread at particular periods, and are, even in their present state, so great an auxiliary means for the alleviation of distress and poverty among the people, that it is incumbent upon the government to watch over them with a jealous eye, and to take care, in extending relief to the poor in general, not to curtail of its fair proportions the relief hitherto afforded to the sick poor—the only species of relief ever vouchsafed to the poor of that country, and to which they have a prescriptive right that ought to be respected.

For these reasons it would seem advisable to conduct the administration of the medical charities *apart* from the poor-law commission—still, not entirely independently of it. A means of connexion might be, to make one of the five medical inspectors, to be appointed under the bills of late brought into Parliament, a chief inspector or medical commissioner, and to associate such chief inspector or medical commissioner, with the Poor-Law Commissioners for the time being; to act together in all matters and things appertaining to the management and medical treatment of the sick poor; and to constitute a board to be vested with the general superintendence and control of the medical charities. By this arrangement the Poor-Law Commissioners would, in effect, exercise such a power as would be sufficient for their purpose, without, however, appearing so much to do it; and the chief inspector, or medical commissioner, being resident for the most part in Dublin, would be able to take cognizance of the reports transmitted to the medical charities' office by the four inspectors, who would be employed in

the investigation of the provincial medical charities.

It is expedient, in the next place, to provide by law for the proper allocation of dispensaries, and for increased hospital accommodation; also, besides raising the funds for this purpose, to render them fixed and secure. Instead of leaving it to one or more interested individuals to originate a dispensary where they please, by procuring an equivalent from the county rates for money alleged to have been subscribed, or to grand juries, to diminish or even annihilate the activity of a charity of which there happens to be no patron at hand, these establishments should be restricted to certain localities and a certain population, and at the same time under such circumstances they should be made compulsory. But as ample powers have been provided, according to the drafts of the bills lately laid before parliament, for changing hospital and dispensary districts, and for raising such sums of money as shall be required for erecting as well as supporting and maintaining the medical charities, there is no occasion for me to insist upon these points.

Another leading defect of legislation is, the exclusiveness of the professional qualification required by law for certain medical officers, and the total omission, on the contrary, of any qualification whatever for the rest.

The surgeon, who is in general the only medical officer attached to a county infirmary, must be a licentiate of the Royal College of Surgeons in Dublin. He has a salary of 100*l.* Irish currency, paid out of the treasury; and he almost invariably holds some other appointment, to the county gaol or lunatic asylum, at nearly the same salary. Moreover, he is frequently provided with apartments in the hospital. The character he thus acquires for surgical skill and dexterity in operating, becomes a monopoly: he has no local competitor, and is enabled, having the entire field to himself, to derive considerable emolument from private practice. While such advantages are secured to this privileged class of practitioners, the medical attendants to the dispensaries, instead of having a fixed salary upon which they can rely, seldom know from year to year what sum they are to receive for their services. It depends

upon the amount of subscriptions and presentments, alike fluctuating and precarious. The funds of the dispensaries have declined so materially in several instances, that they barely suffice for the purchase of medicines; and the means of providing a salary are altogether wanting. Still, the duties of the medical attendants, if well discharged, are very onerous—if they visit the poor, as they ought to do, at their own dwellings. But as they have to depend for their pay upon the chance amount of contributions, and to court subscribers, it is to be apprehended that they will consult the convenience of the rich before the necessities of the poor, and especially as other than humane considerations may have led to their appointment.

The fitness of medical men, whatever may be the class of institutions for which they may be candidates, should be duly certified, and some restriction imposed by law to insure the selection of competent individuals in every instance. Neither should it be any longer permitted to exclude from the county infirmaries the members of the London College of Surgeons, or other persons who shall have obtained a liberal professional education in any university or established school in Great Britain as well as Ireland. But the bill now before parliament not only does this, but more; for while it professes to throw the appointments open, it in fact monopolizes *all* the medical charities for the Dublin Colleges. By the qualification clause, notwithstanding the shew of liberality with which it commences, no person is eligible to the office of surgeon who has not pursued his professional studies in some hospital or medical school for five years, attended hospital practice for three years, and been examined for two hours—this being exactly what is required by the Dublin College of Surgeons, but by none other that I know of. Also, it would tend to the advancement of surgical science and to the benefit of the public, if the number of surgeons to the county infirmaries were increased, as well as the invidious distinction done away with. But more than this is required for the proper regulation of these institutions. They should be converted into general hospitals; physicians and surgeons should be alike appointed, the

beds distributed between them, and all truly necessitous persons admitted, if seriously ill, even without the form of a recommendation, giving a preference always to accidents and fever cases.

However, it is not proposed to interfere with the existing rights of those who are now attached to the County Infirmaries or other medical charities. So long as they shall act in their present capacity, their salaries ought to be secured to them; but there is no sufficient reason why their successors should enjoy the like privileges. True it is, that, for services of a higher order, the rate of remuneration should be increased; but the Infirmaries being placed in towns, where there is opportunity and scope for acquiring private practice, pecuniary compensation is not so much an object to the medical attendant as it is in the country villages, where he depends for his livelihood chiefly, if not entirely, upon the emoluments of the office. Hence, instead of leaving the determination of the amount of salary to the subscribers, in the case of the Dispensaries, which is productive of much abuse, as well as hardship on the part of the medical attendants, and fixing it at an unnecessarily high rate for the County Infirmaries, I think that certain limits ought to be prescribed by law, applicable to all the medical officers in like manner. Thus the salary need not exceed 50*l.* in places containing 10,000 inhabitants. For a less amount of population the salary should be increased; and it should never be less than 100*l.* in the rural districts; while, on the contrary, in places containing 20,000 souls, even a less salary than 50*l.* might suffice; and no pecuniary reward whatever need be given if there be 40,000 souls and upwards, especially if the institution be made available for the purposes of medical education. The distinction conferred by the appointment would insure candidates. It will be necessary, however, to prohibit the medical officers from belonging to more than one institution at the same time, as I met with several instances where two, and with one instance where even four, such appointments were held by one individual.

With a view to encourage private contributions for the support of the medical charities, and to increase their amount, the elections of the medical and

other officers should be vested in the subscribers, as heretofore; also, the number of votes might be made proportionate to the sum subscribed. But the Lord Lieutenant should possess the power of a "veto" in such elections, and, in default of subscribers, should nominate and appoint the said officers, and be able to remove them.

Unless the medical and other officers be brought under control, how will it be possible to carry into effect such rules and regulations as are required for the proper management of the medical charities? This, indeed, is a matter of the first importance, and the administrative machinery to be formed for this purpose should consist of individuals well acquainted with the imperfections and defects, as well as the abuses, which have crept into the present management, or rather through want of management into the present system. Unless an uniform and efficient plan of management be established for the medical charities, but little good, comparatively speaking, will be done by the amendments of the law.

The following are rather matters of *detail* than of principle, and cannot well be defined by law; but full power should be given to the medical inspectors (or any three of them, the chief inspector included), to make such rules and regulations as they shall think fit, respecting the dietary, pharmacy, appropriation of wards and rooms, reception of patients, and respecting the occupation of premises and cultivation of ground belonging to the medical charities; also respecting the description of cases and condition of persons entitled to relief; also respecting the number, denomination, and residence of the medical officers, and the nature and amount of their duties in case of hospital, dispensary, or domiciliary attendance, accidents, vaccination, and midwifery; and the medical inspectors, as aforesaid, should be able to alter such rules and regulations from time to time, as they shall think fit.

The necessity of authorizing the medical inspectors to interfere with the existing management, and to regulate the above very important matters connected with the practical operation of the medical charities, will appear from a concise statement of the principal irregularities and abuses which fell under

my notice as Medical Assistant Commissioner upon the Irish Poor Inquiry.

The medical, or other officer, is purveyor of stores of all kinds for the charity, and upon his own terms, as nothing is obtained by contract; or he becomes the contractor for a particular article of diet, and the dietary is so constructed as to favour its consumption. Frequently no daily diet-table is kept, nor any account of the kinds, quantities, and prices, of the provisions received, issued, and in store.

The medical officer, with his family, occupies the best part of the hospital; he builds for his own accommodation on the premises, or he turns the land belonging to the charity to his own profit.

He resides at a distance of four, six, and even eight miles from the institution of which he has the charge.

He attends only once a week at the dispensary; he does not vaccinate, or he makes a charge for it; he does not attend to midwifery cases; he does not visit out-patients; he delegates the compounding and dispensing of medicines to an ignorant and unprofessional journeyman, or servant; he absents himself from duty without providing an efficient substitute.

The beds are occupied by chronic cases by the month together; by patients with scrofulous ulcers, sore legs, sore eyes, &c.; while those who are suffering from acute febrile, inflammatory, and other internal and very dangerous complaints, are inadmissible into the county infirmaries, according to the existing regulations, and are thus left to perish of disease, for want of that very accommodation which is so needlessly bestowed in the former cases.

It is a common practice for subscribers to insist upon advice and medicines *gratis*, for their servants and dependents of all kinds: so that more than the full worth is had for the money subscribed, and the destitute poor are deprived of a large share of the means intended exclusively for their relief.

In proof of speculation and jobbing in the funds, as well as the chicanery resorted to, to cover abuse in the mode of supplying the drugs, I beg to refer to my report (Dispensaries, Part I., Pharmacy and Management, Appendix B., Poor Inquiry, Ireland).

It still remains to provide against two

very serious evils noticed in my report. For their prevention I would suggest that grand juries should be authorized and required to make presentments for such sums of money as may be necessary to provide for the due instruction and qualifying of a sufficient number of midwives, and that, when this shall have been done, all persons should be prohibited, under pain of a small fine, from engaging in the practice of midwifery, who do not hold a certificate, signed by a lecturer on midwifery in a medical school, or a superintendent of a lying-in charity, and counter-signed by a magistrate or other public functionary; also that all persons, whether medical or otherwise, should be prohibited under like penalty from inoculating with the matter of small-pox.

Lastly, I would suggest that a discretionary power should be accorded to the medical attendant to order certain articles of diet, and even of clothing, to be supplied from the funds of the Dispensary, or other charitable society established for this purpose, and to be distributed to the sick poor under such circumstances, and upon such terms, as the medical inspectors shall determine. If this be objected to as involving the principle of out-door relief, let it be borne in mind that it is almost a mockery of charity to prescribe medicines for the sick, unless they have the means of warmth, and can procure common diluent and demulcent drinks, broths, &c. Physic is a very good thing in its way—by physic I mean drugs—but without such collateral aids it may be worse than useless. The able-bodied poor man may contrive to get enough in the way of sustenance to enable the heart to beat, and to make a little blood for the organ to act upon; but when he is sick and deprived of the power of working, what is he to do unless hospital comforts, or the above requisites, can be procured? I am quite sure that it would be much better, instead of applying large sums to the purchase of medicines, and drugging the poor unnecessarily, as is too often the case, to lay part of the money out in supplying oatmeal, pearl-barley, rice, &c. together with blanketing and flannel dresses. Moreover, I am of opinion that such a principle of relief, if guarded by proper checks, might be acted upon without leading to any great abuse or expense,

and certainly with the most beneficial effects, in the administration of dispensaries.

In conclusion, I beg to state my conviction, the result of experience, that, if the law be amended, and competent persons be selected to carry out its provisions, and make such rules and regulations as suggested, the medical charities being in that case well situated, well supported, and well conducted, will be found a most invaluable means of relief to the sick poor; while the advantages resulting to the country at large, from the establishment of a systematic and efficient plan of public medical aid, will greatly exceed the cost that need be incurred by it.—I am, sir,

Your obedient servant,

W. P. BORRETT,

Fellow of the Royal College of Physicians, London.

Queen Ann Street,
Cavendish Square, March 3, 1833.

EARLY RUPTURE OF THE UTERUS.

To the Editor of the Medical Gazette.

SIR,

I BELIEVE the following case to be one of very rare occurrence (in fact, I am not aware of any similar one upon record); and if you should consider it worthy of insertion in your journal, you will greatly oblige

Your obedient servant,

ROGER SHIRLEY NUNN,

Surgeon to the Essex and Colchester Hospital.

Colchester, Feb. 25, 1833.

On Monday, the 19th of February, I was summoned, about 10 o'clock A.M. to attend Mrs. C., whose husband told me she was extremely ill. Upon visiting her, I found she was in a state of collapse, without any apparent cause, as, upon making a minute inquiry, I learned, that although she was in her fifth month of pregnancy, she had been perfectly well up to the previous evening,—that then, and during the night, she had complained of some pain and uneasy sensations in the abdomen,—and that she had *once* vomited. She had of her own accord taken some castor oil early in the morning, which had operated previous to my seeing her. She died within two hours after my

visit. I had known the woman previously: she was about 25 years of age, and had given birth to one still-born child about twelve months since, when her labour was tedious, but natural. She had since had one miscarriage; in other respects her general health was good. Upon a post-mortem examination, I found the external appearances of the body natural; but in laying open the cavity of the abdomen, a large quantity of coagulated and fluid blood, to the amount of four or five pints, was found covering the hypogastric and pelvic viscera: upon removing this blood, I discovered the membranous envelopes containing the fœtus floating in the abdominal cavity, above and anterior to the uterus, attached, however, to this organ by the funis. On clearing away a mass of coagulum, the uterus was found in its natural position, partially collapsed, having a fissure on its superior and posterior wall, from an inch and a half to an inch and three-quarters in length, immediately over the attachments of the placenta, and through which the membranes, with their contents, had escaped. The placenta remained attached to the fundus uteri, save where it was exposed by the rupture, showing there had been no effort to throw off this body. The body of the uterus was rather thinner and much softer than natural, yet the part ruptured showed no greater indications of disease than the whole substance of the organ; the neck was healthy, and the os uteri closed; the right ovary healthy, the left larger than a pigeon's egg, and hydropic; the bladder was empty, and the rectum free from accumulation; the remaining abdominal viscera quite natural in their appearance.

The peculiarities of the foregoing case would seem to be—the rupture of the uterus at so early a period of pregnancy,—the absence of external violence,—of acute pain, or apparent strong contraction of the womb; nor am I aware of any symptoms in her general health which could at all have led me to suppose that she was suffering from organic lesion of so important an organ; the morbid appearances indicating a softening down of the component tissues of the uterus, rather than actual change of structure, as, judging by external appearances only, it might have been considered healthy.

MEDICAL GAZETTE.

Saturday, March 24, 1838.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso.”
 CICERO.

CAN QUACKERY BE SUPPRESSED?

WE showed, in our late article on this subject, that quackery, far from being suppressed in France, as supposed by the pamphleteer whom we quoted, is comfortably settled there; and that it lifts up its banner, not merely on dead walls, but in the midst of the very Academy of Medicine; for many of the hours of this learned body are employed in sifting the pretensions of nostrums, and reporting to the Minister whether they are worthy of a patent. In fact, next to England, France seems always to have been the country where quackery has flourished the most; from the days of mere mountebanks to those of more refined impostors.

Addison tells a pleasant story of the appearance of a French quack in Paris, with a boy walking before him, and publishing with a shrill voice, “My father cures all sorts of distempers;” to which the doctor added gravely, “The child says true.”

Or, to turn to recent times, we may find some good observations and amusing instances in the *Dictionnaire des Sciences Médicales*, under the head of *Charlatan*; though, in sad truth, the only examples there mentioned, which occur to us at this moment, are irregularities committed by regular members of our corps. One is a story of a physician of Montpellier, who, when he came to a new place, used to pretend to have lost his dog; and then sent the crier about the town to offer a reward of twenty-five louis for bringing it back, taking care at the same time to mention all the doctor's titles and ho-

nours. The townspeople naturally thought that the physician must be both rich and great, to offer so large a reward; and though the dog never was found, patients very frequently were. This facetious story, where the charlatan appears to have had his diploma, tends to lead us to the painful doubt whether the public are not sometimes induced to throw off their allegiance to regular practitioners, by the difficulty of distinguishing them from the intruders, in any thing more material than the possession of a parchment. In such cases, where the regular troops fight with very irregular arms, one is inclined to reverse an old question, and, instead of asking

“*Quid domini facient, audent cum talia fures?*”

to inquire what will the thieves do, when the masters venture on such acts?

Come we now to Austria, and the other states of Germany, where, according to our mistaken fellow-labourer, quackery is suppressed.

Supposing for a moment the assertion to be true, and that not a quack were to be seen from the Rhine to the Baltic, we should still have to weigh the enormous price paid for the exemption, and to consider whether the people of England could be brought to submit to it. This price is neither more nor less than the abrogation of liberty, in speech, writing, or action, and the consequent conversion of men into infants six feet high. In such a state of things the iron hand of authority which attempts to crush the charlatan, presses very hard on the regular practitioner, and intermeddles with him in matters where in Britain no one would dream of the possibility of government interference. Thus in Hanover, and we believe in other German states, the government prescribes the number of punctures to be made in vaccination; and the mode of isolation of persons labouring under small-pox or

scarlet fever, which is enjoined in Prussia, is such as could not be attempted by any but a despotic government. The regulation, however, is evaded—a proof how little even the most absolute authority can do, when opposed to the manners and instincts of the people.

After all, the great difficulty is to ascertain what is really done, and how the laws work, in countries where the press is not free, and where the government attempts to place fetters even on the intercourse of society, and the ordinary topics of conversation*.

In a country like Austria, where even the Prussian journals are deemed too liberal to be circulated, no man can tell what is the actual effect of a given regulation, or pretend to say that a thing does not exist merely because it is not mentioned. Just imagine, if in our own country we were to trust to the garbled accounts and one-sided panegyrics of those who live by a system, or, in other words, were to take official statements for the whole truth, what fantasies we should receive for facts!

Not unlike this are the accounts which the higher classes in such countries palm upon hasty travellers, especially upon those who being ignorant of the language of the people, see every thing through the dim medium of interpretation†.

Thus we are led to the inevitable conclusions that it is very doubtful whether quackery is suppressed in the countries where the pamphleteer supposes this happy phenomenon to have

* A German told us, that at Baden it was deemed *dangerous* to talk about Casper Hauser; that is to say, for some reason, the fate of this singular being was a sore subject with the reigning family, and therefore padlocks were put upon Baden tongues.

† Thus a late traveller represents a prison, in which criminals of the blackest dye are confined at Vienna, as a very pleasant kind of residence—so clean, so wholesome, and the bread so good (just as the water-gruel is with us.) Count Somebody, who showed her about this walled paradise, hinted at only one drawback upon the perfect happiness of the inmates; they are whipped periodically.

occurred; and that it is still more questionable whether the measures adopted for the purpose *there*, would be tolerated one moment *here*. Our well-meaning ally, of Bath, however, feels no doubt upon the subject, and says, that "to argue that measures successfully adopted in every other European country are inapplicable to the free institutions of Great Britain, is absurd and fallacious. If a British government is unable to adopt regulations which enlightened experience has shown to be essential for the preservation of the public health, then its freedom is a curse, and its existence a fiction."

We fear that few among medical men, and hardly any of the laity, will coincide with the opinions expressed in these zealous paragraphs. It is a lamentable thing, unquestionably, that foolish people should be induced to fuddle themselves with drams, under the names of balms and elixirs; and that when they have thus dried up the small portion of brain with which they were originally blessed, they should doggedly bring on an enteritis with colocynth and gamboge in hygienic doses. Yet this mania can never destroy the British constitution, though it may their own; and we cannot agree with the author that the existence of the former is in danger of being reduced to a fiction by any quantity either of purgatives or stimulants.

If, indeed, it were a common thing to hear of Lynch-law being executed on helpless patients; if they were tied to trees while a boxful of No. 1, or No. 2, was forced down the œsophagus; we, too, might cry out for the *paternal* care of the Austrian government: but while no force is exercised upon our deglutition, we must be content with the mingled yarn of liberty, and take the evil with the good. After asserting that the law in continental Europe protects the rights of the qualified practitioner, the author of the pamphlet

says, "This is also the privilege of the legal profession in England, which allows no one to assume the title and powers of advocate except in his own cause." We wonder that he did not see that unqualified advocates can be prevented from pleading in court, but cannot be prevented from giving opinions at their chambers; just as unqualified practitioners of physic do not get appointments in the army or navy, but practise on those who accidentally fall into their clutches. The official discouragement is the same in both cases; only that, from the custom of the professions, the unqualified chamber-counsel would get little or no practice, as his clients, the attornies, would be aware of his ignorance; while the mock-doctor, addressing himself directly to the multitude, and not through any such critical medium, is less easily detected. In the lower walks of the law, however, we believe that a good deal of business is done among the poor and uneducated by unqualified attornies.

Another comparison might be instituted with the remaining learned profession; and we should see here, likewise, how difficult it is to abolish quackery by law. We believe that in this present year, 1838, no one proposes to put down the Jumpers or Irvingites by force. If the war against uneducated empiricism should ever be carried on with the spirit which the Bath pamphleteer desires, it would assuredly be requisite to consider the patients as accomplices. The possession of an embrocation of which he could give no satisfactory account, would subject a sick man to fine or imprisonment; and the excise must be empowered to seize antibilious pills, like *run* brandy or silks. To adopt the question of a former writer, "Will my Lady Bonnet be allowed (like the master of a house under the Conventicle Act) to physic her household and sundry poor

neighbours, provided that her hospital does not exceed twenty beds? Shall we hear of the triumphant seizure of a cask of pennyroyal water? or will rhubarb pies be searched, charged on oath with being made with the root instead of the stalk?" That these severities, if feasible, would do something towards suppressing charlatanism, we do not doubt; the difficulty would be to get them enacted; the impossibility, to put them into execution.

The author whom we have so often quoted does not date his pamphlet from Utopia, and yet his *form of petition for the abolition of quackery* contains the following clause:—"It is therefore humbly proposed, that all patent, quack, and secret medicines, be abolished." To ask for the withdrawal of patents from nostrums is no more than reasonable; but to ask Parliament to abolish all quack and secret medicines, is to ask them to abolish the frailty of human nature; it is humbly to propose, that no knaves be permitted to set traps, nor any fools to fall into them.

We can hope, therefore, for improvement on this score, not from the establishment of a medical inquisition, but,

1st, From the more equitable administration of the laws; so that quacks convicted of the most culpable homicide, or of the unpardonable offence of keeping an unlicensed madhouse, may not be let off almost unscathed.

2dly, From the more general diffusion of sound knowledge, the best preservative against the artifices of the medical impostor.

3dly, Our surest hope would be founded on the disuse of quackish tricks among regular practitioners; and we could appeal to the public with more confidence, if doctors did not, like him of Montpellier, cry dogs which they had not lost, and advertise books which they had not written.

ON ANIMAL MAGNETISM.

No. IV.

THERE now remain for our notice only the most marvellous of the phenomena said to be produced by animal magnetism. Before entering upon them it is of importance to observe, that all the supernatural powers said to be acquired in magnetic somnambulism have seemed to be enjoyed by the founders and early adherents of several sects of religious fanatics, and by those supposed to be either inspired, or possessed by evil spirits, to have sold themselves to the devil, or to have been bewitched. These powers, too, they have generally exhibited during fits of convulsions, trembling, delirium, &c., in short, while in a state of extasis often so similar to that which the magnetizers absurdly call somnambulism, that the same description might serve for either.

The faculties attributed to the possessed and inspired, have been—speaking and understanding of unknown tongues; sudden exaltation of the intellectual faculties; knowledge of future events, and of circumstances occurring at distant places; knowledge of thoughts unexpressed; great development of physical force, and a power of remaining for a long time suspended in the air; all which powers have been also ascribed to the magnetized. In like manner both have always arisen under strong mental excitement in highly irritable persons, and most especially in hysterical women; both have become, as it were, epidemic from imitation, so that in all instances, while a general character has been preserved, there have been some slight peculiarities arising from the copying of the model which the first case by accident or design had presented. Both have been constantly influenced by impressions on the mind.

We shall now proceed to examine these powers only as attributed to somnambulists, remarking, that whoever believes that they are possessed in one set of cases, is bound to believe them to have been present in the others (which are by description their very homologues,) and that, on the other hand, if proved deceptions in the one, we have every reason for suspecting fallacy in the other. No rational man believes now in possession, or in fanatic inspiration, or sorcery. Is there more

ground for believing the power of the weird-sister, mesmerism?

To begin with the faculty of prophecy. There is no evidence that any one of the hundreds of these predictions ever came to pass, except those which related to the return of hysterical or epileptic fits, or of imaginary sensations, or of sleep, either in the prophetess herself, or in the person prophesied to, and that these proved frequently true we are not inclined to doubt. For we know that at whatever time an hysterical girl wishes or expects a paroxysm, she can have one—they lie so near the surface.

M. Bertrand gives an amusing account of how his patients prophesied the returns of their fits and their recoveries. They always fixed a time at which, or very near to which, some clock would strike within their hearing, and the event took place *by that clock*; for if it was altered, the event was delayed or accelerated in correspondence with it. We do not mean to say that in all these cases the patients were intentional impostors—they deceived themselves; for believing that at the time a fit would occur, a real one doubtless did, and that they should hear the clock strike during their sleep or somnambulism is not extraordinary; the expectation of it occupied their minds on falling asleep, and their attention and hearing were therefore alive to it. A similar thing is observable in most persons; if they go to bed extremely anxious to be up at a certain hour, they are sure to wake at that time, and very often at the precise minute on which they had fixed, especially if that be a *striking* minute—as one of the quarters. Such is the summum of magnetic prophecy.

The next power we shall notice is, that of knowing what is occurring at miles distance, in places altogether removed from the senses, and unknown except to the mental eye. There is no reasoning on such a thing as this; but if we believe such statements as that a girl at Strasbourg could, during her sleep, accurately describe Paris, which she had never seen or heard of, except vaguely, or could relate exactly what, at the moment she was speaking, was occurring in a house in the next street, from which nothing was sensible to others, then we have no right to disbelieve that the two Taliacotian noses at Brussels dropped off at the moment

that their original owner died in Naples; or that rubbing healing ointment on a sword would cure the wound it had made; or that applying styptics to a shirt would check the hæmorrhage from its owner's body. For, let it be remembered, these things are not the inventions of those who parodied on them; but the three absurdities we have just mentioned were deemed so well authenticated, that they formed a principal support of Maxwell's theory of a universal fluid, which Mesmer copied, and published as his own. *Yes! from these things Mesmerism sprung.*

It is in this pretended faculty of seeing what is going on at vast distances, that the magnetic practices resemble most closely the tricks of conjurors and magicians. From time immemorial, magicians have been in the habit of exhibiting in mirrors or in clouds of smoke not only the future destinies of those who came to consult their horoscopes, but the forms of those whom each most desired to see, representing them as engaged in the very act which they were at the same instant performing perhaps in a distant land. Our present space will not permit us to do more than allude to this, the favourite practice of the heroines of romances, and refer the reader to Sir D. Brewster's *Natural Magic*, and Sir W. Scott's *Demonology*, for cases, and the explanation. At present it seems to be seriously practised only in Egypt, as described first (we believe) by Lord Prudhoe and Major Felix, and lately by Mr. E. Lane, in his *Account of Modern Egypt*.

With regard to the power of understanding the unexpressed thoughts, M. Bertrand says that the patients were *very seldom* able to do it, and that when they could, it was only by guessing from the expression of his face, as he proved by acting a particular thought by which he was always able to deceive them. It is well known that the same method of judging, or rather guessing, the thoughts, was practised in the declaring of oracles, and by the pretended inspired. As a proof of the difficulty of detecting such impositions, we may mention, that, for a long time, M. Bertrand was inclined to think that by his will he could, as M. Puysegur thought he did, direct the thoughts of his patients to whom it was conveyed without words or looks.

The capability of detecting magnetized things—as water, dresses, trees, &c.—requires still shorter notice. Whenever the patients had to choose *the one thing* out of many, they made mistakes: this happened in several instances before the first Commissioners, and M. Bertrand amusingly describes how he deceived his patients by sending them unmagnetized letters, &c.; which, being supposed by them to be replete with virtue, always produced the usual effects.

We come, lastly, to the incredible statement that the senses may be transferred from their proper organs to the epigastrium, the tips of the fingers, occiput, &c. When we say that we disbelieve the accounts of these cases *in toto*, we must again remind the reader that we do not deny the assertions of magnetizers only, for these fables were told long before their time, and instances are said to have occurred since, in those who have never been magnetized at all. The first magnetic cases were those of M. Puysegur, of whose insanity we have so little doubt that we cannot regard any statement he makes as worth the least consideration. However, while the effects he was said to have produced were the subject of constant conversation at Lyons, there occurred, in M. Petetin's practice, eight cases of catalepsy, in all of which there was transference of the senses. Now this fact explains itself; no other physician, we believe, ever had eight cases of catalepsy, for it is so rare that Cullen doubted its existence, and believed all the cases ever related to have been impostures; and in no case that any one else ever saw was this incredible phenomenon present. The conclusion is clear: eight hysterical women heard of people who had fits, and with them supernatural powers: by the common tendency to imitation, which has constantly made such affections epidemic, they modelled their fits on the new plan, and pretended, or perhaps believed, that they too had the same faculty of seeing without eyes, which (with that love of deception which is so common among hysterical women, that it is sometimes quite characteristic of the disease), they lost no opportunity of exhibiting, and neglected no artifice by which they might appear so endowed. From this time the possession of these powers has been an

object desirable of attainment to every somnambulist; and we have no doubt that every case has been based on deception, either with actual imposture both in the magnetizer and the patients, as in M. Berna's case, or by the patient deceiving herself and those around her, or wilfully carrying on an imposition either for mischief-sake or gain.

A few of the phenomena referred to transference of vision are clearly explicable by circumstances we have already alluded to; as by the apparent exaltation of intellect which some seem to acquire during sleep, when every thing that could distract their attention is removed. Such, among many, are the cases in which, in cerebral disorders, a language long forgotten is again remembered; and those in which things overheard, and apparently forgotten, are recollected, as in an instance mentioned by Coleridge, in which an ignorant servant girl, during delirium, repeated long passages on theology in Latin, Greek, and Hebrew. She had been formerly in the house of an eccentric clergyman, who was fond of walking up and down the kitchen reading aloud. Dr. Abercrombie relates many similar instances. To others we have a clue in the cases where, in dreaming, persons have circumstances revealed to them which, while awake, were hidden, as in that, amongst several given by the same author, in which the gentleman was correctly told, by the shade of his father, where some important papers he had long searched in vain for were laid. Indeed, it is commonly observed that during sleep, with the mind undistracted, the memory is far more lucid than when the mind is harassed in the day. The annals of somnambulency are full of such cases, and every old woman has a store of authentic histories of prophecies, and omens revealed during dreams and sickness; they are the parallels of the magnetic statements, and the same explanations serve for both. The magnetizers, however, have far surpassed the tales of the rock-staff, and have brought, as we have seen, statements on which reasoning (if possible) would be useless. It can only be said, that they are contrary not only to common sense, but to every fact, and law of physical and vital science. If they be true, every thing else is false; the form and colour of objects have no relation to light; light

itself is a chimera, yet matter of the greatest density can neither resist its passage, nor divert its course; the complicated apparatus of the eye is a superfluous ornament; a brain and nerves mere playthings for philosophers to waste their time on.

This, then, is our case. Every credible effect of magnetism has occurred, and every incredible one *is said* to have occurred, in cases where no magnetic influence has been exerted, but in all which, excited imagination, irritation, or some powerful mental impression, has operated: where the mind has been alone acted on, magnetic effects have been produced without magnetic manipulations: where magnetic manipulations have been employed unknown to the patient, and therefore without the assistance of the mind, no result has ever been produced. Why, then, imagine a new agent, which cannot act by itself, and which has never yet even seemed to produce a new phenomenon?

CHEMISTS GIVING EVIDENCE AS SURGEONS.

To the Editor of the Medical Gazette.

SIR,

YOUR publication has hitherto exposed any evil practices towards our profession which have been communicated to you; I therefore do not apologize for troubling you on the present occasion, as I think it part of the duty of a journalist to protect that profession to which he is allied.

If you will refer to the *Times* newspaper of Wednesday last (or Thursday), you will find the details of an inquest held near Golden Square, in which a chemist, in Piccadilly, is related as having been called in to the object of the inquiry there narrated, and his evidence before the jury is given at full length. This witness is styled a "surgeon." I only know the individual by name, but believe he is a very respectable chemist; and as long as he does not travel out of his proper path, there is no fear of his name being brought before the public; but when a person who has not received a medical education, has undergone no medical examination, and belongs to neither of the three medical institutions of the kingdom, renders himself amenable to the law, by taking on himself the responsibility of a medical practitioner, which I can prove has been done by the individual in question, to my own knowledge, in cases of grave importance,

I do not think the Colleges are fulfilling their duties in neglecting to prosecute such a case, nor any member of the profession acting up to the oath he takes on entering his profession, in which he swears to maintain and uphold the respectability of his profession, if he allows it to pass by unnoticed. I take up this question as one of medical policy, and not as affecting an individual; and if he should be prosecuted for meddling with subjects unfitted for his craft, he must remember that the object of the writer of this letter is to do justice to his brethren, as well as to the public; for who can say that a medical man might not have saved the life of the deceased this is merely mentioned for argument, for we are aware no medical man could have done so in the present instance, or have found (after an examination of the body) some other cause of death than that stated by this *sci-atisant* practitioner?—I am, sir,

Your old subscriber,

CYCLOPS.

March 3, 1858.

P.S.—Another instance of a chemist giving medical evidence at an inquest, not three months since, has come to my knowledge; but as the inquiry did not appear in the papers, I abstain from further comment.

HOLLOWAY'S UNIVERSAL OINTMENT.

To the Editor of the Medical Gazette.

SIR,

AN old patient of mine, afflicted with prurigo, expressed a wish to have my opinion of a patent medicine called "Holloway's Universal Family Ointment, or the Prince of Remedies." As I have, in a long practice, uniformly condemned all secret nostrums, I unhesitatingly considered that it would be derogatory to the profession to countenance any of these numerous pretended remedies for the cure of every ill which "flesh is heir to." I therefore, without any investigation, advised my patient to have nothing to do with it. I had lost sight of the circumstance altogether till this day, when a placard, with a frontispiece displaying several ulcerated legs and other embellishments, was put into my hands, by a dispenser of such delicacies, in the public streets. I generally refuse such presents, but seeing a curious set of pictures, I perused the document, and carried it home. But, judge my surprise, when I saw the respectable names of Sir Benjamin Brodie, Mr. Mayo, &c. appended to the list of recommendations for the "Prince of Remedies." I confess I was puz-

zled at this, having been taught to revere the names of those men who, by deep study and important discoveries in their profession, have laid down a character for themselves, *perennius are*. If this ointment has such wonderful virtues, and is so highly recommended by the principal members of our profession, perhaps it would not be unbecoming in me, as a humble member, and eager to seek information, to request, through the medium of your journal, to be apprized of its composition, in order that I may, with others, give my patients the benefit of so great a discovery.

I am, sir,

Your obedient servant,

ROBERT SEMPLE,

Member of the Royal College of Surgeons in London, &c. &c.

Rufford's Row, Islington,
8th March, 1835.

[Mr. Semple will find at page 832 of the present volume a letter from Sir Benjamin Brodie, expressive of his indignation on perceiving the use which had been made of his name in connexion with this nostrum. With regard to Mr. Mayo, as he is made to say that he has found the ointment of use "in ALL the cases in which he has tried it," we cannot but suppose that his testimonial, like that of Sir Benjamin, has been falsified.—ED. GAZ.]

ON THE TREATMENT OF SYPHILITIC BUBOES BY SETON.

By PROFESSOR LEVICAIRE,
Of the Marine Hospital, Lyons.

DR. L. states that he has employed the seton most successfully. His plan is, as soon as he perceives that the bubo contains matter, to pass a strong, round, straight, long needle, carrying a thick thread, in the direction of the fold of the groin. The points of entrance and exit are those at which the gland first begins to soften. He permits the seton to remain for only twenty-four or twenty-eight hours in quiet, and sometimes to promote irritation, and prevent the too rapid healing of the openings, moistens it with a weak caustic solution, and for the first days lays on an emollient poultice. When this is no longer necessary, he dresses it with a handful of cotton (unwrought) in order to promote the exit of the matter, the adhesive inflammation, and the development of granulations. This is supported by a bandage round the loins, and exercises a very gentle, steady pressure. Dr. L. thinks every thing disadvantageous which pro-

motes the absorption of the matter. The matter here escapes along the seton; the walls of the abscess come gradually together; the air cannot penetrate through the opening, which is small, and filled by the seton, and the seton causes a healthy action, by means of which granulations are favoured. No cicatrix remains behind, and only three or four days are sometimes necessary for the healing of the bubo.—*Bulletin Gen. de Ther.* April, 1837, and *Dublin Journal*.

CONCLUSION OF THE VOLUME.

Our readers will perceive that we have given an additional sheet with this number, and postponed the Index till next week. By this arrangement we have been enabled to complete Mr. Hawkins' valuable set of Lectures on Tumors, and to bring to a close several papers, the commencements of which had either previously been given, or which refer to subjects discussed in the present volume.

We have to apologize to many correspondents for the delay—quite unavoidable, however—in the publication of their papers. Dr. Borrett's letter, which is of more recent date than some of those still postponed, has been inserted this week because it refers to a subject which is at the present moment under the consideration of Parliament.

The Lectures of Dr. Williams and Dr. Southwood Smith, interrupted during our last two numbers by press of matter, shall be resumed with the commencement of our ensuing volume; in which we shall also continue those of Sir Benjamin Brodie and Mr. Lawrence, and give the papers of Dr. Clutterbuck, previously announced.

NOTICE.—We cannot insert Dr. Turnbull's remarks on Ipecacuanha: we are not aware of their containing any point not already known.

IRISH APOTHECARIES' HALL.

[THE following was received very soon after the publication of the letter to which it is an answer. The delay in its insertion has been caused by what proves to have been a mis-understanding on our parts as to the wishes and intentions of the writer.—*Ed. Gaz.*]

To the Editor of the Medical Gazette.

SIR,

As I was the author of the letter headed "Queries for Apothecaries," in the *Dublin Evening Mail* of 1st December last, and signed "A Graduate in Medicine, Surgery, and Midwifery, of Dublin, Edinburgh, and London," which, however, was only called forth by a series of violent resolutions against the Irish College of Surgeons, passed on the previous 20th of November, and published in Saunders's Dublin News-letter, of 22nd Nov., by a voluntary "Society of Apothecaries" in this city, you will, I am sure, allow me to reply to a letter in your 18th number, viz. of 20th January, 1838, (pages 655—659) signed "A Professor in the School of the Apothecaries' Hall of Ireland," which attempts to answer, or rather to evade, my former one.

As your pages 667-8 of the same number, under the heading "Irish College of Surgeons—Pharmacy Laws," copy correctly an advertisement which appeared in all the Dublin papers, giving an abstract of our objects, I shall merely refer your readers to them, as sufficiently explanatory of what we really wish and intend to do, which will save space, and avoid repetition, as well as prevent misrepresentation.

According to your requirement, I supply you with my name, (which is probably, however, well enough known already here, in this controversy), though I cannot see, in a question of this kind, which all depends on general reasoning, and on arguments founded on printed documents, not at all on facts, stated on the writer's authority, on either side, how real signatures can be of any value, or add any weight; and, to prevent personalities, I should have thought it wiser, in such a matter, not to sign or require them. For brevity's sake, I shall call the writer in your pages the "Professor," as he calls me the "Graduate of three colleges."

To those parts of his letter which contain personalities about the "Graduate," it would perhaps be as well not to make any reply, except by merely quoting them; but my general plan is, not to leave any thing material unanswered.

As to the "Professor's" insinuation in this sentence, "How, I would ask, is a member of any public body to promote its honour? Is it by being idle, and not exerting the talents with which he may have been endowed? Such a course might serve the purposes of others, perhaps of the 'Graduate,' but it would reflect little credit on himself or his College." My answer is briefly this:—I much suspect, that I have been at any period of my life as little idle as the "Professor," at least, and have perhaps too made more by private or public practice, than any one or two, or possibly three, of his whole body of professors, including himself; and he knows, or should have known, that I have filled three laborious professional

appointments under Government, and others in public institutions. Let him, then, say, was I idle, when in four years only of one of these Government situations, I had to prescribe, as the books showed, 35,296 times, and to pay besides 16,161 visits to the poor, at their own houses? Has he done as much in his whole life? Thus I could negative the insinuation of idleness, without any of the other proofs of activity, energy, diligence, and perseverance, which I might multiply ten-fold. It is very easy for young men to set up as lecturers, if private practice or public duties do not better occupy their time; and a very wise plan it is of "*advertising*" oneself.

To his remarks on the style or grammatical composition of that letter, I shall offer no reply, except to say, let the public read both, (allowing for a few typographical errors by the newspaper printer), and after having thus seen which can write the best English, or the most consecutive and condensed arguments, let them decide. In fact, however, the chief fault of my letter, I should think, was, that its English and its arguments were so plain, as to be incapable of being mistaken or evaded. If, indeed, you would consent to republish my former letter, of which, at the time, I furnished you with a copy in the newspaper, in that hope I should think it quite needless now to answer the "Professor" at all.

Any one reading it will see that he misstates its design, ignorantly or intentionally, when he says, "The main design of the writer of this letter appears to be two-fold; 1st, to throw odium upon the apothecaries' branch of the medical profession; and 2ndly, to promote thereby the attainment of an object at present desired by a party in the Irish College of Surgeons, by degrading it and its members from the station they have hitherto held." As to party or parties in the College, he must know that there are at present none, and that all our late proceedings on the "pharmacy laws" have been unanimous. And as to myself, he knows that I never, at any time, joined any party in the College, on any question, but voted on different sides on various occasions, according to my own views of duty to the College, the profession, and the public. But you will see, by and by, that he

here but echoes what the apothecaries' resolutions had said, though he declares, "I am not in their counsels, nor am I their advocate." True it is, that I held up to just odium and ridicule the exacerbatd resolutions of the volunteer "Society Apothecaries;" it is also true, that I exposed the underhand proceedings of certain apothecaries who try to worm themselves into practice without license or diploma; most true it is, too, that I pointed out the shortcomings and oversteppings of their own "act of incorporation" (of 1791), by the "directors" of the "Apothecaries' Hall;" with the assumptions and encroachments, neglects and omissions, of all three parties, and well each deserved and has felt my reproof; but of the *genuine apothecaries*, as individuals, and of their calling as a needful and useful "profession," I spoke respectfully in different parts of my letter, as follows:— "You (the 'Society of Apothecaries') misrepresent us wholly. The person we highly approve of, and wish to benefit as much as ourselves, is the 'apothecary,' truly named and truly so, as created by that act." "It is the right of the apothecary, by it, to make up our prescriptions." "Did we not solicit your, and others', and all help," only "for the removal of the abuses and imperfections in the existing laws, for regulating the business of an apothecary," and that solely by means "wisely" chosen, when we added "information and suggestions, calculated to forward these objects, shall receive every attention?" "We will do no injury to apothecaries, their Hall, or charter," (or, rather, 'act of incorporation,' for they never had a charter). "We wish well to the Apothecaries' Hall." "We wish its charter (act) improved and confirmed." "To help to protect you against druggists and chemists, now beginning, as in England, to usurp your rights, we are willing to lend our aid." "You say, we wish to 'become apothecaries.'" "Nay, but we wish to make you so, as your charter (act) does." "Be, however, 'assured' of this, gentlemen, we have no enmity to *bona fide* apothecaries. Are they not a necessary branch of our own profession? We have no wish to annul their charter (act); we think it imperfect, defective, inadequate. There are faults, too, in our own (charter). Should you, then, hastily oppose

our taking measures to correct both?"

"And now, gentlemen, take my friendly advice. Know your friends, the surgeons and physicians, from your enemies, the druggists, chemists, Medical-Hall keepers, and unlicensed apothecaries. In future, keep your temper," &c. "Gentlemen, what we want is an equitable general law, to regulate the whole profession, with the education and practical duties of physicians, of surgeons, and of apothecaries, to make mutual inroads impossible, to make pharmacists, druggists, and Medical Halls, keep their proper sphere." "Allow me, with all due personal respect, of course, for you, as individuals, to subscribe myself," &c. And yet the "Professor," in the face of all this, asserts, the surgeon wishes to "wrest from the apothecaries their means of livelihood, if he could, and "to become an apothecary, if he can;" and to "convert the College of Surgeons into a corporation of drug vendors;" and also says, we are "grovelling guardians of the science and honour of surgery;" and that each wishes to "sell a sixpenny draught to a pauper, who cannot give him a fee, and therein find remuneration for his professional service."

As to my assertion, that the persons lecturing at Apothecaries' Hall were, except the one, or perhaps two, who were or are apothecaries, "renegades from the sworn interests and honour of our medical and surgical professions and colleges;" though I did not, as you see, thereby charge them with perjury, as the "Professor" says I did, but only with renegadism or desertion in the day of battle, yet he himself actually tries to prove, as to himself individually, at least, what I had not intended to do as to any; for he quotes the oath that he took by our "charter," as follows:—"I do solemnly swear, that I will observe and be obedient to the statutes, by-laws, and ordinances, of the Royal College of Surgeons;" which "charter," and which "by-laws, statutes, and ordinances," so sworn to, I understand alone and clearly to fix the "sworn interests and honour of the professions and Colleges;" though he cavils as much with the expression as with the duty. Does he not know, and did he not know, before he applied to be appointed at the Hall school, that on the "5th November, 1832," it was "unanimously resolved" by the College,

of which he was a "member," as follows?—

"Royal College of Surgeons of Ireland.—At a meeting of the College, 5th November, 1832, a letter from the Secretary of Apothecaries' Hall having been read, requesting to be informed whether a certificate of attendance on a course of lectures, delivered in it, will be received as a part of the course of education, required by the College, and as a qualification from candidates for letters testimonial, the College unanimously adopted the following resolutions":—

"Resolved—That it appears to the College that the Apothecaries' Hall was established, by the Act of the 31st of Geo. 3. (1791.) cap. 34, for the purpose, as the preamble declares, of obviating the "many and great inconveniences which have arisen from the want of a Hall, amply supplied with medicines of the purest quality, prepared under the inspection of persons well skilled in the art or mystery of such preparations;" and also, because "frequent frauds and abuses have been imposed and practised on many of his majesty's subjects, by the ignorance and unskillfulness of persons pretending to the art and mystery of an apothecary, to the injury of the fair trader, the disappointment of the physician, and the imminent hazard of the lives of his majesty's subjects;" and also, "for the purpose of enabling" the corporation of apothecaries "to create a fund for the erection of such Hall, with such authority, &c. as may in future prevent such frauds and abuses, and thereby tend to preserve the health of his majesty's subjects;" and likewise, as the 22d section of the said Act sets forth, "to prevent any person from opening a shop, or acting in the art or mystery of an apothecary, in Ireland, until he shall have been examined as to his qualification and knowledge of the business," by its "directors."

"Resolved—That the College having been advised by counsel, that the directors of the Apothecaries' Hall are not authorized, by the Act above noticed, to establish a school of medicine or surgery, or to appoint professors, for instructing students in those branches; and being satisfied that the application of the funds of the company, or the appropriation of the Apothecaries' Hall, to such a purpose, is a departure from and

a perversion of, the objects contemplated in that Act, which was constructed as much for the advantage of the physician and surgeon, and the safety of the public, as for the regulation and maintenance of the corporation of apothecaries; the College will not receive as qualification, from candidates for letters testimonial, any certificates granted after this date, from teachers lecturing in, or appointed by the Apothecaries' Hall, but on the contrary will use its utmost efforts to prevent the Apothecaries' Hall from being converted to purposes which the legislature never contemplated." This refusal to join them in an illegal act is one chief cause of their hostility. But we saw clearly through their schemes at once.

Did not the "professor," in the teeth of that unanimous determination of his College, since seek and obtain his professorship a year or two ago? and, what is more, is he not pledged, as a member of the College, by his oath, and still more, if an examiner, to refuse the very certificates that he may give as "professor" at the Hall?

Let your readers judge, whether the "professor" spoke quite correctly, or without concealment of the implied meaning of the above, when he said, this is a "calumny," "an unfounded and disingenuous calumny;" and "there does not exist statute, by-law, or ordinance of the Colleges of Surgeons or Physicians, which forbids a member or licentiate from becoming a professor in any school which may be open to him." Does this unanimous resolution and ordinance not do so, both actually and implicitly, by declaring the whole school illegal? Does this not, both in words and virtually, incapacitate the College members from doing justice to the College and their may-be pupils, if at that school? It may be said, this is unfair. It is not. For the principle on which the College acts is this: any one or more persons may establish a school; and if well conducted, it will be recognized by the College as freely as its own; or the apothecaries may, as individuals, combine to establish a school, with voluntary funds, and if good it will be recognized; but if their corporation diverts a part of its funds to this object; or if they call it a part of their incorporated rights; we believe they infringe on their act, and invade our charter;

and if they further enforce attendance at such illegal school on their apprentices, by the fear of a still more illegal examination, they defraud and oppress them; and the College know this to be the case, and will not be parties to it. Aware of all this, he applied for and fills a professorship in that very school, so that contradictory duties entangle him now. If, he says, he can thus, as I conceive, "strain his conscience to swallow both gnat and camel," I can only pity what I should call both bad taste, and a want of a clear understanding of what I believe to be the meaning of the English words of his oath, though he may believe the contrary. He also says that he swore, "I will, to the utmost of my power, endeavour to promote the reputation, honour, and dignity of the said College." And is he now doing so, by leaguening himself with the violent and indecent resolutions of the Apothecaries' Hall, or of the Society of Apothecaries of Dublin, or of the apothecaries of Cork, Limerick, Galway, and Sligo, so stirred up by the itinerant "Professors" of the Hall, to violence? All I can say is, that his conscience differs very materially from mine. For what are the words that he and his party sanction, and of which he says, he "only hopes that they will continue, as they have commenced, to defend themselves, without forgetting that something is due to the station which they hold in the opinion of society." Let us see; have they done so? The "Secretary of the Hall," in his advertisement of 17th Nov. 1837 (see *Dublin General Advertiser*, 18th Nov. 1837) says, "the College wish to injure the reputation, and trench on the legal rights, of the apothecary profession." "The governor and council of Apothecaries' Hall," by resolution of 24th Nov. 1837, (see *General Advertiser*, 25th Nov. 1837) "unhesitatingly pronounce the words, 'mischievous' and 'dangerous,' applied by the College, as altogether unwarranted and untrue." Now, listen to the words of the College "notice." They were merely these: "a committee was appointed to prepare a petition to parliament, praying for the removal of the abuses and imperfections of the existing laws for regulating the business of an apothecary in Ireland, which are found to be mischievous and dangerous to the public, and oppressive,

injurious, and degrading to the medical profession." This the Apothecaries' Hall call also "threat," "overbearing, and intrusive," and "a monopolizing spirit," and "false statements and injurious attempt." Their "circular, also, of the 7th Dec. 1837, calls it "presumptuous threat of spoliation and monopoly." The "Society of Apothecaries," by resolution of 20th Nov. 1837, (see *General Advertiser*, 25th Nov. 1837,) "with indignation repel" it, as "a jealous and intolerant spirit," "denounce" it, &c. as the "inconsiderate act of a disappointed and headstrong party, which degrades the College." "Threat," "usurpation," "dangerous," "monopoly," "aspersions," "indiscretion," and "abortive," are the only words they can find.

The Cork apothecaries, misled by the itinerators from Dublin, by resolution of 20th Dec. 1837 (see *Cork Constitution* and *Dublin Evening Mail*, of 5th January, 1838,) "have seen, with surprise and indignation, the College of Surgeons' advertisement, most unwarrantably and falsely aspersing the apothecaries' professional character," "attribute to unworthy motives" this "attempt to exclude from practice," by "unjust and invidious exclusion, and desire to protrude the apothecary." The "Galway apothecaries" (see *Galway Patriot* of 17th January, 1838,) similarly misled and misinformed, "have seen with surprise and indignation," &c., "denouncing our practice," they "deprecate and despise the imbecile and futile attempt," and "denounce the attempt as unworthy," "fling back the unworthy, untrue, and libellous imputation," and "desperate project," "engendered by public neglect, and nurtured by chagrin and professional disappointment, and ill-concealed jealousy of the obscure licentiates of the College of Surgeons," who are "inexperienced surgeons," and "unemployed surgeons," and with "total incompetency of the surgeons," "dangerous exercise of the science of physic," and "ignorance of surgeons," want to be "importers of English and Scotch apothecaries."

The Sligo apothecaries, also misled as above (Resolution of 17th January, 1838; see *Dublin Evening Post*, 27th January, 1838,) "view with indignant scorn the opprobrious and unprofessional language," the "futile attempt," of

which "envy and disappointment are the sole actuating cause." Now, please to read over again the College of Surgeons' advertisement, and see if it contains one word justifying such language, either in the part I have already quoted, or in the only other sentence which it contained, as follows: The committee are "also to prepare a bill in conformity with that petition, to be introduced next session, to enable all persons legally authorized to practise medicine or surgery in Ireland, to dispense medicine to their own patients; and further, to prevent them, or any other person who practises medicine or surgery, from compounding or dispensing the prescriptions of other practitioners." Did we wish to impose any restriction on others more than on ourselves?

When the "Professor," as leagued with such men, asks "How have the profession, and Colleges of Physicians and Surgeons, become degraded, by their members becoming professors of the Apothecaries' Hall?" I answer, first by those members who had no regard to the first part of their oath, "to observe and be obedient to the statutes, by-laws and ordinances;" or to the second part, and "to promote the reputation, honour, and dignity of the College, to the utmost of their power," and secondly, by being parties to a system for imposing upon the public under the name of a "license" or a "certificate" "to open a shop" from the Hall (which they now call a "diploma,") a class of imperfectly uneducated practitioners, as their *curriculum* of 9th October, 1837, proves they must be, which may be run through by attending the lectures at two different schools, in nine consecutive months, or at the utmost at one school in eighteen months, after which they get this unauthorized diploma. *Sunt quos curriculo pulverem olympicum collegisse juvant* may well be applied to such a dusty gallop after lectures, to collect this diplomatic suffrages of this would-be College of Pharmacy, and of all other sciences.

Let the Professor say, how can the theory and practice of chemistry, anatomy, physiology, and dissections, materia medica, pharmacy, and therapeutics, theory and practice of medicine, and surgery, forensic medicine or medical jurisprudence, midwifery, clinical lectures, and hospital, &c. &c. be all con-

densed into such a short space of time? and how can any man issue from such a hurried course, fit to carry on all four branches of a difficult profession, as he actively and potentially asserts, by joining that school, and authorizing its advertisements, and giving his co-operation and certificates?

As to the general question in discussion, I need, however, say little on it, as my letter in the *Dublin Evening Mail* put it in so true a light that it is unnecessary for me to try to do it better in your columns; especially, too, as the "Professor's" letter has been already answered, I believe, as to this point, by some "member of the College," in a late number of your *GAZETTE*; and I sent you, the other day, another letter of mine, in the *Dublin Evening Packet* newspaper, of 25th January, 1838, containing a ransacking exposition of the apothecaries' excesses and neglects, shortcomings and transgressions, of their own "act" of incorporation of "1791." I trust you will give it a place in your journal, and I believe your readers will acknowledge it, at least, is unanswerable. Perhaps, indeed, it would not be too much to request your insertion of both these documents, from the newspapers, together with this rejoinder, which would entirely prevent the necessity of my ever trespassing on your columns again on this subject, which, I think, is entirely exhausted in these three letters.

The "Professor" misstates the fact, when he says, "the apothecary is compelled, as well by the wants of society as by the position in which he is placed by others, rather than by himself, to act in the double capacity of the prescriber and dispenser of medicines." Such is not the fact, nor are such the causes. The apothecaries' attempts to become prescribers as well as compounding, are the result of a systematic plan of their own, to quit their legal position and become unlicensed (or, in a few instances, licensed) general practitioners, and displace all above them; so leaving no pure apothecaries to make up, as their act directs, the prescriptions of physicians.

The "Professor" says, "the Hall have accordingly long required the candidates for its license to attend certain courses of medical lectures." I do not at all believe this assertion to be true,

except for a very few late years; and am quite certain, that for nearly all the years since their act of 1791, they never thought of any such requirement. Let him prove they did, and also state when they began to demand each special course. He adds, "the number of these courses has been from time to time increased, until at present a certain certificate of attendance upon each of the branches of medical science included in the ordinary medical and surgical curricula, is required." He should have added, as their advertisement of "9th October, 1837," does, which would explain his words "a certain certificate," "the bare minimum in the different branches has been required;" which lets us into the secret of what a contemptible "curriculum" it is, and how obviously adopted merely to deceive the public by the name of so many lectureships. But will "the Professor" please to state by what section, sentence, or word of the "Apothecaries' Act of 1791," they are authorized to require maximum, or minimum (and not Zero), of any such thing? And do not its sections 18, 22, 24, 25, 27, expressly state the contrary; and that a seven years' apprenticeship, after a preliminary examination as to their school education, and subsequent good answering on pharmacy, are all that is legally requisite? If they require more, cannot any one, by mandamus from the Court of Queen's Bench, compel them to examine and admit him? Was not a young gentleman who was lately rejected by them, on such illegal examination as to other matters, passed on appeal, by the "College of Physicians," after a mere examination in pharmacy, as their Act (23d section) directs? Can he deny or disprove these facts? Will he show any clause, or phrase, or word, in the "Irish Apothecaries' Act," at all like those in the "English Apothecaries' Act," of 12th July, 1815 — viz. "55 George III. chap. 194;" which says, in "sections 14, 15, the court shall examine all persons applying to them, for the purpose of ascertaining their skill and abilities in the science and practice of medicine," &c. &c. and he shall produce testimonials, &c. &c. of a sufficient medical education, &c. &c.?"

The truth is, that all English and Scotch medical men, and all publications

in London and Edinburgh, mistake wholly this Irish question, from not knowing what the word apothecary means in Ireland, and supposing it to mean the same in England. Let me explain it. The apothecaries of Ireland are, by Act of 24th of June, 1791, precisely what the chemists of England are now—namely, mere compounders; and there is no resemblance at all between them and the present apothecaries of England, whose Act of 1815, 55 Geo. III., chapter 194 (by section 14, 15, especially), obliges them to be educated for the purpose of becoming what they really are—"general practitioners in medicine, and apothecaries;" and not the mere manipulators of others' (namely, physicians' and surgeons') prescriptions; as it was clearly intended the Irish apothecaries should be, by the first section of their Act of 1791, which incorporates them, 1st, to prevent the "injury of the fair trader;" 2dly, to prevent "the disappointment of the physician;" and 3dly, to prevent "the imminent hazard of the lives, &c." by "frequent frauds and abuses, imposed and practised on many of his Majesty's subjects," by the "ignorance and unskilfulness of divers persons pretending to the art and mystery of an apothecary;" and the many and great inconveniences which have arisen, first, from the want of a Hall amply supplied with medicines of the purest quality, prepared under the inspection of persons well skilled in the art and mystery of such preparations;" and secondly, from the previous non-existence of a body "to inspect and direct all chemical and compound preparations and experiments."

The Professor says, "But they say the school of the College is a chartered school. A chartered school, indeed! Chartered in an Irish sense of the word,—i. e. a school without a charter. Where is its charter? It has not one: the School of Physic has a charter, but it has not. Albeit it has been set forth in medical almanacks as one of two chartered schools with which Dublin is provided, and as "established by act of parliament. It was established by a body having a charter, and so has the school of the Apothecaries' Hall, but no more. That charter was originally granted, as I will show in another com-

munication, for another purpose, and contained no mention whatever of a school, from one end to the other." To pass over his ridicule of his own country, which reminds one of the proverb about the "dirtiness of the bird that befouls its own nest," I say the precise reverse is the fact, and he does not seem to know the difference between a charter and an act. The school of the College of Surgeons is established, not by act of parliament even, but by royal charter. The College of Physicians has a charter, but the School of Physic (as now completed), I believe, has not, but is established only by an act of parliament. The apothecaries have not any charter at all, nor does their act authorize a school. Has he ever read the College of Surgeons' charter, to which he signed his name and swore to conform? Does it not say, "Whereas, King George the Third, duly considering that the regulation of the profession of surgery was of the utmost importance to the public, and highly necessary to the welfare of mankind, and that the public sustained great injury from the defects in the system of surgical education in Ireland, and that the regularly-educated surgeons of the city of Dublin (who had become a numerous and considerable body) found themselves incompetent, from the want of a charter, to establish a liberal and extensive system of surgical education in our said kingdom, by letters patent of 11th February, 24th year of his reign (1782, I think), did establish a College or Corporation of Surgeons, in the city of Dublin, by the name of the Royal College of Surgeons in Ireland. And whereas this wise and benevolent design and intention of our royal father has, from that period to the present day, had the most beneficial influence by improving the profession of surgery, and thus promoting the welfare of the nation at large, and particularly by providing a sufficient number of properly-educated surgeons, as well for the service of the public in general as for that of our army and navy.

"And whereas we are graciously pleased to approve of the said institution and foundation, and conceiving that certain alterations may be made in said charter, so as to constitute a corporation in our said city of Dublin, of

regular, able, learned, and experienced practitioners in surgery, endowed with powers, jurisdictions, and privileges, convenient and requisite for enforcing a due course of regular education for the apprentices and students of surgery, previous to their tendering themselves to the College for examination; and further empowering the corporation to create a fund (payable by their members, licentiates, apprentices, and others, applying for instruction and examination) sufficient for keeping the several buildings and *schools* of said College in proper repair; enlarging them when required, and supplying the library and museum thereof with suitable books and anatomical preparations, as well as for discharging all salaries and defraying all other expenses which the said College may incur. Know ye, therefore, that we, of our special grace, certain knowledge, and mere motion, in compliance with the humble petition of the President and Members of said Corporation in College assembled, and upon the surrender made by the said President and Members, of the aforesaid letters patent, granted by our royal father which we have graciously accepted, and according to the tenor and effect of our letters, under our privy signet and royal sign manual, bearing date at our Court, at Windsor, the 2d day of June, 1828, in the ninth year of our reign, and now enrolled in the Rolls of our high Court of Chancery of Ireland, have granted, ordained, constituted, and appointed, and by these presents for us, our heirs and successors, do grant, ordain, constitute, and appoint, &c." Let the "Professor" now say, are not the *schools* of the College *chartered*, and recognized as a part of the charter, and all their expenses, too, provided for by it?

Let him produce one word from the "Irish Apothecaries' Act of 1791," which in words, or by implication, or in any way whatever, speaks of, or suggests, or intimates, or implies, a school of any kind (except each Master's shop), in connexion with the Hall, as the College of Surgeons' charter expressly does.

The "Professor" mystifies the whole question when he says, we "object to the apothecaries educating themselves as well as possible in all branches;" or

that we object to any one "lecturing to them or for them;" or to their becoming general practitioners, by taking out, in addition to the apothecaries' license, medical and surgical diplomas in the usual way. We never did. All we object to is, their depriving us of the services of well-educated apothecaries, by turning away their own and their pupils' time, and their funds, to objects unauthorised by their Act, and compelling their apprentices to attend lectures, and produce certificates, which it does not require or authorise; and still more do we object to their attempting to compel us still to send our prescriptions to them, after they have tried to become rival practitioners, and ceased to be willing to attend to their business of making up our prescriptions as pharmacopolists.

The "Professor" says, that the "Graduate of the Three Colleges," "stands forth the intemperate partisan of one, and the vilifier of another of them." I hope it is no shame to be a member of three Colleges, in the three capitals of the empire. He then adds, "How, let me ask, is such conduct to be reconciled with a due regard to the interests and honour of these corporations?" and then closes by a sentence, of which I profess myself wholly unable to understand the meaning of one part:—"Perhaps he may say my signature is only assumed and fictitious. I answer, it matters not; light objects indicate the current of the air. This circumstance, trifling as it may be, proves how little principle is concerned in the matter, and how dead to its obligations is he who voluntarily places himself in such a position." This seems to assert, that he himself is as light as a feather tossed by the wind; and that, in signing his name, he has little principle, and is dead to the obligation of that little. It just strikes me, however, that perhaps he meant to speak of me, as embarrassed by connexion with three Colleges. I have never felt so, for the duties to all three are identical, namely, to support their honour and dignity; and this is best, and truly, and only done, by supporting the honour and dignity of the whole medico-surgical profession, as one complete whole. But let him say, is not every one employed by the Apothecaries' Hall obliged, by section eleven of their Act, to "swear

that he will be true and faithful to the said Governor and Company." &c. &c. If he has taken this oath, it is inconsistent with his previous oath at the College; for the Hall Directors are systematically pursuing illegal plans to injure the College and its schools, and to interfere with medical and surgical education. If the Directors have not administered this oath to him and his colleagues, they all acknowledge thereby the illegality of their school and professorships, for they are obliged by their Act to make all persons "employed by them" take it; and they thus, too, confess, they have no right to employ any persons but "inferior agents and servants."

As to intemperance, let the reader judge, after perusing all his letter, and all of mine, which is intemperate. As to the Edinburgh University, I did not speak at all of its curriculum or character. As to his assertion of my vilifying the London College, he states what is not true; my only words were, "I am a member of both (Dublin and London Colleges of Surgeons), and know that the London course of study and nature of examination are very inferior to those in Dublin." Did I not speak truth? Does the "Professor" not know it? The one I passed in 1815, the other in 1818, and therefore have the best reason to know it; and I fully believe it to be so still (though in a less degree), from their inferior curriculum in London, the less time taken up in examination, the fewer examiners of each candidate, and the passing of men there who had failed here: this I regret. This is no vilification, but truth simply stated, that a defect may be corrected.

Our College has no monopoly, either by charter or by law. An Act of Parliament says, that all surgeons to country hospitals in Ireland, shall be graduates of our College. This is the act, not of us, but of the legislature, on a conviction that it is due to our superior education. But not so the Apothecaries' Act, which, by a vile monopoly, excludes every English and Scotch apothecary, however well educated, from practising in Ireland, unless examined again in Dublin. No word of our charter excludes any surgeon from Ireland; nor do we even require an apprenticeship. The only principle for

which we contend is, that studies and examination should be identical and equivalent in all the Colleges and Universities; and as soon as they are, all exclusive privileges and monopolies will necessarily cease, as they ought. Let this principle be fixed by law; and let any man who has passed a proper examination before any proper College, be equally privileged in all others, and also not liable to be subjected to a second examination on crossing the Tweed or the Channel, and we will offer no opposition to the legislature's abolishing its own act, above mentioned. Is not that fair? Would not there be then a free trade, and free competition in College education, and no favour or monopoly? That is all our wish.

I end by the "Professor's" "Alas! how weak and fallible an attribute is reason, when blinded by intemperate zeal and overweening selfishness." Has he not become intemperately zealous for his own interest, as connected with his professorship at the school of the Apothecaries' Hall, which my letters have helped to put in jeopardy? Had he no selfish object in seeking it? Did they never previously, and do they not now, call him in to consultations, as a *douceur* for his aid of their plans? Does he lecture gratis? Does he get no *quid pro quo* in this way or any other? Let him point out one single instance in which I have sought any selfish object, either in the College or out of it, or in any other act of my public or private life. What possible selfish interest could I, or any of us have, in thus exciting the hostility of most of the apothecaries? Has he none in currying favour with them? Can apothecaries not serve or disserve physicians or surgeons in various open and concealed ways? My zeal is for the good of the profession, and the safety of the public, and against my own pecuniary interest, as he well knows.

I have the honour to subscribe myself
Your obedient servant,

A GRADUATE IN MEDICINE, SURGERY,
AND MIDWIFERY, OF DUBLIN,
EDINBURGH, AND LONDON.

Jan. 31, 1835.

IRISH COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

I owe it equally to you and to myself to address to you this letter, which I have been prevented from doing earlier by the circumstances which have intervened since my last.

In saying that you had been led into error, I had no intention of preferring a complaint against you, and therefore I used the word "led," because I felt assured that the cause of the error lay elsewhere.

At such a distance you cannot understand the precise position of the several parties, and I suspect that you are under the impression that the College of Surgeons in Dublin is constituted similarly to that in London. Such is not the case. In the former there is no permanent "ruling body," or Council, as there is in the latter. The ruling body of the Dublin College is the majority of the day; that majority may not be the same on two successive days; it *may* even, with exception of the officers of the College, consist of different individuals on different days, and the majority of one day may, according to prescribed forms, undo or counteract the acts of that of the preceding one: such is the constitution of our College. It is, in fact, a democratic one, but devoid of that check which is so necessary to the safety of all democratic constitutions, viz. responsibility. We are responsible only to ourselves, *unless we violate our charter or the laws of the realm*. Next, sir, our committee is not our ruling body, but our responsible servant. We have many committees appointed for particular purposes, but never authorised to assume the "authority of the College" itself, and the acts

of our committees never become acts of the College until they have been submitted to it, and received its adoption and sanction. It appears, then, to me, that I can no more be said to have entered the lists against the College in any sense, than a member of either party in the House of Commons can be said, because of his opposition to the other, to have entered the lists against the House.

Now, with regard to the letter of which I have complained, you have done me a great service by stating the fact that it was dated "Royal College of Surgeons, Dublin," and signed "C. O'Keefe, Registrar." These are the ostensible guarantees for the authenticity of any communication having been made by the authority of the College; and you were, in my opinion, fully authorised, under the circumstances, to say that it was so. But it has since appeared that it was *not* done by authority of the College; at the time, my letter had not been brought under its consideration, and that it was the act of the committee, to which it thought fit to attach the name and authority of the College. My letter has been made the subject of discussion in the College during the past week. The course and result of the discussion, however, I refrain from adverting to at present, in order that my adversaries may not have cause to complain; but I am at liberty to state, inasmuch as he has avowed himself, that the author of the reply to my first letter is Dr. Maunsell, Professor of Midwifery in the School of the College of Surgeons.

I conclude, reminding you that his pledge is as yet unredeemed.

I have the honour to remain,

Your obliged and obedient servant,

B. ALCOCK.

Dublin, March 17, 1838.

INDEX TO VOL. XXI.

(VOL. I. FOR THE SESSION 1837-8.)

A.

ABDOMEN, clinical lecture by Mr. T. B. Curling on a case of punctured wound of the, 567.
Abcess, case of, of the liver, 747.
Accidents, reports of, treated at the London Hospital, 142, 192, 222, 270, 303, 349, 398, 431, 479, 551, 624, 672, 749, 783, 863, 912, 942.
Accoucheurs, Mr. Coles's hints for, 379.
Acetabulum, case of perforation of the, caused by a fall on the trochanter, 992.
Ackerley, Mr. Yates, on the use of tartar emetic and opium in spasmodic affections, 56.
Acupuncture, Mr. King on, in ascites, 332.
Advertising, indecent mode of, 263.
Air, M. Velpeau on the introduction of, into the veins, during operations, 953, 1011.
Alcock, Mr. J. Rutherford, on the means of transporting the wounded from the field of battle, 652.
Alcock, Dr. on the proposed changes in the Royal College of Surgeons in Ireland, 909*, 932, 941*, 1040*.
Aldis, Dr. on a case of rheumatism, 340; on reverberation of the voice in diseases of the chest, 610; report of cases of chorea, with remarks, 935.
Aldis, Sir Charles, presentation of, 852.
Alkaloids, Mr. Meeson on the action of chlorine on the, 224.
Allnatt, Dr. on the recent low atmospheric temperature, 752.
Almanack, the British Medical, notice of the, 592.
Amaturosis, Dr. Cox's case of, with paralysis of the eyelid, 531.
Anatomy, chair of, in Dublin, Dr. Harrison's address on commencing his course of lectures, 350.
Aneurism of the heart, Mr. Thurnam's cases of, 829.
 ——— popliteal, Mr. Hadwen on a case of, 941.

Animal magnetism, expose of, 824, 856, 986, 1034.
Animals, results of experiments on, with the blood of cholera patients, 779.
Ankles, Mr. Banner on a case of compound dislocation of the, 243.
Anus, imperforate, Mr. Gorham on a case of, 528.
Aorta, Dr. Watson on some of the morbid conditions of the valves of the, 450.
Apothecaries' Hall, lists of gentlemen who have received certificates, 80, 112, 144, 192, 224, 272, 304, 352, 400, 432, 480, 512, 592, 672, 752, 944, 992, 1040.
Apothecaries' Hall in Ireland, remarks on the new regulations of the, by a Professor in the School, 655.
Apothecary, Mr. Norton on the education of the, 17.
Arteries, Mr. Labatt on the varieties of the, in the human system, 7.
Arteritis, Mr. Norman on, 666.
Ascites, Mr. King on acupuncture in, 55, 332.
Ashwell, Dr. on hæmorrhage from the unimpregnated uterus, associated with tumors of varying degrees of induration and malignancy, 263.
Asphyxia, Dr. Cape on artificial respiration in, 59.
Aspland, Mr. on the physiological and pathological relations of the heart, 781.

B.

Banner's, Mr. report of surgical cases admitted into the Liverpool Northern Hospital from Sept. 1, 1836, to Sept 1, 1837, 241.
Barrett, Mr. on a new stethoscope, 575; cases of hydatids reported by, 801.
Bayonet wound, clinical observations on a recent case of, by Mr. S. Cooper, 390, 474.
Bazin, Mr. on the fibrous membrane beneath the pleura pulmonalis, 780.
Beaumont, Mr. on the treatment of fractures by plaster of Paris casts, 589.

- Bell, Sir Charles, on the discoveries of, 734.
 Bell, Mr. on delirium tremens, 897.
 Belladonna, Mr. Maclure's remarks on, given as a prophylactic against the contagion of scarlet fever, 363.
 Bellingham, Mr. on the motions and sounds of the heart, 23.
 Black, Dr. on the epidemic influenza, 23.
 Birkett's, Mr. cases of syphilis, with remarks, 942.
 Bishop's, Mr. remarks on *lepra vulgaris*, 888.
 Black vomit, Mr. McDiarmid on a case of, in an African, 850.
 Bonnet, M. on the composition and absorption of pus, 408, 440, 489.
 Books, analyses and notices of:—Dr. Quain's elements of anatomy, part 1, 132; series of anatomical plates in lithography, by Quain and Wilson, *ib.*; Dr. Turner's elements of chemistry, sixth edition, 133; Edinburgh Dissector, *ib.*; *Cyclopædia of Anatomy and Physiology*, 134; Müller's Elements of Physiology, *ib.*; Dr. Graves' lecture on the functions of the lymphatic system, 213; Dr. Clutterbuck's Essay on Pyrexia, 215; recent German works, 216, 591; Thomson's London Dispensatory, 580; Mr. Jones on the first changes in the ova of the mammifera, 692; recent publications on the nervous system, 734.
 Borrett's, Dr. suggestions for the better regulation of the Irish medical charities, and remarks upon the bills of late introduced into parliament for that purpose, 1026.
 Brain, on the microscopic structure of the, and of the tissues intermixed with it, 747.
 Brain and spinal marrow, Mr. Dendy on effusions into the, 862.
 Brewster, Sir David, on the changes in the crystalline lens, and the cause and cure of cataract, 523.
 Bridgewater union, editorial observations on the, 424; notice of a pamphlet on the subject of the, 824.
 British Association for the advancement of science, papers connected with medicine read at the meeting in Liverpool, 23.
 Brodie, Sir Benjamin, clinical lecture by, on disease of the kidney, 106; on varicose veins and ulcers of the leg, 184, 264.
 Broughton, the late Mr., 80.
 Brown's, Dr. case of menstruation at an advanced age, 730.
 Budd, Dr. and Mr. Bush, report by, of twenty-one cases of cholera which occurred in the Seamen's Hospital Ship Dreadnought, between the 8th and 28th of Oct. 1837, 478.
 Burials, weekly account of, 32, 80, 112, 144, 192, 224, 272, 304, 352, 400, 432, 480, 512, 560, 592, 624, 672, 752, 784, 832, 864, 944, 992, 1040; general bill for the year, 1038.
 Burrows, Dr. George, on a case of chronic laryngeal disease, complicated with phthisis, 50.
- C.
- Cæsarean operation, Mr. Ward's case of, 817.
 Cape, Dr. on artificial respiration during convulsive fits in children, 59.
 Cataract, Sir D. Brewster on the cause and cure of, 523.
 Certificate, refusal of a, to a pupil, 263.
 Certificates for insurance offices, editorial observations on the question by whom the fees should be paid, 299.
 Chapman, Mr. on nitrate of silver in cutaneous diseases, 96.
 Charterhouse Square Infirmary, letter from "A Governor" respecting the complaint of the exhibition of a board in front of the institution, 510.
 Cherry, Mr. on the transport of the wounded, 732.
 Chemists giving evidence as surgeons, impropriety of, 1037.
 Chest, lectures on the physiology and diseases of the, including the principles of physical and general diagnosis, delivered during the spring seasons of 1836 and 1837, at the Anatomical School, Kinner-ton-Street, by Charles J. B. Williams, M.D.F.R.S.:—Introductory remarks on the claims of diseases of the chest to be separately considered, 1; importance of studying their physical as well as their general signs, 2; illustrations, *ib.*; practical insufficiency of either class of signs separately, 3; advantages of studying both rationally, 4; analysis of the mechanism of respiration, 5; forces and mechanism concerned in dilating the chest, upwards, outwards, and downwards, 6; forces which diminish the cavity of the chest, *ib.*; modifications, *ib.*; internal mechanism of respiration, 33; form of the air-tubes and cells, *ib.*; structure of the air-tubes, *ib.*; cartilages, 34; blood-vessels of the lung, 35; chemistry of respiration, 36; changes of the air and of the blood, *ib.*; physical cause of the change of colour of the blood, *ib.*; adaptation of mechanism to chemical action, 37; ciliary motions of the bronchial mucous membranes, 38; vital relations of respiration, 81; respiration an instinctive action, *ib.*; its relations to the nervous system, 82; nerves of the lungs, *ib.*; nerves of the muscles of respiration, *ib.*; mutual dependencies of the lungs, the nervous system, and the heart, illustrated by a diagram, 83; asphyxia—its causes and pathology, 85; why the circulation ceases in asphyxia, 86; Dr.

Alison's experiments, *ib.*; succession of death through the organs, 87; hybernation, *ib.*; various effects of cold on the functions, *ib.* Physical examination of the chest, 113; modes of studying the topography of organs, *ib.*; examination of the chest by inspection and feeling, 114; natural form of the chest, 115; postures for inspection, *ib.*; examination of the motions of the chest by sight and touch, *ib.* The nature and properties of sound, 116; sound a kind of motion, *ib.*; explanation of vibrations of sound, 146; effect of sound on the molecules of bodies (illustrated by diagrams), *ib.*; explanation of the duration of sound, of pitch, harmony, and discord, 147; conduction of sound, 148; reflection of sound, *ib.*; modified echoes, *ib.*; sources of sound, *ib.*; modes of increasing and transferring sound, 149. Acoustic properties of the chest tested by percussion, 193; causes of the sound of percussion, *ib.*; modes of percussion, immediate and mediate, 194; varieties of the sound in different regions, 195; in different states of respiration, *ib.*; practice of percussion, *ib.*; acoustic properties of the lungs manifested by the motions of respiration, 196; sounds of respiration—inspiration, expiration, *ib.*; tracheal, bronchial, and vesicular sounds, *ib.*; varieties of the sounds, puerile respiration, &c., 198; duration of the sound of respiration, &c. 199; the rhonchi, 273; importance of the rhonchi as signs, 275; sounds of the voice, *ib.*; natural sounds, their causes and regions, *ib.*; morbid sounds, 276; bronchophony, *ib.*; ægophony—pectoriloquy, 277; metallic and amphoric resonance, *ib.*; pectoral fremitus, *ib.*; sounds of friction, *ib.*; tabular view of the sounds of the organs of respiration, 278; methods of auscultation, 353; directions for percussion, *ib.*; pleximeters, 354; immediate auscultation, *ib.*; advantages of mediate auscultation, 355; the stethoscope—its principles and construction, *ib.*; different kinds of stethoscope, *ib.*; directions for using the stethoscope, 357. Examination of the chest through the vital properties or functions of its organs, 433; analysis of the general symptoms of diseases of the chest, *ib.*; dyspnoea, its nature and value, 434; frequent breathing, *ib.*; feeling of oppression, *ib.*; power of divers, &c., 435; Professor Faraday's mode of enabling a person to hold his breath, *ib.*; table of the causes of dyspnoea, 436; cough, its nature and causes, 436; catarrhal cough, 437; hacking cough, *ib.*; irritable and nervous cough, *ib.*; convulsive cough, 438; wheezing cough, 439; hooping cough, *ib.*; hollow cough, *ib.*; varieties from the state of the bron-

chial secretion, &c., *ib.*; expectoration, 513; explanation of the act, *ib.*; the matter of expectoration—its nature and value as a sign, 514; signs derived from the form and weight of sputa, 516; pain, its nature and value as a sign, 517; modes of testing the sensibilities of the chest, *ib.* Examination of the chest through the vital properties or functions, 593; analysis of the general symptoms (concluded), *ib.*; symptoms connected with the circulation, *ib.*; analysis of the pulse, *ib.*; varieties of the pulse, *ib.*; state of the pulse in diseases of the organs of respiration, 595; symptoms from the venous and capillary circulation, 596; symptoms, *ib.*; varieties of respiration, *ib.*; mensuration of the chest, 116; measurement of fever, or increased heat—perspiration, *ib.*; symptoms from the state of the secretions and other functions, 597; respective value of the physical signs and general symptoms, *ib.* Diseases of the air-tubes, 673; general pathology of inflammation of the mucous membrane, *ib.*; bronchitis, *ib.*; mild bronchitis, 674; signs and course, *ib.*; treatment of a "cold" by palliatives, 675; by opium, 676; "dry method," *ib.*; severe bronchitis, 678; signs and course, *ib.*; treatment, 679; asthenic bronchitis, *ib.*; bronchitis of infants, 680. Chronic bronchitis—pathology, 753; course and signs, *ib.*; treatment, 754; croup—pathology and signs, 755; treatment, *ib.*; hooping cough—signs, 756; treatment, *ib.*; diseases of secretion, 757; pituitous catarrh, *ib.*; pathology and signs, *ib.*; treatment, *ib.*; dry catarrh, 758; pathology and signs, *ib.*; treatment—alkaline attenuants, 759; bronchial hæmorrhage, *ib.* Altered sensibility or mobility, 833; spasmodic asthma, *ib.*; pathology and course, *ib.*; physical signs, 835; extent and effects of the bronchial spasm, *ib.*; paralytic or atonic asthma, 836; mode of production and signs, *ib.*; treatment of the paroxysm, *ib.*; general treatment, *ib.*; signs of improvement, 837; treatment of paralytic or atonic asthma, *ib.*; treatment of increased sensibility of the bronchial membrane, 838. Changes of structure, 913; thickening of the membranes, *ib.*; hypertrophy of the longitudinal fibres—rigidity, *ib.*; pathology and signs, 914; treatment, *ib.*; dilatation of the bronchi—varieties, *ib.*; pathology and mode of production, 915; symptoms and effects, 917; physical signs, and their distinction from those of phthisis, 918; amphoric sound on percussion, *ib.*; treatment and prevention, *ib.*; ulcers of the bronchi, 919, Chirayitine, quina, &c., Mr. Schweitzer's remarks on, 173.

- Chlorosis, Mr. Curling's report of a case of, treated by M. Louis at La Pitié, 555.
- Cholera, Dr. Graves on the treatment of, 100; the report of its re-appearance in an epidemic form without foundation, 220; Dr. Venables on salts of lead in, 259; recollections of, its nature and treatment, by Dr. W. Griffin, of Limerick, 572, 606, 643, 688, 724, 844, 880.
- Cholera insurance societies, Mr. H. L. Smith on, 212.
- Chorea, Mr. Turner's case of, from pregnancy, 532; Dr. Aldis's report of cases of, with remarks, 935.
- Choroid gland, or choroid muscle, of the fish's eye, Mr. Wharton Jones on the, 650, 864.
- Circulation, Mr. Molloy on the influence of the, in producing certain cerebral affections, 553.
- Clark, Sir James, a baronetcy conferred on, 224.
- , Dr. on medical relief to the poor, 896.
- Clendinning, Dr. on the functions of the encephalon and cerebellum, 795.
- Clutterbuck's, Dr. essay on pyrexia, reviewed, 215.
- Coles', Mr. hints for accoucheurs, 379; on the position during delivery, 671.
- College of Surgeons, lists of gentlemen who have received diplomas, 272, 434, 784, 944; Mr. Tyrrell elected a member of the Council in the room of the late Mr. Earle, 864.
- Conquest's, Dr. account of the results of tapping the head in nineteen cases of hydrocephalus, 967.
- Convulsions, puerperal, Dr. Lee's report of thirty-four cases of, 11.
- Cooper, Mr. Bransby, on hernia, 111.
- Cooper, Mr. Samuel, note from, respecting a case of fatal bayonet wound, admitted into University College hospital, 350; observations on the case, addressed to the pupils, 390, 470; some further observations by, on the case, 474; letter from, on the subject of a challenge from Mr. Wakley, 478; letter from a Student of University College, relative to a meeting of students there, 510.
- Cory, Mr. on the induction of premature labour, 126.
- Cowan, Dr. on the acoustic principles of the stethoscope, 155.
- Cox's, Mr. case of amaurosis and paralysis of the eyelid, 531.
- Cox's edition of Cooper's surgery, complaint respecting, 590.
- Cox, Dr. Travers, on a cyst found at the under surface of the liver, 991.
- Crane, Dr. on gangrene of the lungs, 558.
- Cresote, Mr. Saunders on the employment of, as an odontalgic remedy, 942.
- Crompton, Mr. on injuries of the eye by percussion caps, 175.
- Cross, Mr. on the employment of nitrate of silver in the gonorrhœa of females, 99.
- Crystalline lens, Sir David Brewster on the changes in the, and the cause and cure of cataract, 523; case of ossification of the, 943.
- Curling, Mr. T. B. on the entozoa, or internal parasites of the human body, 518, 598, 634, 712, 791; on rupture of the heart and aorta, 894.
- Cut throat, severe case of, 111.
- Cyclopædia of anatomy and physiology, notice of the, 134.

D.

- Death, signs of, 29.
- Delirium tremens, practical observations on, by Dr. Munk, 759; Mr. Bell on, 897.
- Dendy, Mr. on effusions into the brain and spinal marrow, 862.
- Denham, Mr. on a case of glanders in the human subject, 549.
- Dick, Dr. on the nature and treatment of the different forms of porrigo, 328, 332, 494; on the employment of gunpowder as a medicine, 590.
- Directions, medical, for the use of pedestrian travellers, 831.
- Discoverers, the rival, pretensions of Dr. Hall and Dr. Grant, 903.
- Dispensaries in London, editorial observations on, 260.
- Dissection, editorial observations on the supply of subjects for, 179.
- Drugs, monthly lists of, on sale in the English market, 31, 191, 351, 559, 751, 911, 1039.
- Du Neaume, Mr. on a case of hydrophobia, from which the patient recovered, 538; further particulars of the case, 660.
- Du Potet, Baron, on animal magnetism, 17; on mesmerism, 291, 336, 375, 419, 463, 498.
- Dysmenorrhœa, Dr. Macintosh on, 23.
- Dysmenorrhœa, chlorate of soda in, 271.

E.

- Earle, Mr. J. W. on the formation of pus, 660.
- Earle, Mr. Henry, notice of the death of 665; intended tribute to, 824, 864, 943.
- Eden, Mr. on normal and abnormal dentition in adults, 348.
- Edinburgh Dissector, notice of the, 133.
- Editorial articles:—A prospect and a retrospect, 19; a few words to students,

- 70; the starving experiments, 102; regulation of lunatic asylums, 134; on the supply of subjects for dissection, 179; professorship of pathology in University of London, 216; dispensaries in London, 260; certificates for insurance offices, 299; on the remuneration of medical men, 341; neglect of the sick poor, 385; Bridgewater Union, 424; on the practical teaching of medicine, 467; on medical examinations, 503; a case of life insurance, 546; poisonous candles, 577; case of supposed idiocy, 613, 663; another death from starvation, 693; lapse of legacies from insanity, 738; conviction for malapraxis in midwifery, 770; the University of London, 820; Dr. Elliotson on the proposed lectures on pathology, 852; military punishments, 854; the rival discoverers, 903, 930; illustrations of medical competition, 927; why is quackery successful? 981; can quackery be suppressed? 1031.
- Elliotson, Dr. and the proposed lectures on pathology, 851.
- Ellis's, Mr. cases of uterine disease, 211.
- Embryology, Mr. Miller on, 251.
- Emphysema, vesicular and interlobular, Mr. Curling's report of cases of, treated by M. Louis, in *La Pitié*, 111, 139.
- Enamel cards, pernicious effects of, 661.
- Encephalon and cerebellum, Dr. Clendinning on the functions of the, 795.
- Endocarditis, Mr. Thurnam on some of the effects of, and particularly on the scutiform thickening of the aortic valves, 645.
- Enteritis, Mr. Curling's report of two cases of, treated by M. Louis at *La Pitié*, 55.
- Eutozoa, Mr. T. B. Curling's lectures on the:—*acephalocysts*, 520; *echinococcus*, 522; *ceraria seminis*, *zoosperms*, or *matozoa*, 598; *trichina spiralis*, 599; *cysticercus cellulosæ*, 601; *tania solium*, 602; *bothriocephalus latus*, 634; *polystoma pingvicolæ*, 635; *distoma hepaticum*, or *liver fluke*, *ib.*; *filaria medinensis*—*medina*, or *Guinea worm*—*dracunculus*, 636; *filaria oculi*, 637; *filaria bronchialis*, 638; *tricocephalus dispar*, *ib.*; *spiroptera hominis*, 712; *strongylus gigas*, *ib.*; *ascaris lumbricoides*, *lumbricus teres*, or common round worm, 714; *A. vermicularis*, 717; spurious worms, 793; the ectozoa, or parasitic insects, *ib.*
- Estlin, Mr. on a case of retention of urine from tumors within the bladder, 541.
- Examinations, medical, editorial observations on, 50.
- Examiners, hints for, 73.
- Exhibition, indecent, in Charter-house Square, 399.
- Exostosis of the foot, Mr. Falcon on a case of, 179.
- Experiments, the starving, editorial observations on the, 102; results of, on animals, with the blood of cholera patients, 779.
- Eye, Mr. Crompton on injuries of the, by percussion caps, 175.
- F.
- Falcon, Mr. on a case of large exostosis of the foot, 178; on a case of transposition of the viscera, 731.
- Faraday, Dr. on the phenomena of electric induction, 703; on the nature of fatty bodies, and the application of stearine to the manufacture of candles, 745; on the atmosphere of this and other planets, 910.
- Fasting woman, a, 347.
- Femur, Mr. Banner on a case of united fracture of the, 249; Mr. Grantham on a case of fracture of the, with fracture of the epiphyses, 799.
- Fergusson, Dr. on yellow fever, 1021.
- Fever, epidemic, M. Staberoh on the eruption attending it, 973.
- Fever, tertian, sweating of blood from the feet in, 28.
- Fever, malignant remittent, Mr. Macdiarmid on, 444.
- Fever, typhoid, Mr. Curling on two cases of, treated by M. Lewis, 620.
- Fever, malignant, of British Guiana, Dr. William Fraser on the, 640; Dr. Fergusson on, 1021.
- Field, Mr. note from, in reply to some editorial observations on the inquest on Mary Stonard, 783.
- Finch, Dr. on lunatic asylums, 333.
- Fistula, recto-vesical, Mr. Banner on a case of, 244.
- Fœtus in utero, Dr. Lilburn on the means of ascertaining the vitality of the, 63.
- Forbes, Dr. James, notice of the death of, 352.
- Ford's, Mr. report on scurvy, 160, 256.
- Forensic Medicine, Dr. Southwood Smith's lectures on:—Introductory remarks, 225; object of medical science not merely the removal of disease—available to the ends of justice, *ib.*; why forensic medicine is included in the medical curriculum, *ib.*; the medical man often the most important witness in courts of justice, 226; in all questions relating to the public health, 227; why it is necessary to make forensic medicine a distinct branch of study, 230; term proper for the designation of this branch of science, 231; precise province of the medical witness—of the lawyer, *ib.*; subjects included in the field of forensic medicine, 233; tabular view, 234.—ON EVIDENCE, 305;

acquaintance with the nature of evidence necessary to the medical witness, *ib.*; insufficiency of common sense, *ib.*; desirableness of systematic knowledge, 306; sources from which such knowledge may be derived, *ib.*; evidence—testimony, *ib.*; complex evidence, *ib.*; facts the subject matter of evidence, 307; principal and evidentiary facts, *ib.*; physical and psychological facts, *ib.*; positive and negative facts, *ib.*; cause of belief in evidence, *ib.*; analysis, *ib.*; experience, 303; mental law to which belief in evidence is referable, *ib.*; experience the cause of belief in evidence, 309; cause of belief in testimony, *ib.*; evidence, personal or real, 311; evidence the source of human knowledge, 101; legal evidence, *ib.*; medical evidence, *ib.*; legal decision founded on evidence, *ib.*; consequence of fallacious evidence, *ib.*; probative force of evidence, 402; how incorrectness or incompleteness produces false judgment, *ib.*; false judgment, *what, ib.*; degrees of probative force, *ib.*; standard degrees, *ib.*; qualities by which the probative force of evidence may be raised above or below the standard, 403; perjury and bias, *ib.*; expression of strength and persuasion, *ib.*; Bentham's scale, 404; direct and circumstantial evidence, *ib.*; facts and inferences, 405; chain of evidence, 406; cumulative nature of circumstantial evidence, illustrated by the case of Captain Donellan, *ib.*; confirmative and infirmative facts, *ib.*; fallaciousness of evidence, *ib.*; fallaciousness of direct evidence—of circumstantial evidence, 482; cases in illustration, *ib.*; misdecision sometimes the inevitable consequence of ignorance—ignorance which science subsequently removes, 483; induction as to punishment, 484; doctrine of Livingston on the punishment of death, *ib.*; doctrine of Bentham, 485; doctrine of Paley, *ib.*; application of the general doctrine of evidence on the special subject of forensic medicine—practical rules thence deducible for the collection of facts and induction of inferences, 561; restrictions on the deposition of evidence in the English courts of law, 625; penalties impossible on the medical witness for non-attendance, 628; courts of law in which the medical witness may be called upon to give evidence, *ib.*; apparent death, 705; errors as to the fact of death, *ib.*; signs of real death—cessation of the circulation and respiration, 706; uncertain signs, *ib.*; certain signs, *ib.*; rigidity, *ib.*; putrefaction, 707; loss of muscular contractility, *ib.*; causes of death, *ib.*; external violence, 708; natural disease,

ib.; diseases of the nervous system, *ib.*; structures of cranium, *ib.*; dura mater, 709; idiopathic, *ib.*; connected with affections of the ear, 710; gorged condition of the blood-vessels of the dura mater, 711; distension and corrugation of the dura mater, 785; inner surface spotted with clusters of red points, *ib.*; deposition of matter between its laminæ, 786; deposition of bone, *ib.*; tumors, *ib.*; diseases of the sinus, *ib.*; diseases of the glandulæ pæchioni, *ib.*; adhesions between the dura mater and the arachnoid, 708; effusion of serum between the dura mater and arachnoid, *ib.*; effusion of blood, *ib.*; aneurismal sacs, *ib.*; ossification of the arteries, *ib.*; diseases of the arachnoid and pia mater, *ib.*; increased vascularity sometimes accompanied with the deposition of false membrane, 788; thickening and loss of transparency, 789; effusion of serum tinged with blood, *ib.*; ecchymoses, *ib.*; deposition of lymph, pus, or fibrin, *ib.*; looseness or separation of the membranes, *ib.*; preternatural firmness of adhesion, 790; tumors, *ib.*; serous cysts, *ib.*; flattening of the convolutions, *ib.*; hypertrophy of the brain, *ib.*; inanition, 791; change of colour in the cineritious substance of the brain, 865; change in consistence, *ib.*; laceration—ulceration, 866; scrofulous tubercles, *ib.*; change of colour in the medullary substance, *ib.*; ecchymosis—cloudiness, 867; medullary substance of a grey colour, *ib.*; ramollissement, *ib.*; diffuse suppuration, *ib.*; encysted abscess, *ib.*; induration, 863; these changes sometimes unattended with any appreciable symptoms during life, *ib.*; effusion of serous fluid into the ventricles, *ib.*; coagulable lymph, or purulent matter, poured into the ventricles, 869; effusion of blood into the ventricles, *ib.*; apoplexy—premonitory symptoms, *ib.*

Fracture, Mr. Adams' report of cases of, admitted into the London Hospital, 26; Mr. T. M. Greenhow on the treatment of, 124; rare case of, of the humerus, 189; Mr. Banner on a case of, of the second lumbar vertebra, 248; simple, of the lower extremities, Mr. Sweeting on the treatment of, by plaster of Paris casts, 452, 750; Mr. Beaumont on the treatment of, by plaster of Paris casts, 569; Mr. Ingle on the treatment of, by the same means, 850; compound, of the leg, case of, followed by amputation, with clinical remarks by Messrs. White and Guthrie, 932; M. Velpeau's treatment of, 143.

Fullagar, Mr. on a case in which fatal convulsion followed the operation of *navus*, 529.

G.

- Gangræna pulmonum, case of, 27.
 Gangrene of the lungs, Dr. Crane on a case of, 558.
 Gardner, Dr. remarks by, shewing that the purulent ophthalmia of infants is of two species, 16.
 Gastritis, Mr. Curling's report of a case of, treated by M. Louis, at La Pitié
 German publications, recent, critical notices of, 29, 32.
 Glanders, Mr. Denham on a case of, in the human subject, 549.
 Goadby, Mr. on the skeleton of insects displayed through a microscope, 780.
 Gonorrhœa of females, Mr. Taylor on the application of the solid nitrate of silver in the, 63; Mr. Cross on the employment of nitrate of silver in, 99.
 Gorham's, Mr. observations on the pulses of infants, 321; on a case of imperforate anus, 528; on a case of fungoid disease of the kidney, 764.
 Grantham, Mr. account by, of a large sphacelating wound of the integuments, 454; on a case of fracture of the femur, with separation of the epiphyses, 799.
 Gratuitous services of medical men, remarks on, by "Medicus," 380.
 Graves, Dr. on the treatment of cholera, 100; on the most convenient mode of making sugar of lead pills, 144; lecture on the functions of the lymphatic system, reviewed, 216; remarks on phrenologists and Dr. Elliotson, being a postscript to his introductory lecture, 729.
 Gray, Mr. on the formation of shells, 830.
 Greenhow, Mr. T. M. on the treatment of fractures, 124.
 Gregory's, Dr. report on small-pox, 860.
 Griffin's, Dr. W. of Limerick, recollections of cholera, its nature and treatment, 572, 606, 643, 688, 724, 844, 880.
 Gunpowder, Dr. Dick on the employment of, as a medicine, 590.
 Guy's Hospital report, 73.
 Guy's Hospital Physical Society, papers read at the:—Mr. Bransby Cooper on hernia, 111; Dr. Guy on the effect of posture on the pulse, 190; Dr. Ashwell on hæmorrhage from the unimpregnated uterus, associated with tumors of varying degrees of induration and malignancy, 268; Mr. Eden on normal and abnormal dentition in adults, 348; Mr. Bliff on the difficulty of diagnosis in the commencement of malignant diseases in the abdomen, 479; Mr. Molloy on the influence of the circulation in producing certain cerebral affections, 553; Mr. Norman on arteritis, 666; Mr. Aspland on the physiological and pathological relations of the heart, 781; Mr. Denny on effusions into the brain and

spinal marrow, 862; Mr. Birkett on syphilis, 942.

Guy, Dr. on the effect of posture on the pulse, 190.

H.

- Hadwen, Mr. on a case of popliteal aneurism, 941.
 Hæmatemesis, Mr. Curling's report of a case of, treated by M. Louis, at La Pitié, 556.
 Halford, Sir Henry, on the results of the successful practice of physic, 774.
 Hall, Dr. Marshall, and Mr. Newport, 930, 985.
 Halliday, Sir Andrew, on the malignant fever of British Guiana, 639; Dr. Ferguson in reply, 1021.
 Harbord, Mr. on the effects of a blow on the stomach, 61.
 Hare, Mr. on curvature of the spine, 23.
 Hawkins', Dr. F. case of hydrophobia, 205.
 Hawkins', Mr. Casar, lectures on tumors; see "Tumors, Mr. C. Hawkins' lectures on."
 Heart, Mr. Bellingham on the motions and sounds of the, 23; second report of the London Committee of the British Association on the motions and sounds of the, 392; Mr. Aspland on the physiological and pathological relations of the, 781; Mr. Thurnam on a case of rupture of the, and on hæmorrhage into the pericardium, without rupture of the heart or great vessels, 813; Mr. Thurnam on aneurism of the, 839.
 Heart and aorta, Mr. T. B. Curling on rupture of the, 894.
 Hernia, strangulated, case of, 25; Mr. Bransby Cooper on, 111; necessity of exemplifying the intricate parts of, in works on anatomy, 223; strangulated, case of, 429; strangulated, two cases of, 671.
 Hernia, femoral, difficult diagnosis in a case of, 552.
 Hill, Mr. on the system of medical attendance under the new Poor-Law, 68.
 Hingeston's, Mr. J. A. remarks on rheumatism, 367.
 Hip, case of irreducible dislocation of the, 25.
 Holloway's universal ointment, note from Sir C. Brodie respecting, 832; from Mr. Semple, 1037.
 Hôpital de la Pitié, Mr. Curling's reports of cases treated at the, 109, 139, 541, 620.
 Humerus, Mr. Thompson on a rare case of fracture of the, 189.
 Hunterian oration, delivered by Mr. Trauers, brier account of the, 824.
 Hydatids, Mr. Barrett's cases of, 801.
 Hydrocephalus, Dr. Conquest's account of the results of tapping the head in nineteen cases of, 967.

Hydrophobia, Mr. Jones on a case of, 73; another case, 192; Dr. F. Hawkins' case, 205; Mr. Du Neume on a case of, from which the patient recovered, 538, 660.
 Hydrops articuli, on the employment of tartar emetic in, 907.
 Hysteria, Mr. Saudys' anomalous case of, 765.
 Hysteria, Mr. Jacob on a case of, 976.

I.

Idiocy, supposed, editorial observations on a case of, 613, 662.
 Iliff, Mr. on the difficulty of diagnosis in the commencement of malignant diseases of the abdomen, 479.
 Inflammation, chronic, morbid alterations in the articular tissues from, 76.
 Influenza, the epidemic, Dr. Black on the, 23.
 Inhalation, Sir C. Scudamore on, in phthisis pulmonalis, 804.
 Ingle, Mr. on the treatment of fractures by plaster of Paris casts, 850.
 Inquest involving "a very nice point," 741.
 Insanity, editorial observations on the lapse of legacies from, 738.
 Insurance certificates, fees for, 670.
 Insurance offices, medical men ought to be remunerated by the, 942.
 Irish College of Surgeons, pharmacy laws, 667.
 Irish College of Surgeons and Apothecaries' Hall, reply to a Professor in the School of the Hall, by a member of the College, 732, 767; contradiction of statements respecting the, 819; editorial observations on the controversy regarding the, 907; Dr. Alcock on the proposed changes in the, 900*, 932, 941*, 1040*.
 Irish medical charities, Dr. Borrett's suggestions for the better regulation of, and remarks upon the bills lately introduced into parliament for that purpose, 1026.
 Irritation, spinal, Dr. G. Watson's cases of, 811.
 Iritis, Mr. Lawrence on a case of, combined with scaly syphilitic eruption, 473.

J.

Jaw, Dr. Lawrie on a case of amputation of the lower part of the, 64.
 Jeffreys', Mr. Julius, strictures upon Dr. Arnott's treatise upon warming and ventilating, 959, 1017.
 Jones, Mr. Wharton, on the ova of man and mammiferous brutes, as they exist in the ovaries before impregnation, 680, 719; observations by, on the pathology of sta-

phyloma, 847; on the so-called choroid gland, or choroid muscle, of the fish's eye, 650, 864.

K.

Kerrison, Dr. on the education of general practitioners, 126.
 Kidney, clinical lecture by Sir Benjamin Brodie, on disease of the, 106; fungoid disease of the, Mr. Gorham on a case of, 764.
 King, Mr. on acupuncture in ascites, 55, 332.

L.

Labatt, Mr. Hamilton, on the irregularities in the human arterial system, 7.
 Labour, premature, Mr. Cory on the induction of, 126.
 Laced stockings, Mr. Ridge on the injurious effects of, 899.
 Lawrence's, Mr. clinical lectures:—on fracture of the skull, with depression and injury of the dura mater and the brain, and on cancer of the lips, 345; on encysted tumors of the eyelids, on penetrating wounds of the eye, on syphilitic iritis, and strumous ophthalmia, 471; on the venereal disease, 616; on syphilis, 743.
 Lawrie, Dr. account by, of a case of amputation of a part of the lower jaw, 64; account by, of the dissection of an old dislocation of the thumb, with remarks and experiments, 93.
 Laycock, Mr. on the reaction of the saliva upon red and blue litmus and turmeric paper, 43; cases of pulmonary affection, with remarks, 456.
 Lead colic, case of, from swallowing small shot, 940.
 Lectures, table shewing the amount of fees at different schools, for unlimited attendance on those required by the College of Surgeons and Society of Apothecaries, 30.
 Lee, Dr. Robert, report by, of thirty-four cases of puerperal convulsions, 11; account by, of the case of a female with four mammae and nipples, 666.
 Legacies, editorial observations on the lapse of, from insanity, 738.
 Lepra vulgaris, Mr. Bishop's remarks on, 838.
 Life insurance fees, note respecting, from "A Physician," suggesting a mode for the profession to express their sentiments respecting, 512; editorial observations on a case of, 546.
 Lilburn, Dr. on the means of determining whether a fetus in utero be alive, 63.
 Liver abscess, case of, 747.

- Liverpool Northern Hospital, Mr. Banner's report of surgical cases admitted into the, from Sept. 1, 1836, to Sept. 1, 1837, 241.
 London Hospital reports, 25, 142, 192, 270, 303, 349, 398, 431, 479, 551.
 Lord, Mr. on the anatomy of the organs of circulation in the scolopendra, 892.
 Lovegrove, Mr. on a remarkable case of triplets, 530.
 Lunatic asylums, editorial observations on the regulation of, 134; Dr. Finch on, 333.

M.

- Macdiarmid, Mr. on malignant remittent fever, 444; on a case of black vomit in an African, 850.
 Macintosh, Dr. on dysmenorrhœa, 23; on the diseases of stone-cutters about Edinburgh, 24; on the morbid anatomy of cholera, ib.
 Mackenzie, Dr. on a case of tubercular leprosy, 67.
 Mackintosh, Dr. of Edinburgh, notice of the death of, 220.
 Macleod's, Dr. lectures on rheumatism and its effects, see "Rheumatism, Dr. Macleod's lectures on."
 Maclure's, Mr. remarks on the extract of belladonna, given as a prophylactic against the contagion of scarlet fever, 363.
 Madden, Mr. on the connexion between nerves and muscles, 23.
 Magnetism, animal, the Baron du Potet's defence of, 17.
 Magnetism, animal, exposé of, 824, 856, 986, 1034.
 Martin, Mr. on a case in which a tobacco-pipe was broken in the urethra, 255.
 Midwifery, remarks by Mr. M'Ivor connected with, 611; editorial observations on a recent conviction for malapraxis in, 770.
 Military punishments, editorial observations on, 854.
 Miller, Mr. on embryology, 251.
 Minto's, Mr. report on scurvy, 258.
 M'Ivor, Mr. remarks by, connected with midwifery, 611.
 Medical witnesses' bill, an account required from Mr. Baker, of the application of the subscriptions received by him for defraying the expenses attending petitions to parliament on the subject of the, 271.
 Medical and Chirurgical Society, papers read at the:—Mr. Phillips on the result of amputations in this and other countries, 304; Mr. Travers on removal of the clavicle, 396; abstract of a report of twenty-one cases of cholera that occurred in the Seamen's Hospital Ship Dreadnought, between the 8th and 28th of October, 1837, 478; history of a female who has four mammae and nipples, by Dr. K.

- Lee, 666; Mr. Widmer's narrative of a case in which the parotid gland was extirpated, ib.; Dr. Wilson on two cases of tumors pressing upon the superior vena cava, causing œdema of the face and superior extremities, ib.; Mr. Thurnam on aneurisms of the heart, 829; Mr. Hadwen on a case of popliteal aneurism, 941; Mr. Stafford on division of stricture of the rectum high up in the gut, ib.; Dr. Travers Cox's description of a cyst found at the under surface of the liver, 991; Mr. Vincent's observations on the dislocations of phalanges of the fingers and toes, ib.; Mr. Stafford on the perforation of the third lobe of the prostate gland, 992.
 Medicine, editorial observations on the practical teaching of, 467.
 Medicine and surgery, late improvements in, 777.
 Medico-Botanical Society of London, report of a paper read at the, by Mr. Saunders, on the employment of creosote as an odontalgic remedy, 942.
 "Medicus," remarks by, on the gratuitous services of medical men, 380.
 Meeson, Mr. on the action of chlorine on the alkaloids, 224.
 Meningitis, Mr. Parratt in a case of, with suppuration in the ventricles, 978.
 Menstruation, Dr. Brown's case of, at an advanced age, 730.
 Mesmerism, Baron du Potet de Sennevoy on, 291, 336, 375, 419, 463, 498.
 Meteorological Journal, 32, 80, 112, 144, 192, 224, 272, 352, 400, 432, 512, 592, 624, 672, 704, 752, 784, 832, 864, 944.
 Molloy, Mr. on the influence of the circulation in producing certain cerebral affections, 553.
 Morgan's, Mr. report on scurvy, 295.
 Morphia, new test of the presence of, 28.
 Morton, Mr. on the symptoms of strangulated intestine, 506; on a fatal case of strangulated hernia, in which the symptom of vomiting was present before the operation was performed, 588.
 Müller, Professor, on the human voice, 39, 88; elements of physiology, reviewed, 134; notice of a portrait of, just published, 400.
 Munk, Dr. practical observations by, on delirium cum tremore, 759.
 Murray, Sir James, notice of a paper read by, at the meeting of the British Association for the Advancement of Science, in Liverpool, the object of which was to prove that various diseases of the nervous system arose from the presence of certain salts in the blood, 23.
 Muscle, case of rupture of a, 24.
 Myriapoda and arachnida, Mr. Newport on the anatomy of certain structures in the, which have been thought to have belonged to the nervous system, 970.

N.

- Nævus, Mr. Fullagar's case of fatal convulsion during the operation of, 529.
 Nash's, Mr. observations on quarantine, and description of the lazaretto at Marseilles, 533.
 Nematoidea, new genus of, 29.
 Nerves, review of recent publications on the subject of the, 734.
 Nervous system, Rev. W. Whewell on the history of discoveries in the, 525.
 Newport, Mr. George, on the anatomy of certain structures in myriapoda and arachnida, which have been thought to have belonged to the nervous system, 970.
 Norman, Mr. on arteritis, 666.
 Norton, Mr. on the education of the apothecary, 17.
 Nunn, Mr. on early rupture of the uterus, 1030.

O.

- Operations, various, at St. George's, 138, 220.
 Ophthalmia, purulent, of infants, Mr. Gardner on, 16.
 Ophthalmia, strumous, Mr. Lawrence on a case of, 474.
 Optic nerve, Mr. Solly on the office of the cerebral extremity of the, 351.
 Ossification, case of, of the crystalline lens, 943.
 Ova of man and the mammiferous brutes, Mr. Wharton Jones on the, as they exist in the ovaries before impregnation, 680.

P.

- Paracentesis thoracis, notice by Dr. Watson of a successful case of, omitted in a late clinical lecture on the subject, 783.
 Parratt, Mr. on a case of meningitis, with suppuration in the ventricles, 978.
 Pathology, editorial observations on the establishment of a chair of, in the University of London, 222; discussion in Edinburgh regarding the institution of a, in that University, and letter from Lord John Russell on the subject, 222.
 Pericardium, adherent, Dr. Watson on the diagnosis in, 544.
 Philip, Dr. A. P. W. on the practical inferences which result from some late physiological investigations respecting the laws of the vital functions in the more perfect animals, 255, 284, 312.
 Phrenologists and Dr. Elliotson, Dr. Graves' remarks on, 729.
 Phthisis pulmonalis, Sir C. Scudamore on inhalation in, 304.

- Physic, Sir Henry Halford on some of the results of the successful practice of, 774.
 Physician, a resurrectionist, 823.
 Placenta, remarkable case of inflammation and suppuration of the, 937; Mr. Wetherfield on disease of the, 981.
 Pleurisy, Mr. Curling's report of cases of, treated by M. Louis, in La Pitié, 109, 554; clinical lecture on, by Dr. Watson, 606.
 Pleura pulmonalis, M. Bazin on the fibrous membrane beneath the, 780.
 Poisoning, supposed case of, 79; Mr. Tyson on a case of, with cream of tartar, 177.
 Poisonous candles, editorial observations on the effects of, 577; extract from the report of the Westminster Society on, 585.
 Poor-law, Mr. Hill on the system of medical attendance under the, 78; editorial observations on the starving experiments, 102; petition against, from the Provincial Medical Association, 269; editorial observations on the neglect of the sick, 385; the Bridgwater union, 424; Dr. Clark on medical relief to the poor, 896.
 Porrigio, Dr. Dick on the nature and treatment of the various forms of, 328, 332, 494.
 Portio dura, Mr. Alexander Shaw on the physiology and pathology of the, 164.
 Position during delivery, Mr. Coles on the, 671; remarks on the same subject, by "Forceps," 672.
 Potet de Sennevoy, Baron du, on Mesmerism, 291, 336, 375, 419, 463, 498.
 Presbyopia and cataract, remarks on, by a "Student of the Eye," 334.
 Prichard, Mr. on a case of fatal disease of the stomach, 576.
 Promotions, medical, in the navy, 784.
 Prospect, a, and a retrospect, 19.
 Pulmonary affections, Mr. Laycock's cases of, with remarks, 456.
 Pulse, Dr. Guy on the effects of posture on the, 190; Mr. Gorham's observations on the, 321; cause of the variations of the different positions, by a Guy's Student, 557.
 Purpura hæmorrhagica, case of, which terminated fatally, 26.
 Pus, M. Bonnet on the composition and absorption of, 408, 440, 489; Mr. J. W. Earle on the formation of, 660; observations on the formation of, by Medicus, 889.

Q.

- Quackery, editorial observations on the causes of the success of, 981; the possibility of its suppression considered, 1031.
 Quack medicines, method of putting, 558.
 Quackery, petition against, from Leeds Me-

dical Society, 668 ; means for diminishing the amount of, 669.
 Quacks at Truro, 511.
 Quain's, Dr. elements of anatomy, Part I. reviewed, 132 ; his anatomical plates, *ib.*
 Quarantine, Mr. Nash's observations on, and description of the Lazaretto at Marseilles, 533.

R.

Remuneration of medical men, editorial observations on, 341.

Rheumatism and its effects, Dr. Macleod's lectures on:—atmospheric vicissitudes the chief cause of rheumatism, 117 ; effects of hereditary predisposition, *ib.* ; relative prevalence according to sex and age, 118 ; fibrous tissues and seat of rheumatism—supposed continuity of these, *ib.* ; symptoms—pain the most general, but not universal, 119 ; divisions of rheumatism, *ib.* ; rheumatic fever, 120 ; seat of the pain, *ib.* ; the inflammation not confined to the ligaments, 121 ; absence of permanent organic change in the part inflamed, *ib.* ; nature of the constitutional disturbance, 122 ; diagnosis between rheumatic fever and gout, 124 ; an inflammatory affection of the heart and its membranes the most common complication of rheumatic fever—this long known in England, though but lately in France, 150 ; M. Bouilland's views, *ib.* ; class of cases in which pericarditis is most frequent—this occurrence erroneously attributed to blood-letting, 151 ; local symptoms of pericarditis, 152 ; auscultation and percussion, 153 ; general symptoms, 155 ; importance of attending to the expression and posture of the patient, *ib.* ; maniacal delirium sometimes indicative of rheumatic inflammation of the heart, 199 ; cases in illustration, 200 ; immediate effects of rheumatism on the pericardium, and on the interior of the heart—description of the anormal appearances, 201 ; secondary changes resulting from rheumatism of the heart, 202 ; diseases of the valves—hypertrophy and dilatation of the cavities, 203 ; signs of these, *ib.* ; synovial rheumatism—its seat, 279 ; difference between it and the preceding form, *ib.* ; permanent changes produced in the affected joints, *ib.* ; nature of the deposit, *ib.* ; carbonate of lime and lithate of soda, 280 ; suppuration of the joints an occasional consequence of synovial rheumatism, *ib.* ; causes and symptoms of the disease, 283 ; pericarditis very rare in synovial rheumatism, which, however, may be transferred to the membrane of the chest or head by metastasis, 357 ; cases in illustration, 358 ; the eye some-

times affected, 360 ; other complications, *ib.* ; tables and calculations, showing the ages, duration of treatment, and other circumstances, connected with acute, chronic, and synovial rheumatism, 361.

Rheumatism, Dr. Aldis on, 340 ; Mr. J. A. Hingeston's remarks on, 367.

Ridge, Mr. on the injurious effects of laced stockings, 899.

Robertson's, Dr. remarks on a note in Dr. Elliotson's Physiology, 460.

Royal Institution, papers read at the:—Dr. Faraday on the phenomena of electric induction, 703 ; on the nature of fatty bodies, and the application of stearine to the manufacture of candles, 748 ; Mr. Goadby on the skeletons of insects seen through the microscope, 780 ; Mr. Gray on the formation of shells, 830 ; Dr. Faraday on the atmosphere of this and other planets, 910.

S.

Saliva, Mr. Laycock on the re-action of the, upon red and blue litmus, and turmeric paper, 43.

Sandys', Mr. anomalous case of hysteria, 765.

Saunders, Mr. on the employment of creosote as an odontalgic remedy, 942.

Scapula, Mr. Banner on a case of compound fracture of the coracoid process of the, 247.

Schweitzer's, Mr. remarks on chirayitine, quina, and cinchonæ, 173.

Scirrhus of the pylorus, Mr. Curling's report of a case of, treated by M. Louis, 622.

Seemple, Mr. note from, respecting Holloway's universal ointment, 1037.

Shaw, Mr. Alexander, on the physiology and pathology of the portio dura, 164.

Scolopendra, Mr. Lord on the anatomy of the organs of circulation in the, 892.

Small-pox at Paris, 560.

Scudamore, Sir C. on inhalation in tubercular phthisis pulmonalis, 804.

Scurvy, report of assistant-surgeon Ford on, 160, 256 ; Mr. Hunter's report on, 208 ; Mr. Morgan's report, 295.

Shells, Mr. Gray on the formation of, 830.

Silver, nitrate of, Mr. Chapman on the use of, in cutaneous diseases, 96 ; Mr. Cross on its employment in the gonorrhœa of females, 99.

Skull, Mr. Banner on a case of compound fracture of the, in which the bone was removed, 247 ; clinical lecture on fracture of the, with depression and injury of the dura mater and the brain, and on cancer of the lips, 345.

Small-pox, Dr. Gregory's report on, 860.

Smith's, Dr. Southwood, lectures on foreign

- sio medicine—see "Forensic medicine, Dr. Southwood Smith's lectures on."
- Smith, Dr. H. L. on cholera insurance societies, 213.
- Solly, Mr. note from, respecting an inaccuracy in the report of the evidence attributed to him in the case of Charles Morris, 423; on the office of the cerebral extremity of the optic nerve, 851.
- Somnambulism, Baron du Potet on, 463.
- Spine, Mr. Hare on curvature of the, 23.
- St. Bartholomew's Hospital reports, 23, 76, 396.
- St. George's Hospital reports, 106, 138, 220, 302, 429.
- Staberoh, M. on the eruption attending epidemic fever, 973.
- Starvation, another death from, 693.
- Stafford, Mr. on division of stricture of the rectum high up in the gut, 941; on perforation of the third lobe of the prostate gland, 991.
- Staphyloma, Mr. Wharton Jones on the pathology of, 847.
- Stearine, Dr. Faraday on the application of, in the manufacture of candles, 748.
- Stethoscope, a new, invented by Mr. Barrett, 575.
- Stomach, Mr. Whitehouse on a case of perforation of the, 610; Mr. Prichard on a case of fatal disease of the, 576.
- Strangulated intestine, Mr. Morton on the symptoms of, 506.
- Stricture, impervious, case of—newly-modelled operation, 77.
- Stricture of the rectum, Mr. Stafford on division of, high up in the gut, 941.
- Students, a few words to, 70.
- Sugar of lead pills, Dr. Graves on the most convenient mode of making them, 444.
- Sweeting, Mr. on the treatment of simple fractures of the lower extremities by means of plaster of Paris casts, 452, 750.
- Syphilis, clinical lecture on, by Mr. Lawrence, 743; Mr. Birkett's case of, with remarks, 942.
- T.
- Taliacotian operation, case of, 396.
- Tartar emetic and opium, Mr. Yates Ackersley on the use of, in spasmodic affections, 56.
- Tartar emetic, observations on the employment of, in hydrops articuli, 907.
- Taylor, Mr. on the application of the solid nitrate of silver in the gonorrhœa of females, 63.
- Testicle, sloughing of a portion of the; cure, 249.
- Thompson, Mr. Hale, on a rare case of fracture of the humerus, 189; case of singular nervous attack, 335.
- Thomson's, Dr. A. T. conspectus of the Pharmacopœias, omissions in, 350; his London Dispensatory reviewed, 580.
- Thumb, account by Dr. Lawrie of a dissection of an old dislocation of the, with remarks and experiments, 93.
- Thurnam, Mr. on some of the effects of endocarditis, and particularly on the scutiform thickening of the aortic valves, 645; on rupture of the heart, and on hæmorrhage into the pericardium, without rupture of the heart or great vessels, 813; on aneurisms of the heart, with cases, 829.
- Thursfield, Mr. account by, of the case of a female with three mammæ, 898.
- Toes, Mr. Banner on a case of mortification of the, 248.
- Torpedo, new experiments on the, 142.
- Transposition of the viscera, Mr. Falcon on a case of, 731.
- Travers, Mr. Benjamin, on removal of the clavicle, 396.
- Triples, remarkable case of, related by Mr. Lovegrove, 530.
- Tumors, encysted, of the eyelids, Mr. Lawrence's clinical observations on, 471.
- Tumors, Mr. Cæsar Hawkins's lectures on;—definition of tumor, 838; modes of formation, *ib.*; causes, 839; inflammation of, 840; destruction, by ligature of vessels, *ib.*; rapidity of growth, *ib.*; texture influenced by situation, *ib.*; analogous and heterologous formations, *ib.*; physical characters, 841; malignancy, *ib.*; classification, 842; serous or aqueous encysted tumors, 871; hydatid encysted tumors, 874; congenital encysted tumors, 878; bursal encysted tumors, 879; osseous tumors, 919; tumors of or upon the bones, *ib.*; conversion of natural textures into bone, *ib.*; new formations of bone, 920; sarcomatous tumors, 921; adipose tumors, *ib.*; fibrous tumors, 924; neuromatous tumors, 926; conglomerate or pancreatic tumors, 945; conglobate tumors, 946; simple conglobate tumors, *ib.*; tumors in the parotid gland, 947; tubercular conglobate tumors, 948; scrofulous tumors, 949; cystic tumors, 950; tuberculous cystic tumors, 951; circumstances in which cysts are met with in tumors, 952; theories with regard to cysts in tumors, 953; on the nature and properties of malignant diseases, 993; verrucous tumors of cicatrices, 995; carcinomatous tumors, 996; definition—various forms of carcinoma, *ib.*; period of life—hereditary?—existing causes, 997; history of the cancerous tumor—treatment, general and local—operation for, 998; fungous tumors, 1002; fungus hæmatodes, 1003; encephaloid or medullary tumor, 1008; melanosis, *ib.*
- Turner's, Dr. elements of chemistry reviewed, 133.

Turner's, Mr. case of chorea from pregnancy, 532.

Tyson, Mr. on a case of poisoning with cream of tartar, 177.

U.

University College, fees at, 80.

University of London, editorial remarks on the proposal for establishing a pathological chair in the, 216, 344; on examinations on the subject of religion, 429; oversight in the charter of the, 696; resolution of the committee of the, with respect to examinations in theology, 784; on editorial observations on the, 820.

Urethra, Mr. Martin on a case in which a tobacco-pipe was broken in the, 255.

Urine, Mr. Estlin on a case of retention of, from tumors within the bladder, 541.

Urticaria, singular production of, 77.

Uterine hæmorrhage, case of, cured by ergot of rye, 398.

Uterus, Mr. Ellis on diseases of the, 211; Mr. Munro on early rupture of the, 1030.

V.

Varicose veins and ulcers of the leg, clinical lecture on, by Sir B. Brodie, 184, 264.

Veins, M. Velpeau on the introduction of air into the, during operations, 953, 1011.

Velpeau, M. on the introduction of air into the veins, 953, 1011.

Velpeau's, M. treatment of fractures, 431.

Venables, Dr. on salts of lead in cholera, 259.

Venereal disease, clinical lecture on, by Mr. Lawrence, 616.

Vincent, Mr. on the treatment of dislocation of phalanges of the fingers and toes, 991.

Vital functions, Dr. A. P. W. Philip on the practical inferences which result from some late physiological investigations respecting the, in the more perfect animals, 235, 284, 312.

Voice, Professor Müller on the, 39, 83;

Dr. Aldis on reverberation of the, in diseases of the chest, 610.

W.

Wakley, Mr. and Mr. S. Cooper, correspondence on the subject of the bayonet wound case, 431.

Ward's, Mr. case of Cæsarean operation, 817.

Watson, Dr. on some of the morbid conditions of the valves of the aorta, 450; on the diagnosis in adherent pericardium, 544; clinical lectures by, on pleurisy, 696; note from, respecting a case of paracentesis thoracis, 783.

Watson, Dr. G. on a case of spinal irritation, 811.

Warming and ventilating, Mr. Jeffreys' strictures upon Dr. Arnott's treatise upon, 959, 1017.

Westminster Hospital reports, 26, 77, 111, 932.

Westminster Medical Society, papers read at the:—Mr. Thomson on a rare case of fracture in the humerus, 189.

Wetherfield, Mr. on diseases of the placenta, 981.

Whewell, Rev. W. on discoveries in the nervous system, 525.

Whitehouse, Mr. on a case of perforation of the stomach, 610.

Widmer, Mr. account by, of a case in which the parotid gland was extirpated, 666.

Williams', Dr. lectures on the physiology and diseases of the chest—see "Chest, Dr. Williams' lectures on the physiology and diseases of the."

Wilson, Dr. J. on two cases of tumors pressing upon the superior vena cava, causing œdema of the face and superior extremities, 666.

Wound, punctured, involving the diaphragm, spleen, stomach, and liver, 302; of the abdomen, clinical lecture on a case of, by Mr. T. B. Curling, 567.

Wounded, Mr. Cherry on the transport of the, 732.

Y.

Yellow fever, Dr. Fergusson on, 1021.
